In patients with a history of anaphylaxis or inability to be skin tested because of antihistamine use or dermatographism, *in vitro* testing of allergen-specific IgE antibody can be measured from serum. Specific IgE is quantified by plotting of values on a curve for total serum IgE. Historically, the first IgE-specific test was the radioallergosorbent test. The suspected allergen was bound to an insoluble material, and the patient's serum was added. Antibodies to the allergen in the serum would bind. When radiolabeled antihuman IgE antibody was added, it would bind to those IgE antibodies bound to the insoluble material. Subsequently, the unbound antihuman

IgE antibodies were washed away. The resultant amount of radioactivity present quantifies the serum IgE for the specific allergen. This test, however, is currently not being used because it requires a radioactive isotope and expensive equipment. Although other tests have been developed such as the MAST (multiple allergen simultaneous test) and the capsulated hydrophobic carrier polymer system that can provide more accurate *in vitro* tests and test multiple allergens, these tests are less sensitive and more expensive than the *in vivo* skin testing for allergy detection (223,224).

Management

Avoidance

Total avoidance of allergens is the safest and most effective therapy of AR, however, compliance can be difficult since this affects patients daily life activities, dwellings, and life styles and can be expensive to implement. Measures include, but are not limited to, pet avoidance, use of allergen-impermeable encasings on the bed and all pillows, use of an air conditioner, and keeping the windows closed to reduce pollen exposure (225). There have been few studies demonstrating the effectiveness of avoidance in patients with AR. The Allergic Rhinitis and its Impact on Asthma (ARIA) guidelines (226) report that there is lack of sufficient evidence for the effectiveness of avoidance of house dust mites or pet animal dander (227). This is in contrast to the mandatory avoidance by patients with occupational rhinitis, as illustrated by the European Academy of Allergy and Clinical Immunology, which stated that the safest and most effective treatment for occupational AR is the strict avoidance of the offending allergens (228). Avoidance is an example that what makes sense does not always translate into effective treatment.

Pharmacotherapy

Therapy for AR is usually step-wise, depending on the severity and duration of the symptoms. Figure 25.9 shows the stepwise pharmacologic management of AR as proposed by the ARIA guidelines (226). The medications used are: oral antihistamines, intranasal antihistamines, intranasal steroids, leukotriene receptor antagonists, intranasal cromolyn, decongestants, and saline irrigations.

Oral antihistamines are effective in relieving most allergic nasal symptoms except for nasal congestion. The 2008 ARIA guidelines (226) recommended the use of second-generation antihistamines over the first-generation antihistamines because of the sedative effects of the earlier first-generation antihistamines such as diphenhydramine. Topical steroids are the most effective drug for the treatment of pediatric and adult AR. Many studies have looked at the combination of an intranasal corticosteroid with an antihistamine or leukotriene receptor antagonist, but most have concluded that combination therapy is no more effective than monotherapy with intranasal corticosteroids (229,230). One published study showed that the combination of fluticasone and azelastine was superior to treatment with either alone in patients with moderate to severe AR (231). This type of combination is supported by several other currently unpublished clinical trials. For this reason, combination therapy should be considered in patients who have moderate to severe symptoms, who respond incompletely to monotherapy with an intranasal steroid.

A summary of the pharmacologic treatment guidelines is shown in Tables 25.7 and 25.8. Patients are usually evaluated after 2 to 4 weeks for response to medical treatment. If they have an excellent response, the medications should be continued with gradual step down. If there is a partial response, persistent symptoms should be addressed and treated. Whereas allergic eye symptoms frequently improve with nasal steroids or oral antihistamines, isolated or residual eye symptoms often respond to topical ocular antihistamines. If ocular symptoms persist, it warrants referral to an ophthalmologist to consider other ocular diseases, which mimic AR.

Considerations in Select Populations

More systemically bioavailable nasal corticosteroids, such as beclomethasone temporarily reduce linear growth in children (232–234). Monitoring of growth in children receiving these agents is recommended. In the elderly, who may have increased susceptibility to somnolence from antihistamines, nonsedating antihistamines are recommended. The major symptom of elderly patients with rhinitis is often profuse watery rhinorrhea, which is most responsive to anticholinergic agents.

In pregnant patients, the greatest concern for congenital malformation is present during the first trimester. FDA pregnancy risk categories guide usage in this population. Nasal cromolyn is the safest medication in pregnancy. Cetirizine, chlorpheniramine, loratadine, and tripelennamine are FDA pregnancy category B, whereas many other antihistamines have a category C rating. Category B medications have not shown any adverse effects on pregnancy or the fetus, usually based on animal studies. Intranasal budesonide has a category B rating, whereas other nasal corticosteroids are rated category C (235). Oral decongestants should be avoided in the first trimester because of the risk of gastroschisis in the newborn (236). Systemic decongestants are also banned for use in competing athletes.

Immunotherapy

Allergen-specific immunotherapy (SIT) provides relief for patients who have severe symptoms. It modulates the immune system, and has the potential to alter the natural history of the disease. Immunotherapy is still clinically effective even several years after cessation (237). Pollen immunotherapy in children with seasonal allergic rhinoconjunctivitis decreases bronchial hyperresponsiveness

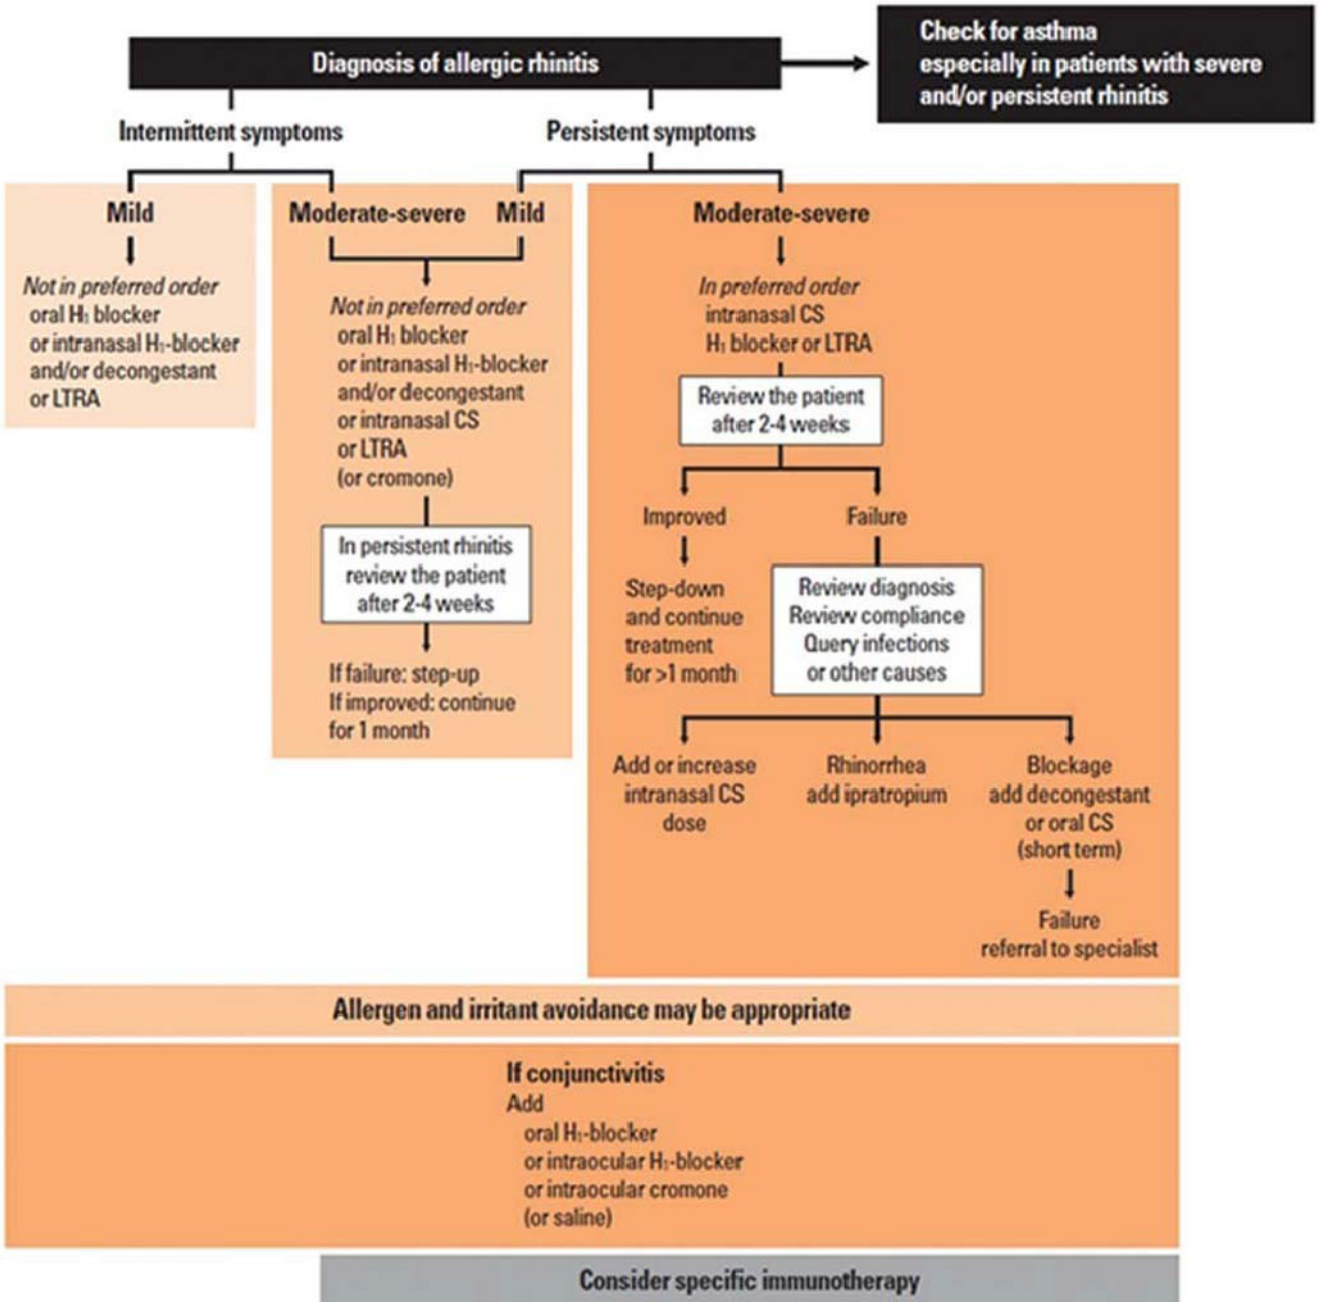

Figure 25.9 Rhinitis management. (Adapted from Bousquet J, Khaltaev N, Cruz AA, et al. Allergic Rhinitis and its Impact on Asthma (ARIA) 2008 update (in collaboration with the World Health Organization, GA(2)LEN and AllerGen). *Allergy* 2008;63(Suppl 86):8–160.)

and development of asthma symptoms for at least 2 years after treatment (238). A Cochrane Systematic Review and meta-analysis of 15 trials on the efficacy of SIT for seasonal allergy with standardized allergens (22) found an overall significant reduction in symptom scores. The ARIA (239) concluded that injection immunotherapy for inhalant allergens was effective for seasonal and perennial AR. In a double-blinded, placebo-controlled trial of the effect of grass and birch pollen found that a combination of SIT, and omalizumab was superior to either treatment alone in reducing nasal and ocular symptoms (240).

The immune mechanisms involved in successful immunotherapy are not fully known. One of the first measurable changes with immunotherapy is an increase in allergen-specific IgG4. In SIT, allergen-specific IgE increases initially during treatment, then steadily decreases to pretreatment levels during maintenance (241,242). The IgG4 antibodies block IgE activity, which is consequently associated with decreased mast cell and basophils activation and release of preformed mediators. In the late response, these "blocking" antibodies prevent the IgE-mediated presentation of antigen to T cells (243,244). In addition to changes in IgE

TABLE 25.7 CLINICAL RECOMMENDATIONS FOR THE TREATMENT OF AR

Clinical Recommendation	Evidence Rating
The initial treatment of mild to moderate AR should be an intranasal corticosteroid alone, with the use of second-line therapies for moderate to severe disease.	A
Compared with first-generation antihistamines, second-generation antihistamines have a better adverse effect profile, including less sedation (with the exception of cetirizine [Zyrtec]).	A
The adverse effects and higher cost of intranasal antihistamines, as well as their decreased effectiveness compared with intranasal corticosteroids, limit their use as first- or second-line therapy for AR.	A
Although safe for general use, intranasal cromolyn (Nasalcrom) is not considered first-line therapy for AR because of its decreased effectiveness at relieving the symptoms of AR and its inconvenient dosing schedule.	C
Nasal saline irrigation is beneficial in treating the symptoms of chronic rhinorrhea and may be used alone or as adjuvant therapy.	B
Although dust mite allergies are common, studies have not found any benefit to using mite-proof impermeable mattress and pillow covers.	A
Interventions without documented effectiveness in the prevention of AR include breastfeeding, delayed exposure to solid foods in infancy, and the use of air filtration systems.	B

A, consistent, good-quality patient-oriented evidence; B, inconsistent or limited-quality patient-oriented evidence; C, consensus, disease-oriented evidence, usual practice, expert opinion, or case series.
For information about the SORT evidence rating system, go to http://www.aafp.org/afpsort.xml.

and IgG, B lymphocytes increase IgA and IgM production. Theoretically, this boosts the barrier function against antigen penetration at mucosal surfaces (245,246). The IgA increase with subcutaneous immunotherapy (SCIT) is of the subtype IgA2, and has been correlated with an increase in nasal TGF-β and monocyte IL-10 expression, which in turn are associated with the development of tolerance in allergic patients (238).

Immunotherapy induces allergen tolerance by a number of mechanisms. Some studies have shown a shift away from a Th2 to a Th1 cytokine profile with the production of IL-10 locally and peripherally, whereas others have shown that this occurs locally only in the nose (247–249). Tolerance may occur as a result of the increase in the number of allergen-specific suppressor T cells, T_{reg} cells, following immunotherapy (250–254). The production of IL-10 by T lymphocytes was also found to be important in successful immunotherapy (255).

Successful grass pollen immunotherapy in a study by an increase in the ratio of IFN-γ to IL-5 mRNA+ cells in the nasal mucosa was present in one study in patients experiencing symptom relief with grass SCIT, providing evidence for T-cell-subset switching at the protein level (256). Successful SCIT-treated patients showed a rise of signaling lymphocyte activation molecule, a Th1-associated gene with *in vitro* stimulation of T lymphocytes with pollen and mite-sensitive asthmatics, successfully treated with SCIT, demonstrated an increase in the IFN-γ to IL-4 ratio again showing the shift away from an allergic Th2 profile to that of a Th1 profile (257).

TGF-β downregulates T-cell inflammatory and cytotoxic inflammation. It also affects B cells and macrophages (252). SIT is effective because it immunoregulates or suppresses the allergic response.

Adverse reactions to SIT were divided by Calderon et al. (239) into local reactions and systemic reactions. The systemic reactions were further divided into early (occurring within 30 minutes) and late (after 30 minutes). Local reactions not requiring treatment occurred in 92% of the active immunotherapy group versus 33% of the placebo group. Local reactions requiring treatment occurred in 10% of the active SIT group and in 4% of the placebo group. Systemic reactions required adrenaline in 0.13% of the cases in the active SIT group. Within the anaphylaxis group, fatalities occur in around 4 per year (258). The risk of anaphylaxis and the rare risk of death, require that SIT be regulated and only administered by those trained to perform to the highest safety standards.

Sublingual Immunotherapy

Another promising treatment is sublingual immunotherapy (SLIT). Numerous studies demonstrate SLIT effectiveness in decreasing symptoms and use of medications (259) in AR, and in reducing the development of allergic asthma in children (260). Prolonged treatment appears to show persistent efficacy after stopping (261,262). It appears to be as effective as SIT for certain populations and antigens, and less so in others. ARIA (263) reported strong evidence for SLIT efficacy in AR. One of the most attractive features of SLIT is its safety profile, with most adverse reactions consisting of mild and self-resolving throat pain or itching; however, at least three nonfatal anaphylactic reactions have been reported with SLIT (264–266). Other systemic side effects include abdominal pain, conjunctival itching, rhinitis, and urticaria.

Calamita et al. (267), in a meta-analysis found SLIT beneficial in treating asthma treatment, but that the magnitude of improvement was small.

CONCLUSION

The development of AR pivots on the interplay between genetic predisposition and environmental exposure. The pathophysiology of AR illustrates the complexity of the immune system and the importance of a basic understanding of immunology for the otorhinolaryngologist. Many of the cells and cytokines implicated in allergic diseases are involved in other disease processes as well. An understanding of AR pathophysiology is foundational to understanding the management and treatment of this highly prevalent, bothersome, and quality of life impairing disorder.

HIGHLIGHTS

- AR, is classically characterized by itching, sneezing, rhinorrhea, and congestion, and is mediated by IgE or type I hypersensitivity.
- AR is a risk factor for the development of asthma, and the risk increases with the greater severity and persistence of rhinitis.
- Impairment of the innate immune system is probably one cause of CRS.
- The cells associated with innate immunity include neutrophils, monocytes, mast cells, eosinophils, basophils, and DCs and is a first line defense against newly encountered pathogens.
- Innate immunity controls and eliminates infection with the help of the complement system, NK-cell activation, and TLR activation. If the innate immune system is unable to remove pathogens, the adaptive immune response is activated.
- The adaptive immune system, in contrast to the innate immune system, is highly specific in nature, and it benefits from gene rearrangement, and, unlike the innate immune systems, is capable of developing memory.
- Igs, glycoproteins composed of mostly polypeptides and a small carbohydrate component, account for 20% of total plasma proteins. Igs function to aggregate toxins or bacteria. In normal adults, IgG, which has the most prominent role in memory immune responses, constitutes approximately 75% of the total serum Igs.
- AR is an immediate hypersensitivity reaction that is mediated by IgE in response to an otherwise innocuous antigen.
- The development of AR pivots on the interplay between genetic predisposition and environmental exposure. Environmental triggers include allergens such as dust mite, molds, animal dander, and the pollens of trees, grasses, and weeds.
- A family history of atopic diseases is a risk factor for the development of AR.
- The early response to the allergen occurs within minutes and is characterized by mast cell degranulation and the release of preformed mediators, including histamine and proteases, which leads to vasodilatation, vasculature leakage of fluids, and glandular and neural stimulation. It is symptomatically characterized initially by itching, then sneezing, rhinorrhea, watering of the eyes, and then, nasal congestion.
- The late response to nasal challenge with antigen occurs hours after antigen exposure with a recrudescence of allergic symptoms mediated by influx of cellular elements such as eosinophils (responding to the early phase release of IL-5) and activated T cells.
- The history, and physical examination provide the basis for further evaluation in AR. The gold standard for allergy testing is *in vivo* antigen-specific skin testing although both false positives and false negatives can occur. Treatment of AR involves avoidance usually with implementation of environmental controls, medications. and/or immunotherapy.

- Intranasal steroids are the most effective drug for the treatment of pediatric and adult AR.
- Allergen-SIT is used for seasonal and/or perennial AR, and is usually employed in patients with severe, prolonged, or refractory symptoms. SIT modulates the immune system via mechanisms not completely understood, but probably involve IL-10 and T_{reg} cells, and a shift from Th2 to a Th1 bias. SIT and SLIT are the only interventions with the potential to alter the natural history of the disease.

26 Allergy Testing

James W. Mims

Allergic rhinitis is one of the most common conditions that otolaryngologists treat (1). While the diagnosis of allergic rhinitis is founded on clinical impression, allergy testing plays an important role in distinguishing allergic rhinitis from nonallergic inflammation. Inhalant allergies may also play a role in comorbidities that are disproportionately represented in otolaryngology patients including allergic asthma, atopic dermatitis, allergic conjunctivitis, sinusitis, allergic ear disease, and allergic laryngeal manifestations. While history and physical exam provides the clinical suspicion of hypersensitivity, allergy testing is necessary to determine which allergens are most likely causing the allergic symptoms.

INFLUENCES ON ALLERGY TESTING ACCURACY

Before discussing different types of allergy testing, there are four principles that help to understand and interpret allergy test results. Each complicates our tendency to interpret allergy testing as a "black/white" decision where a positive test represents clinical disease and a negative test removes allergy from the differential diagnosis. We also look at research from food and venom allergy to clarify these points. The four principles are as follows:

Positive Tests Prevalence and Allergic Disease Prevalence

Positive allergy test results are more common than clinically bothersome allergic symptoms.

The Center for Disease Control evaluated a sample of 10,508 individuals selected to represent the U.S. population with skin prick tests (SPT) as part of the Third National Health and Nutrition Survey. Common aeroallergens were used with appropriate positive and negative controls. They reported at least one positive test in 53.9% of subjects (2). However, a 2009 national survey by the Center for Disease Control found that 11.8% reported "respiratory allergies."(3) Similarly, a positive SPT for food has a reported unacceptable specificity of about 50% (4). In venom allergy, 3% of the population has systemic allergic reactions to bees, while 20% have positive skin or specific IgE (sIgE) tests (5). Thus allergy testing should only be performed in individuals with symptoms of allergic disease, and test results must be interpreted in the context of the patient's history.

Negative Allergy Tests and Allergic Reactions

Allergic disease, including anaphylaxis, can be seen after negative allergy tests.

Rhinitis symptoms in patients with negative allergy testing are designated as nonallergic rhinitis. However, in food and venom anaphylaxis, there is no designation of nonallergic anaphylaxis. In food allergy, a negative sIgE test for peanut in a child suspected of peanut allergy occurs in about 10% to 20% of children who will have an allergic response on double-blinded placebo-controlled peanut challenge (6). In venom allergy, there are reports of sting anaphylaxis after negative tests, but these events are rare and less likely to be fatal (5). While negative tests are useful, they do not always exclude clinical allergic disease.

There are at least four possible reasons for false negative tests. First, some individuals test positive only during a certain window after exposure, so testing may be negative outside that time frame. Second, allergen extract material used in testing does not always match an individual's "real world" exposures. Third, some hypersensitivity reactions, even anaphylaxis, are not IgE mediated (e.g., contrast dye anaphylactoid reactions are not IgE mediated [7]). Fourth, there is a theory of local allergy in which the immunologic process in the nose may not be mirrored by mast cells in the skin (8).

Sensitivity and Tolerance

Testing sensitivities and clinical tolerance can change over time.

Since positive allergy tests do not always correlate with clinical symptoms, having a positive allergy test is termed an "allergic sensitivity." Those who suffer from IgE-mediated ragweed allergy, should produce sIgE to ragweed, and have bound sIgE to ragweed on their mast cells and basophils. However, it should be noted that when they are treated with immunotherapy for their allergy, the sIgE does not become undetectable (or even consistently reduce) (9). Despite this, their allergy symptoms improve or may resolve. This suggests that the mechanism of developing tolerance does not require a reversal of the sensitization process. Rather, tolerance has a distinct mechanism that likely involves specialized T cell lymphocytes that regulate inflammation, called T-regs (10). Although semantically paradoxical, sensitization and tolerance can coexist.

Studies that have investigated the natural history or development of allergic disease demonstrate that sensitization and tolerance can vary over time (11). The controlling factors in this are not well understood, but exposure to allergen likely plays a role.

Variability in Allergen Extract

All allergy testing relies on source allergen extracts that have significant biologic variability.

Both allergy skin and laboratory testing require use of raw biologic material. For example, testing for ragweed pollen requires the collection, purification, and sterilization of ragweed pollen (12). Creating an allergen extract is an inexact process and biologic diversity exists between different extract manufactures and even different lots of extract from the same manufacturer. Several common allergens are standardized; however, most allergen extracts are not standardized (13). Along with variation in allergen extract, allergic individuals express diversity not only to what source they are allergic to, but differ in the specific molecular epitopes their sIgE binds (14). Most allergenic sources, such as cat, have multiple molecular proteins to which human IgE can bind. This leads to confusion with terminology as an "allergen" can refer to a source (i.e., cat), a particle (dander), a protein (Fel d 1), or a molecular epitope. The allergens defined by the molecule are named by a convention, the first three letters of the genus, first letter of the species, and sequential number of the identified molecule. For cat, *Felis domesticus*, the first molecular allergen was Fel d 1. Cat has eight identified allergens, Fel d 1-8 (15). If more than 50% of the clinically allergic population produces IgE to a specific molecular allergen, it is termed a "major allergen." Fel d 1 is a major allergen shared by more than 80% of the cat allergic population. As such, cat allergen extracts are standardized by their Fel d 1 content (13). If a person allergic to cat was sensitized only to Fel d 4, they could test negative if the extract, standardized to Fel d 1, did not have an adequate concentration of Fel d 4. This is especially problematic for sources without major allergens, with multiple allergens, or with nonstandardized extracts (many of the molds, tree pollens, and nonragweed weed pollens). Individuals sensitized only to the minor allergens are at risk for false negative tests. In conclusion, all allergy testing is only as good as the allergen extract.

If these four concerns are valid, the diagnosis of allergic rhinitis is primarily a clinical diagnosis. In individuals with a clinical history suggestive of allergy, allergy testing is useful and can direct use of medication, guide environmental control strategies, and identify candidates for immunotherapy.

SELECTING ALLERGENS FOR TESTING

Inhalant allergens are generally divided into groups by source. The main groups are pollens, molds, epidermals, and arthropods (16). Allergen qualities that effect their selection in testing include cross-reactivity, potency, and abundance. An example of cross-reactivity is demonstrated in pollens. Timothy and fescue grass pollens come from different plants but are antigenically very similar (17). A sensitized person who tests positive for one will reliably test positive for the other as they bind the same sIgE sites that can be proved through competitive inhibition. As such, it is not necessary to test an individual for both (16). However, many of the molds are antigenically distinct and testing for Alternaria may not cross-react with other regionally antigenic mold spores (16). Potency, or antigenicity, refers to the strength of reaction produced by the exposure. While grass pollen is less abundant than tree pollen, grass pollen is more potent. Generally, if a sensitized person were tested to an equal amount of grass and tree pollen, they would likely develop a larger reaction from the grass pollen. Pine pollen is an example of a pollen that can be very abundant but not potent and tends not to cause symptoms (18). However, small quantities of cat dander can elicit symptoms because it is potent (19). As such small quantities of cat allergen, such as found in dust collected from a school, may be clinically significant. Abundance is obviously important and explains the seasonal and regional allergies to different pollens.

Pollen allergens are subdivided into trees, grasses, and weeds. Allergenic pollens are typically spread by wind rather than by insects (bees). Pollens are relatively large airborne particles that tend to impact in the nose and conjunctiva rather than the lower airways due to size. For this reason, pollens tend to clinically exacerbate allergic rhinitis and conjunctivitis, while smaller mite, dander, and mold allergens play a larger role in asthma. Pollen allergy tends to be intermittent or seasonal (20–22).

Tree pollens tend to be released in the spring and the abundance causes significant clinical allergy (22). Most tree pollen exhibits modest cross-reactivity and usually testing

one allergenic tree from each family is sufficient. The local variety of trees differs across North America. Thus practitioners will need to gather information about their local pollens. Allergen extract providers, publications, botanists, and environmental agencies are often reasonable sources of information. Common allergenic trees include oak, cedar, and birch. Grass pollens exhibit high potency and high cross-reactivity (21). Selecting one grass from each family represented in the region is sufficient. In most areas, three representative grass pollens will suffice. Grass pollen is most prevalent in the summer. Weed pollen is present in the summer and fall. Ragweed is a potent, abundant, and widely distributed pollen that tends to be released in the late summer and early fall. Weed pollens have less cross-reactivity than grass and vary significantly by region (20). It is sensible to research local antigenic weeds and create a panel that accounts for cross-reactivity.

Inhalant mold allergy is produced by the air-borne mold spores. Spore counts typically range between 5,000 and 50,000 spores/m^3 of air (23). A person typically breaths around 3 m^3 daily. (For reference, a moderate grass pollen level would be 5 grains/m^3.) Multiple factors make testing for mold allergy problematic. There are over one million species of mold that have been identified, but less than 80 are known to play a role in respiratory pathology (24). Multiple factors including poor resources to obtain regional mold data, changing taxonomy, and the sheer quantity of routine exposure further complicate mold allergy. Additionally, spores collected from the single mold strain can vary substantially in antigenicity. And, cross-reactivity between molds varies. Molds within the same genus can be antigenically distinct and molds of different families sometimes display significant cross-reactivity. Despite this, mold is a commonly identified sensitivity and immunotherapy for some molds has been shown to be effective (24).

Proteins on animal dander are frequently antigenic. As such, common household pets like cats and dogs are frequently included on testing panels for persistent allergy symptoms. Fel d 1 is the major allergen found in cat saliva and dander but the function of the protein is unknown (19). Cat allergen has been identified in dust collected from schools, and living with a cat is not required to become sensitized (19). Dander tends to be a small particle and is frequently a trigger for allergic asthma. Beyond dog and cat, the patient's history should be used to guide testing. Guinea pigs, laboratory animals, farm animals, and pet birds are other frequent sources of allergic sensitization in exposed atopic individuals (25).

Arthropod allergy mostly encompasses dust mites (26) and cockroach. However, sometimes a careful history can lead to other concerns; an obscure example would be Asian ladybug sensitization for those living in log cabins (27). Dust mite allergy is very common. Dust mites thrive in humid temperate regions and feed on the gram of human skin each person sheds daily. They are found in high quantity in pillows and mattresses but also found in furniture used frequently. They are microscopic and do not cause symptoms in nonsensitized individuals. There are two common dust mite species in the United States, *Dermatophagoides farinae* and *Dermatophagoides pteronyssinus. Blomia tropicalis* can be found in southern regions approaching tropical climates. Cockroach allergy is especially problematic for childhood asthma in urban settings (28).

ANTIGEN SCREENS

Smaller panels of 9 to 15 selected allergens have been shown to correlate well with larger batteries of allergy tests (29,30). Regional antigenically distinct trees and weeds along with a grass from each family represented in the region are commonly selected pollens. Most screening panels would also include dog, cat, *D. farinae*, and *D. pteronyssinus*. Common allergenic molds including *Alternaria*, *Aspergillus*, Hormodendrum, *Helminthosporium*, and *Penicillium* are frequently tested. Sometimes with skin or sIgE screening, several allergens are combined as a mix, for example, tree mix, grass mix, or mold mix.

ALLERGY SKIN TESTING

In 1865, Charles Blackley suspected he had allergic rhinitis, abraded his skin, and bandaged grass pollen grains over the wound. An intense cutaneous response developed and allergy skin testing was discovered (31). Blackley had performed a version of a scratch test, which is today discouraged because of inconsistencies with the technique (32,33). However, skin testing remains the most popular form of allergy testing in the United States. There are two main variables in skin testing: How much allergen is used, and how deeply it is placed into the skin. SPT uses devices with single or multiple tines dipped in allergen extract to place the allergen into the epidermis of the skin (32). Intradermal testing (IT) uses a small needle to raise a wheal intradermally. (The same technique is used in the purified protein derivative test for tuberculosis.)

Skin testing is popular for multiple reasons. Results are available in minutes. Multiple allergens can be tested at once (a weakness of nasal challenge testing). Systemic allergic reactions are rare. Costs are reasonable. For inhalant allergens, it has been argued that it is more sensitive than sIgE tests (32).

However, skin tests are subject to multiple variables. Skin test results vary with the extract, selected device (34), patient age (35), anatomic location (36), medication, season of the year (37), criteria for interpretation, mechanics of applying the test, and coexisting skin conditions (38). A study by Nelson et al. illustrates the variation encountered in one of the above-listed variables, extract potency. Nelson et al. compared standardized extracts for major allergen content in micrograms. They analyzed the micrograms of major allergen in 28 different *D. pteronyssinus* extracts standardized

to 10,000 AU/mL. The micrograms of major allergen varied nearly fivefold from 68 to 385 μg/mL. Variability for cat extract ranged twofold and orchard grass ranged eightfold (39). Nonstandardized extracts have shown up to a 100-fold variability (40). Despite these problems, positive skin allergy tests in patients selected by allergic history and physical findings have correlated with challenge tests and identified patients who benefited from allergen-specific immunotherapy in randomized controlled trials (41).

Skin testing should always be performed with positive and negative controls (42). Positive controls use histamine to generate a response. The most common reason for a negative response to a positive control is medication use by the subject. Antihistamines, tricyclic antidepressants, and systemic beta agonists are known to inhibit skin test responses and should be discontinued 72 hours prior to skin testing. Negative controls contain the diluent used in allergen extracts. This can vary between extracts but many extracts include glycerin as a preservative, phenol for bacteriostasis, and buffered saline. The diluent can cause a nonspecific reaction usually attributed to the glycerin or skin conditions such as dermatographia. It is not uncommon for allergic individuals to have small reactions from negative controls possibly due to the glycerin. When allergen skin tests are measurably greater than the small reactivity observed after negative control, the allergen test can be interpreted as positive at the discretion of the physician (42).

Skin Prick Tests

SPT is performed with a variety of techniques and devices. Most dip a device with single, dual, or multiple tines into concentrated allergen extract and press into the skin of the ventral forearm firmly with a gentle rocking motion. The prick usually leaves an impression without bleeding (Fig. 26.1). The skin should be marked so that the tests can be identified. Test results are read at a set time, usually 20 minutes. A positive response generates a wheal (raised skin) and flare (erythema) response. While the wheal or flare can be used to determine a positive response, generally a wheal 3 or 4 mm greater than the negative control response is used. Historically, a 1+ to 4+ scale has been used but has been criticized as it is not standardized (43). The greater than 3 mm wheal has greater sensitivity and less specificity than the greater than 4 mm wheal. There is a risk that any allergy skin testing could cause a systemic allergic reaction, thus allergy skin tests should be administered where treatment of anaphylaxis is immediately available. Patients undergoing allergy skin testing should be observed 20 to 30 minutes after skin testing. All patients

C

Figure 26.1 Skin Prick Test. **A:** SPT applied with a device that places eight tests simultaneously. **B:** Indentations on the skin after a SPT. Of note, no bleeding. **C:** Skin wheal and flare reaction from a positive control (**upper right**) using Histamine base 6 mg/mL. Other sites are negative.

undergoing allergy skin testing require attention to interfering medications and skin conditions, positive and negative control tests, and an environment where anaphylaxis can be managed. There are several excellent reviews of SPT in the current literature (32,42,44).

Intradermal Skin Testing

Allergy extract is diluted before applying intradermally. IT with full strength extracts has an unacceptable risk of systemic reaction, and the results do not correlate well with clinical disease. However, there is no universally accepted dilution for IT. IT is optimally performed using a 26 or 27 gauge unattachable needle joined to a 1 mL syringe to minimize "dead space." The skin is prepped with alcohol and approximately 0.01 mL volume is injected into the dermis to form a 4 mm wheal. The 4 mm wheal will enlarge to a 5 mm wheal by diffusion (not a hyperreactivity response) (42). Wheal and flare determine a positive response and the wheal should be 2 mm or greater than the negative control. (Fig. 26.2) If the negative control is 5 mm, a positive response would be 7 mm or greater read at 10 to 20 minutes (32,42). Another method of measuring a positive response, primarily used in research, is the longest diameter of the wheal or flare added to the orthogonal (or perpendicular) diameter (12). (This convention is used because the wheal and flare responses are not predictably circular.) We discuss the use of IT in three situations: single IT, intradermal dilutional testing (IDT), and in blended techniques.

Single Intradermal Testing

Single IT generally refers to the placement of a single IT after a negative SPT. In theory, the patient has been screened by the negative SPT as not highly sensitive, which allows the IT to be safely placed. There is little agreement on the dilution to use, but a typical scenario might dilute the concentrated extract an additional 25 times. For example, 0.1 mL of a nonstandardized extract labeled 1:20 weight/volume (w/v) could be added to 2.4 mL of diluent creating a 25-fold dilution of strength "1:500 w/v." One paper concluded that SPTs and IT tests were roughly equivalent when

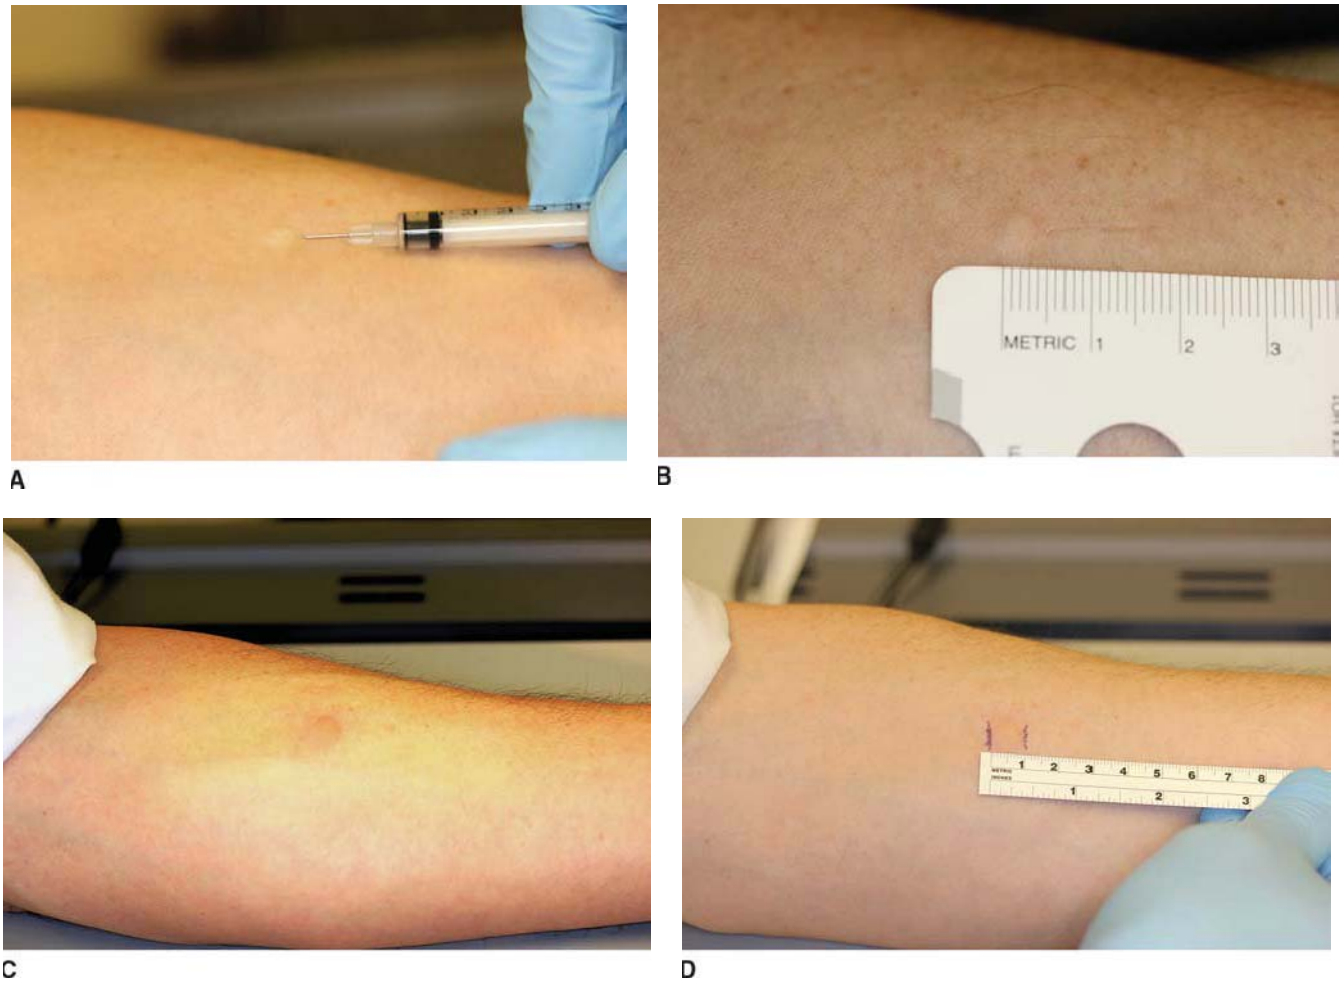

Figure 26.2 Intradermal Test (IT). **A:** Placement of Intradermal allergy test with a 27 gauge needle. **B:** Initial wheal measures 4 mm. **C:** Wheal response to 0.004 mg/mL Histamine base at 10 minutes (positive control). The histamine response will have the same appearance as a positive allergen response. **D:** Measuring the response at 10 minutes.

the IT extract was diluted 1,000-fold (33). For example, Figures 26.1 and 26.2 show similar skin reactions. Figure 26.1 (SPT) uses a histamine base of 6 mg/mL, and Figure 26.2 (IT) uses a histamine base of 0.004 mg/mL (roughly a 1,000-fold difference in concentration).

The clinical interpretation of a positive IT test after a negative SPT for the same extract is controversial (45). Two studies have examined SPT negative, IT positive patients for cat (46), and grass (47) allergy. These studies did not show a significant difference between SPT negative, IT positive patients and SPT negative, IT negative patients for symptoms recorded over the grass pollen season, grass pollen nasal challenges, exposure to a house with cats, or cat extract nasal challenge. These suggested that when the SPT was negative, clinical allergic symptoms were unlikely regardless of the IT result. However, the studies were small and both cat and grass are potent allergens with standardized extracts. When using a nonstandardized extract, a negative SPT might not be as predictive. Ultimately, knowledge of the allergen extract, clinical suspicion based on allergic history and physical findings, and test results must be combined into a clinical impression.

Intradermal Dilutional Testing

IDT (42) does not start with a negative SPT, but rather testing begins with very small amounts of allergen extract placed intradermally (e.g., greater than 100,000-fold dilution). Negative tests are followed by stronger dilutions at 5- to 10-fold intervals until either positive reactions occur or no reaction is observed. IDT is used by the FDA for allergen standardization and in clinical venom allergy testing. IDT, based on the work of Herbert Rinkle (48), was historically the primary allergy test used by many otolaryngologist. While antigen standardization began with ragweed in 1975, most allergen extracts were and still are nonstandardized and based on units of w/v. W/V is the grams of raw material divided by the volume of extract. Similarly, one could describe the strength of a cup of coffee by the weight of the dry coffee and the volume of water used. (Some nonstandardized antigens use Protein Nitrogen Units, a measure of total protein, which can correlate poorly with the small portion of antigenic proteins.) The most common w/v extracts were 1:20 and w/v is still a common unit used. Rinkle used fivefold dilutions of 1:20 w/v extracts diluted six times (Table 26.1).

ITs would begin with Dilution no. 6. If no. 6 was negative, a Dilution no. 5 was placed, then continuing progressively stronger. He observed that clinically allergic individuals tended to develop a 7 mm wheal and if the next more concentrated dilution was placed, a 9 mm wheal would form (Fig. 26.3). This pattern of two consecutive wheals that enlarged 2 mm or more from the prior dilution suggested allergic sensitization. The first wheal that enlarged more than 2 mm was called the "endpoint" and the second wheal the "confirming" wheal. He suggested that when the endpoint wheal was unexpectedly large

TABLE 26.1 FIVEFOLD DILUTIONS OF ALLERGEN EXTRACT

Concentrate	1:20 w/v
Dilution no. 1	1:100 w/v
Dilution no. 2	1:500 w/v
Dilution no. 3	1:2,500 w/v
Dilution no. 4	1:12,500 w/v
Dilution no. 5	1:62,500 w/v
Dilution no. 6	1:312,500 w/v

Nonstandardized allergen extracts frequently use w/v as a unit and the most common extract strength is 1:20 w/v. The Dilution no. 1 can be made by mixing 1 mL of extract "Concentrate" with 4 mL of diluent. Although the Dilution no. 1 is designated as 1:100 w/v by convention, it may not have the same biologic reactivity as an extract produced with 1 g of raw allergen and 100 mL of extracting fluid.

(e.g., 13 mm) or there was no confirming wheal that the test be judged negative or repeated on another date. One of the reasons for the popularity of IDT among otolaryngologists is that the "endpoint" responses can be used to calculate the amount of antigen placed in vials for starting immunotherapy. The IDT results help assure the vials were sufficiently dilute to inject safely. Disadvantages of IDT include that it requires multiple ITs for each allergen, is time consuming, requires technical proficiency, requires preparation of multiple dilutions of each allergen, and is inconsistently reimbursed. Also, IDT is controversial as to what constitutes a negative test. Generally, the controversy surrounds the no. 2 dilution. If only the no. 2 dilution is positive, it is similar to the testing scenario where a patient is SPT negative, but single IT positive discussed above. Thoughtful interpretation is warranted.

Blended Techniques of Skin Testing

The disadvantages of IDT testing caused some authors to look for techniques that provided the quantitative endpoint information of IDT while applying fewer skin tests. Jack Krouse

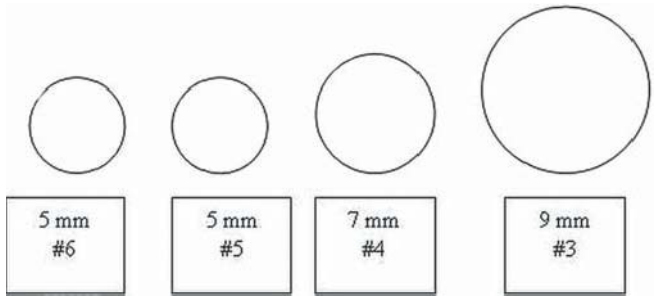

Figure 26.3 IDT example. The circles represent the wheal sizes 10 minutes after placing a 4 mm wheal of fivefold dilutions. The increase from 4 to 5 mm is independent of hypersensitivity and expected. The no. 6 dilution on the left would be placed first, and if negative then a no. 5 dilution placed. In this example, the no. 4 dilution increases to 7 mm suggesting a positive response (the endpoint) and the no. 3 dilution increases greater-than or equal to 2 mm more than the no. 4 "confirming" the reaction is not spurious.

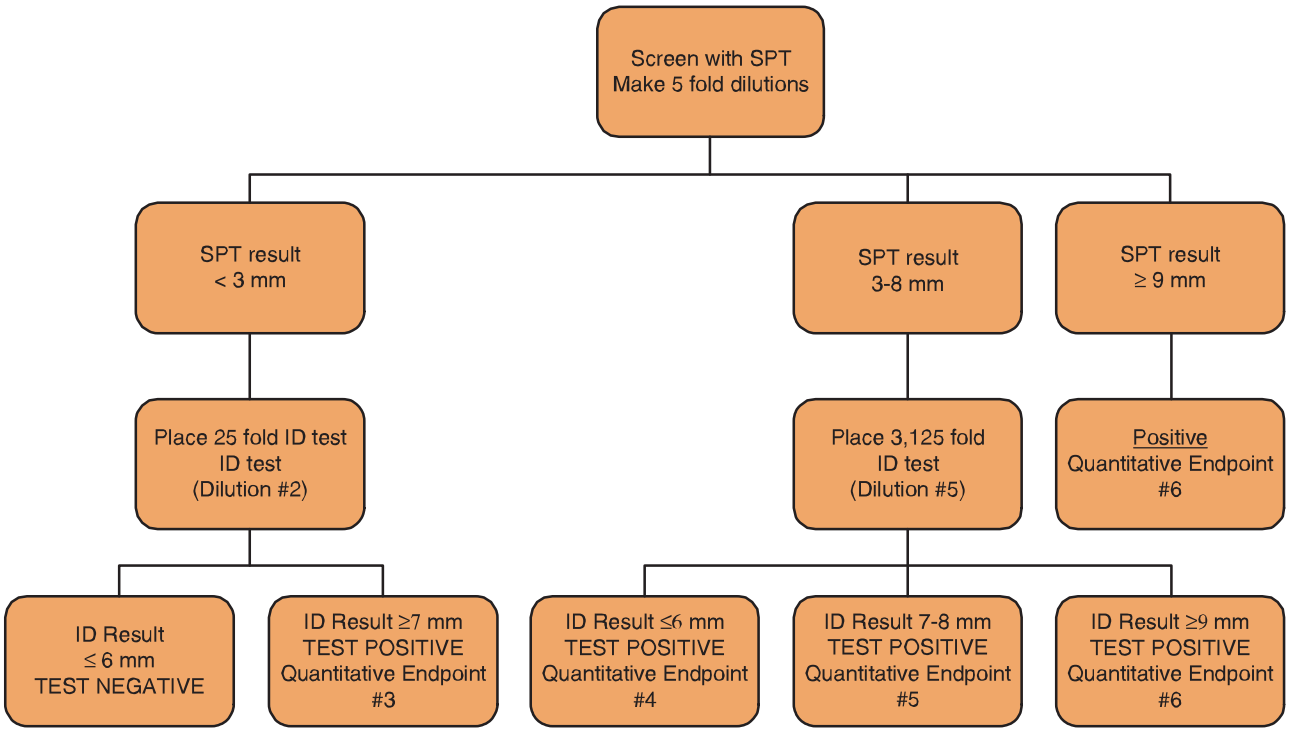

Figure 26.4 MQT testing algorithm Fivefold dilutions are prepared from allergen extract and the initial test is a SPT from the allergen extract. The results of the SPT are read at 10 to 20 minutes and an ID test from the specified dilution is placed according to the algorithm. MQT test provides a postive/negative result and an "endpoint" quantification similar to IDT with fivefold dilutions. MQT, Modified Quanitative Testing; SPT, Skin Prick Test; ID, Intradermal Test. Adapted from Krouse JH, Mabry RL. Skin testing for inhalant allergy 2003: current strategies. *Otolaryngol Head Neck Surg* 2003;129:S33–S49.

advocated "Modified Quantitative Testing" (MQT) (42,49). MQT testing starts with a SPT and depending on the size of the reaction, a dilution is recommended for an ID test. Based on the SPT and ID results, a quantified result is established in addition to a positive/negative result (Fig. 26.4).

Similar to IDT, endpoints provided by MQT can also be used to calculate a safe starting dose for immunotherapy. Of concern, the MQT algorithm can lead to placing a no. 2 IT dilution after a negative SPT test, which is again controversial.

sIgE Testing

In 1921, Prausnitz and Küstner (50) reported temporary tranference of fish allergy after intentional blood transfusion between the authors. The molecule responsible for their observations, IgE, was isolated independently by two groups using differing techniques in the late 1960s (51,52). Methods to assess specific allergies using sIgE in the sera or plasma were developed soon after and have been refined over the years. While different methods are used in different laboratories, they are all held to the same quality controls by the 1998 Clinical Laboratory Improvement Ammendments in the United States.

All sIgE testing has a common strategy. The specific allergen being tested, for example cat dander, is adhered to a fixed substrate (e.g., a paper disk, string, or sponge). The patient's serum or plasma is exposed to the fixated allergen and the patient's IgE specific to that allergen binds. The remaining serum is washed away leaving only IgE bound to the allergen. Labeled monoclonoal IgG molecules are then added and bind to the IgE. The IgG molecules are nonhuman antibodies produced against human IgE. The unbound IgG is washed away and the label is used to semiquantitatively measure the remaining bound IgG, which correlates to the patient's bound IgE. The labels used include radioactive isotopes, flourescent markers, or enzymes that catalyze a reaction that produces a measurable substance (53) (Fig. 26.5).

Initially, sIgE measurements in the 1970s were inconsistent (54,55), but modern sIgE tests agree reasonably well with skin testing (56). But, few studies have directly compared skin testing and sIgE testing to blinded allergen challenges or natural exposures. Many authors have concluded that sIge testing is slightly less sensitive than SPT (53), but the lack of a gold standard for clinical inhalant allergy makes it difficult to know which test is the most accurate.

Advantages of sIgE testing include the ability to test for multiple allergens from a single needle stick, test reults are not influenced by medication use or skin conditions, there is no risk of anaphylaxis, and the test yields semiquantitative information. Disadvantages cited have included cost; however, cost to the patient is not much different per antigen. Other disadvantages include a longer delay for the test

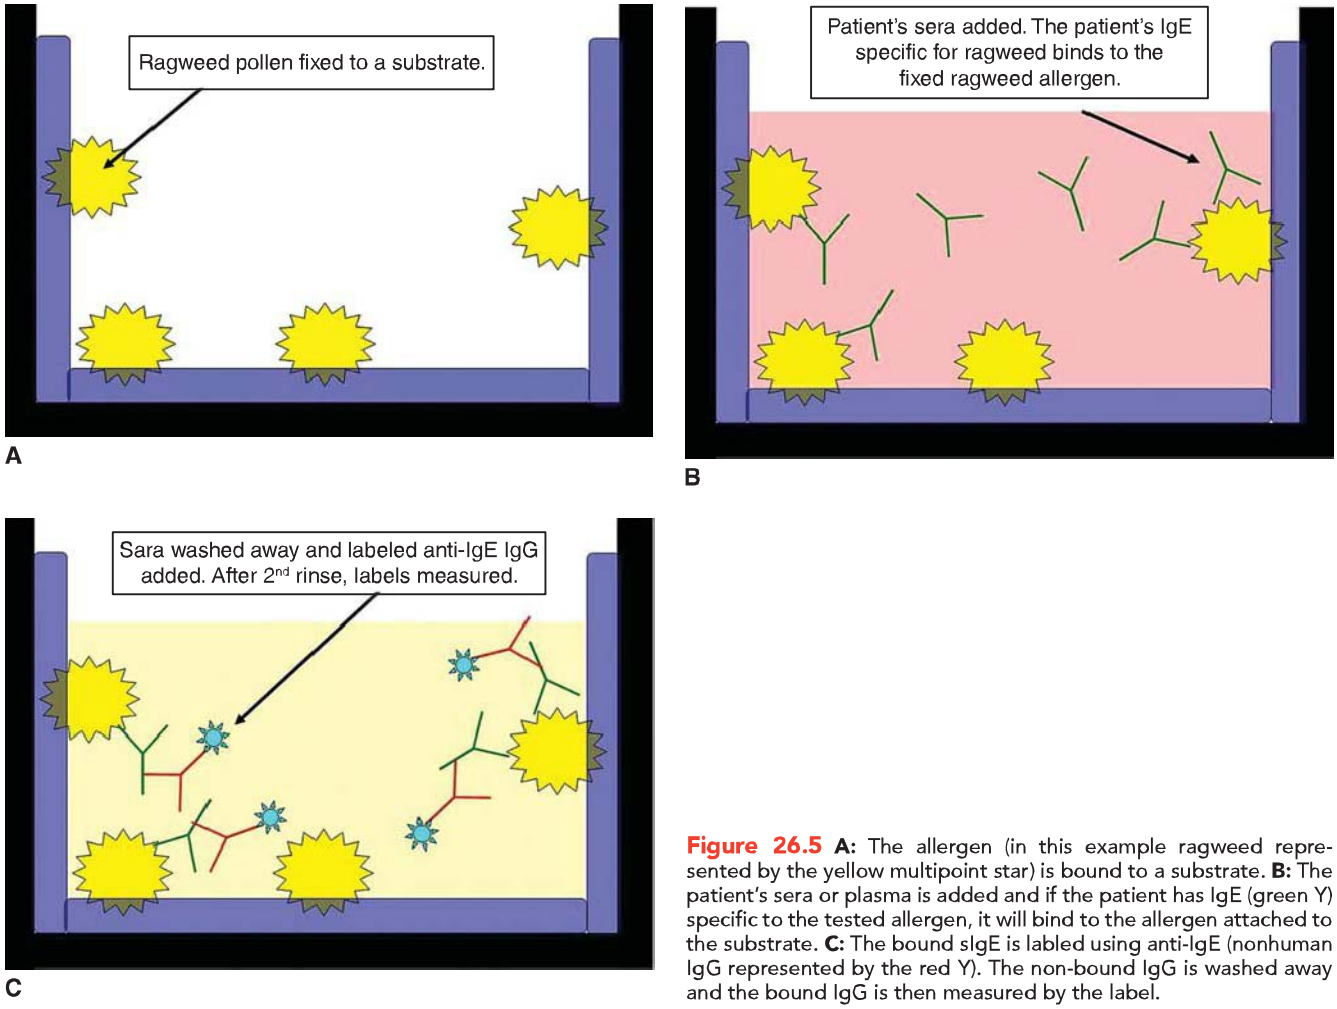

Figure 26.5 **A:** The allergen (in this example ragweed represented by the yellow multipoint star) is bound to a substrate. **B:** The patient's sera or plasma is added and if the patient has IgE (green Y) specific to the tested allergen, it will bind to the allergen attached to the substrate. **C:** The bound sIgE is labled using anti-IgE (nonhuman IgG represented by the red Y). The non-bound IgG is washed away and the bound IgG is then measured by the label.

results than with skin testing. Like skin testing, the clinical signifcance of detectable, but low levels of IgE generates controversy. Also, sIgE testing, as with skin testing, is dependent on the quality of the extracted allergen used.

Another difference between sIgE and skin testing relates to immunotherapy. In skin testing, the same allergen extract is used for skin testing and immunotherapy. In sIge testing, the allergen used in testing and immunotherpy are likely from different manufactures. Especially for nonstandardized allergens, this change of manufacturer is potentially problematic.

Total IgE

IgE crosses the placenta minimally and increases with age in both atopic and nonatopic patients. IgE is scarce and comprises only 0.0005% of the total immunoglobulins of the average adult (57). Total IgE is elevated in atopic conditions such as atopic dermatitis, atopic asthma, allergic fungal sinusitis, and allergic rhinitis. Unfortunately, overlap of atopic and nonatopic total IgE levels limits clinical utility (57). Recently, it has been proposed that the ratio of sIgE to total IgE ratios may be clinically relevant. Higher sIgE/tIgE rations were associated with more severe allergic symptoms. Specifically, high sIgE/tIgE ratios were seen in food and venom allergy where systemic reactions are more common than most inhalant allergy (58). As two sIgE molecules must cross-link to the allergen on the surface of a mast cell to signal degranulation, it is theorized that cross-linking may be more likely as the IgE specific to that allergen constitutes a higher percentage of the total IgE.

INTERPRETING ALLERGY TESTS

Allergy tests should be obtained when a patient's history and physical exam suggest allergic disease and testing results will assist in symptom management. Allergens tested should be reasonable candidates to explain the patient's symptoms. If a patient complained of allergy symptoms only in spring season while living in southeastern United States, testing for ragweed or reindeer may not be sensible.

The degree of testing reactivity is observed by the wheal and flare size in SPTs and quantified in sIgE testing, MQTs, and IDT. It is tempting to correlate higher reactivity with symptom severity; however, multiple studies have not found a correlation (59).

In food allergy, comparisons between the sIgE level and the probability of a reaction on a double-blind

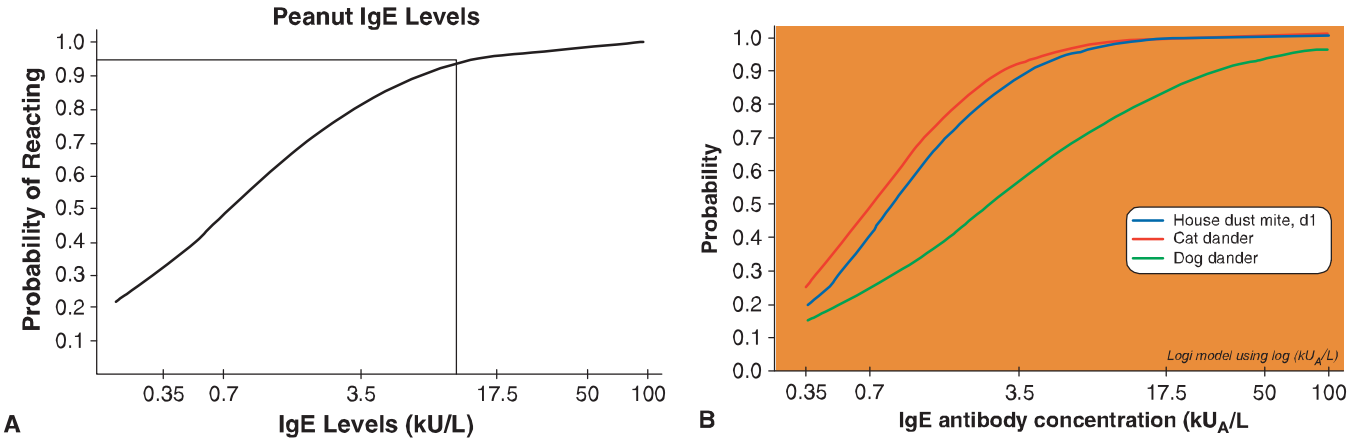

Figure 26.6 Probability of clinical allergy versus sIgE levels (kU/L) **A:** Probability of reacting on a peanut challenge plotted against IgE levels in a population suspected of peanut allergy. A negative IgE test of 0.35 kU/L does not exclude a positive reaction after peanut challenge. Reprinted from Elsevier Limited, License 2677361287765 from Table VI in Sampson H. Update of food allergy. *J Allergy Clin Immunol* 2004;113:805–819, with permission. **B:** Inhalant (Dust mite, Cat, and Dog) Probablity calculated from clinical evaluations plotted against sIgE levels for inhalant allergens. placebo-controlled food challenge do correlate. In food allergy, sIgE levels are more accurate when the sIgE is high. This has led to thresholds of sIgE levels that confer a greater than 95% confidence that a reaction would be seen on a food challenge. If a child with a history suspicious for peanut allergy has a sIgE greater than 15 IU/kL, they have a greater than 95% chance of having a positive reaction during a peanut challenge (6). It is difficult to generate the curves for inhalant allergy because the validity of challenge tests is not as well agreed upon. However, when sIgE levels for inhalant allergens were compared to diagnosis by an allergist based on SPT, history, and physical, a similar probability curve was observed (60) (Fig. 26.6).

HIGHLIGHTS

- Positive allergy tests are more common than clinically symptomatic allergic disease. Because of a significant false positive rate, allergic disease is primarily a clinical diagnosis based on history, physical exam, and knowledge of local allergens.
- Allergens have several properties that affect the symptoms they cause. A clinician's familiarity with the potency, size, abundance, distribution, and cross-reactivity of common allergens is useful in selecting allergens for testing.
- Allergy sensitivity may be assessed by SPT, sIgE tests, IDT, single ITs, and blended tests.
- Allergy testing is necessary to identify individuals who would benefit from allergen-specific immunotherapy. Allergy test results can also guide pharmacologic therapy and environmental control strategies.

27 Diagnostic Imaging

Jenny K. Hoang *Adam M. Becker*

Computed tomography (CT) and magnetic resonance imaging (MRI) are indispensable radiologic modalities for the evaluation of the paranasal sinuses. These cross-sectional techniques allow for multiplanar visualization, and are superior to plain radiography for resolution of small anatomical structures and lesions. The aim of this chapter is to describe the role of imaging, and the imaging approach to common sinus pathologies.

INDICATIONS FOR SINUS CT AND MRI

Sinonasal imaging is performed for two main indications: inflammatory disease and mass. The choice between use of CT and MRI depends on the clinical scenario. The common indications for CT and MRI of the paranasal sinuses are reviewed in the American College of Radiology Appropriateness Criteria (1). A summary of the indications is found in Table 27.1.

CT has a role in both inflammatory disease and investigation of a mass because of its superior bone resolution. In the case of inflammatory disease, CT is most commonly performed for recurrent acute or chronic rhinosinusitis. There is little yield for imaging in acute and subacute rhinosinusitis since these are clinical diagnoses that are managed nonsurgically (1,2). Exceptions are if complications are suspected, or if the patient has comorbidities that predispose to complications, including diabetes, immune compromised state, or a past history of facial trauma or surgery (2).

MRI is not ideal for visualizing bony structures and generally has no role in uncomplicated inflammatory disease. The strength of MRI is its superior soft tissue resolution, which allows differentiation between three possible causes of sinus opacification on CT: a solid mass, inflammatory mucosa, and an obstructed fluid-filled sinus. Thus, the main roles of MRI are in characterizing suspected masses, staging malignancies, and surveillance of treated neoplasms. MRI is also superior to contrast-enhanced CT for evaluation of the orbit and brain in the setting of complicated rhinosinusitis or invasive fungal sinusitis.

IMAGING TECHNIQUES

Table 27.1 summarizes the physical principles, protocols, and potential risks of CT and MRI. It is important for the clinician to be familiar with these basic concepts and the terminology used to describe imaging findings.

CT Terminology

The shades of grey on CT are described with the terms "density" or "attenuation." High density indicates a "whiter/brighter" appearance on CT, as seen with proteinaceous secretions, allergic mucin, and calcification. The wide range of density values detected by CT (spanning >2,000 Hounsfield units) cannot be displayed on a single set of images; therefore different "CT windows" are used to display a single scan (Fig. 27.1). In the era of electronic picture archiving, CT windows can be changed easily with shortcut buttons. For sinus imaging, "bone windows" are used to display the fine detail of osseous abnormalities or calcifications within a mass. "Soft tissue windows" are also routinely reviewed and have higher contrast to help demonstrate the narrow density differences between soft tissue and fluid.

MRI Terminology

The shades of grey on MRI are described with the term "intensity." The combination of signal intensities on different sequences (e.g., T1 and T2) and the use of intravenous contrast help to infer the tissue properties (Fig. 27.2). For example, simple fluid is hypointense (darker) on T1 sequences, hyperintense (white/brighter) on T2 sequences and does not enhance.

TABLE 27.1 COMPARISON OF CT AND MRI PRINCIPLES, PROTOCOLS, INDICATIONS AND POTENTIAL RISKS

	CT	MRI
Physics Principles	• An x-ray source rotating around the patient emits highly collimated x-ray beams at various angles around the patient. • Detectors opposite the x-ray source register the x-ray beam after it is partly absorbed by the patient. • The x-ray attenuations received by the detectors are converted into images.	• Spinning protons of hydrogen atoms in the body are aligned by a high-strength magnetic field. • A radiofrequency wave is introduced to excite the protons. When the radiofrequency wave is turned off, spinning protons relax and emit a signal. Different tissues have different signals and these signals are converted into images.
Protocol	• Data acquisition in the axial plane. • Multiplanar reconstruction of axial images into sagittal and coronal planes. In many centers this has eliminated the need for direct coronal imaging with the patient in prone position. • No intravenous contrast unless intraorbital or intracranial complications.	• T1-, T2- and postcontrast fat-saturated T1-weighted images in the axial and coronal planes.
Indications	• Acute and subacute sinusitis in immunodeficient patient. • Acute and subacute sinusitis with associated orbital complications and/or neurologic deficit. • Recurrent acute or chronic sinusitis (possible surgical candidate). • Sinonasal polyposis. • Sinonasal obstruction, suspected mass lesion.	MRI and CT are complementary for the following indications: • Acute and subacute sinusitis with associated orbital complications and/or neurologic deficit. • Sinonasal obstruction, suspected mass lesion.
Potential risks	• Uses ionizing radiation. Minimizing use of radiation exposure is especially important in young adults and children. • Iodinated contrast can worsen renal impairment, cause lactic acidosis in diabetic patients on Metformin, and has a very small risk of anaphylactic reaction.	• Implantable devices such as cardiac pacemakers, cochlear implants, metallic intraocular foreign bodies can be preclude MRI scanning. • Use of Gadolinium contrast in patients with renal failure is associated with a risk of nephrogenic sclerosing fibrosis.

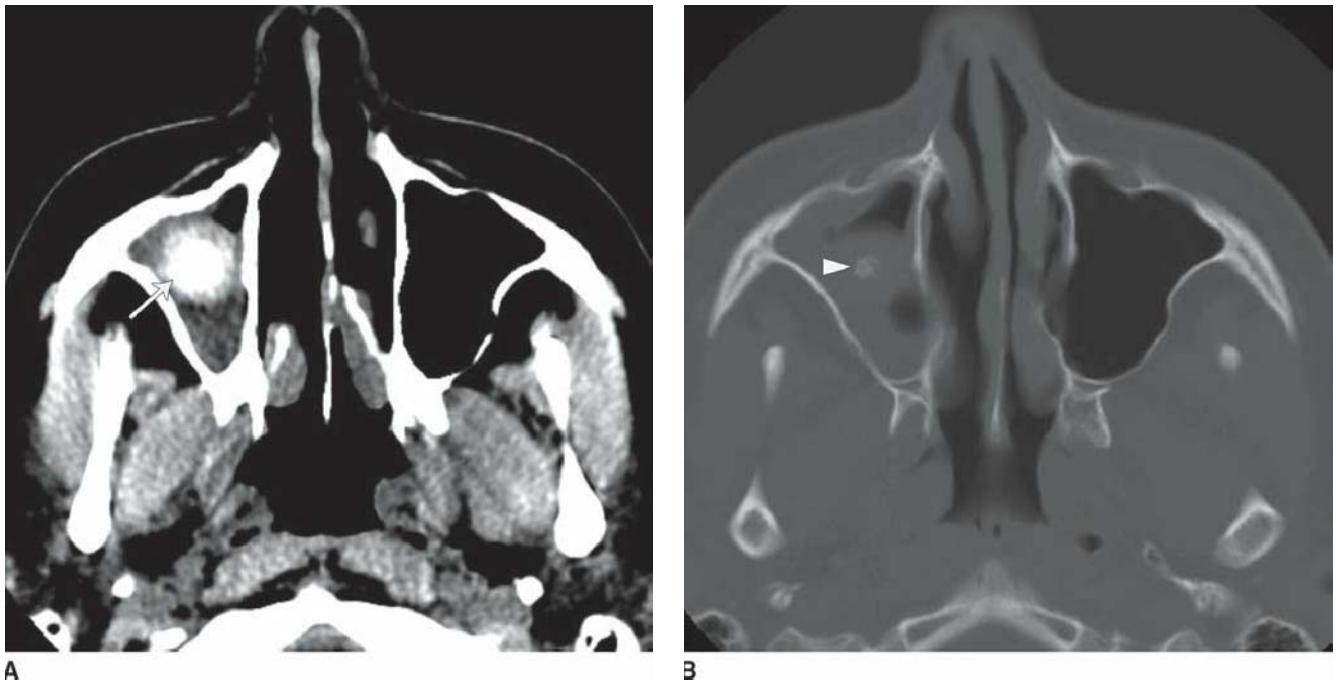

Figure 27.1 Fungus ball in soft tissue and bone windows. **A:** Axial CT image with soft tissue windows shows a right maxillary sinus high-density rounded mass (*arrow*). **B:** Axial CT image with bone windows shows central calcification (*arrowhead*) within the mass. Note that the fungus ball and mucosa have different density appearances on soft tissue window, which cannot be appreciated on bone windows. On bone windows, the calcifications and bony structures are more conspicuous.

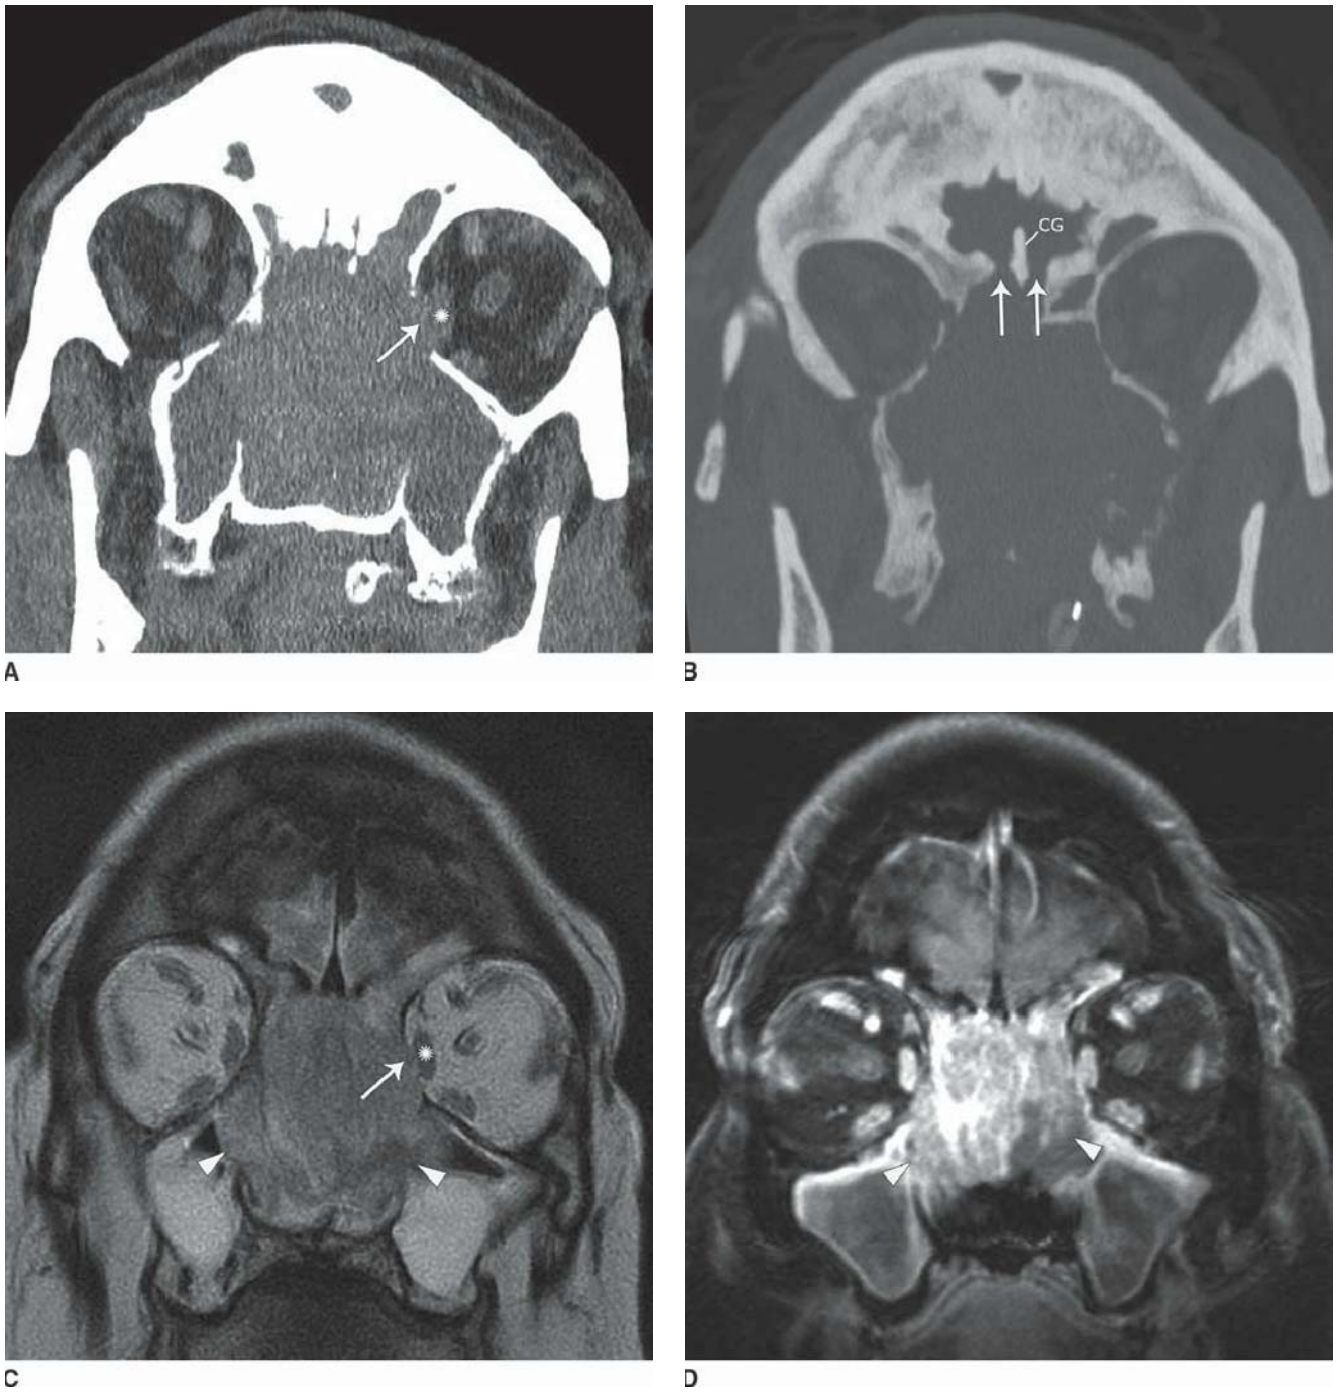

Figure 27.2 Sinonasal carcinoma with invasion of anterior cranial fossa and bony orbit. Differences between CT and MRI. **A:** Coronal CT image shows complete opacification of the bilateral nasal cavity and paranasal sinuses. There is bony destruction at the medial wall of the left orbit (*arrow*) with loss of fat plane around the medial rectus muscle (*asterisk*). **B:** Coronal CT image shows bony destruction at the cribriform plate (*arrows*). CG, crista galli. **C:** Coronal T2-weighted MRI image more clearly depicts the difference between isointense tumor mass (*arrowheads*) filling the nasal cavity and hyperintense inflammatory fluid in the maxillary sinuses. Tumor bows into the orbit (*arrow*), but a smooth contour suggesting that the periorbita is intact. The medial rectus muscle (*asterisk*) has normal signal and size. There is no intracranial mass despite anterior skull base bony destruction. **D:** Coronal enhanced T1-weighted MRI image shows enhancing tumor in the nasal cavity (*arrowheads*) extending into the frontal sinuses. Note that MRI is better than CT in differentiating between tumor and fluid-filled maxillary sinuses, which are T2 hyperintense and nonenhancing.

Other sequences, such those as with fat-saturation or suppression, can help to confirm fat content and make enhancement more conspicuous when the high signal of fat is nulled.

IMAGING APPROACH

Rhinosinusitis

CT is the principal modality used in imaging rhinosinusitis. A systematic approach to interpretation includes evaluation for the following: (a) signs of inflammatory sinus disease, (b) underlying mass or the presence of complications, and (c) anatomical and critical variants that may make future surgery more difficult or hazardous (3).

Imaging Findings of Rhinosinusitis and Sinonasal Polyposis

A mild degree of mucosal thickening is a common, but nonspecific finding on sinus CT. It can be found in acute or chronic rhinosinusitis, but may also be seen in asymptomatic patients. Nasoethmoidal mucosal thickening can also be part of the physiologic nasal cycle (4). Therefore, the presence of mucosal thickening should be interpreted in context with the clinical history and physical examination.

More specific signs of *acute rhinosinusitis* include dependent air–fluid levels and bubbly or strandy secretions (Fig. 27.3). CT cannot differentiate between bacterial and viral sinusitis. An uncommon, but possibly underdiagnosed

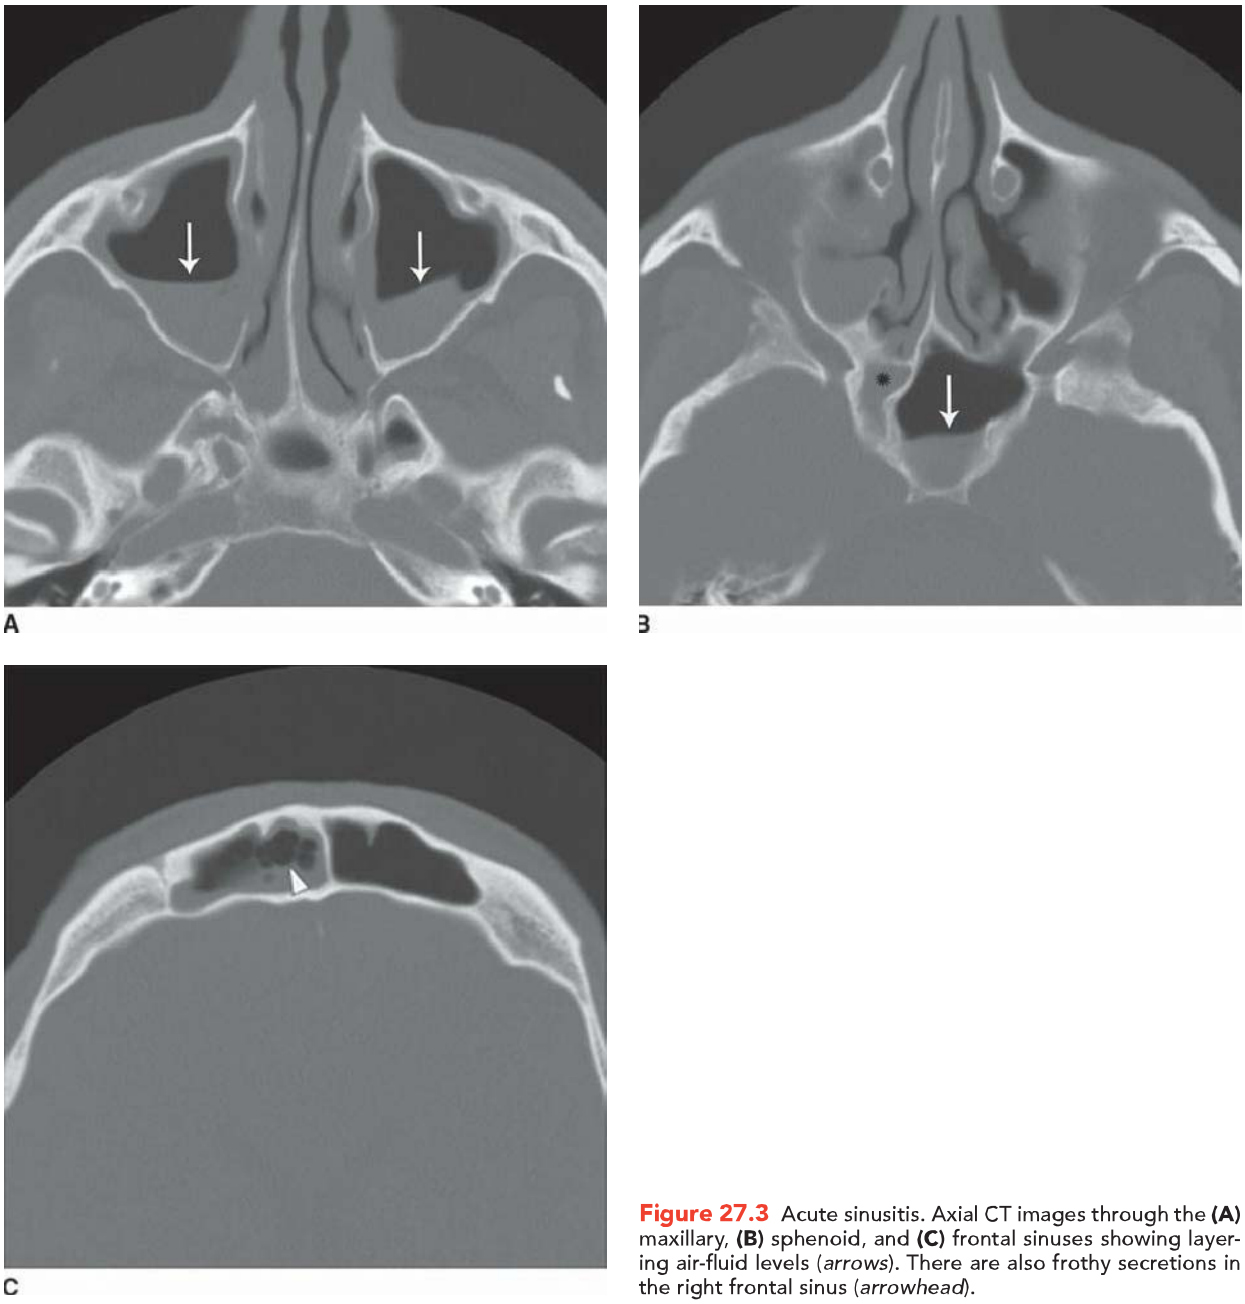

Figure 27.3 Acute sinusitis. Axial CT images through the **(A)** maxillary, **(B)** sphenoid, and **(C)** frontal sinuses showing layering air-fluid levels (*arrows*). There are also frothy secretions in the right frontal sinus (*arrowhead*).

Figure 27.4 Odontogenic maxillary sinusitis. Coronal CT image shows a left molar periapical abscess (*arrowheads*) contiguous with the left maxillary sinus in keeping with an oroantral fistula. There is mucosal thickening and possibly fluid in the left maxillary sinus. Other paranasal sinuses are normal.

cause of acute maxillary sinusitis is odontogenic infection. This should be suspected if the CT findings of sinusitis are severe in the presence of an oroantral fistula, periodontal lucency (abscess), or a tooth root projecting into the maxillary sinus (Fig. 27.4) (5). The typical finding in *chronic rhinosinusitis* is significant mucosal thickening or opacification in a nonexpanded sinus, often with ostial obstruction. A characteristic, but less common sign of chronic rhinosinusitis is sclerosis and thickening of bony sinus walls, particularly seen in the sphenoid and maxillary sinuses (Fig. 27.5). Chronic rhinosinusitis may also be associated with high-density opacification that often represents viscous or desiccated secretions, but can also be a sign of coexisting allergic fungal rhinosinusitis or fungus ball.

In correlating clinical symptoms with the pattern of disease on imaging, the sites of drainage pathway obstruction are of particular interest when planning endoscopic sinus surgery (ESS). There are three paranasal drainage pathways on each side that need to be evaluated for obstruction and the cause of obstruction: the ostiomeatal complex (OMC), frontal recess, and sphenoethmoidal recess (SER). The coronal plane is most similar to the endoscopic view and enables excellent visualization of the OMC (Fig. 27.6). The SER is best viewed in the axial and sagittal plane, and the frontal recess is best evaluated with a combination of coronal and sagittal imaging (Fig. 27.6).

Sinonasal polyposis is characterized by low-density polypoid lesions that fill the bilateral nasal cavity and the sinuses (Fig. 27.7). The polyps can obstruct the drainage pathways at multiple sites, resulting in retained secretions and opacification of sinuses. In neglected cases, they can exert pressure on bony structures leading to expansion of the sinonasal cavity and bony remodeling rather than focal bony destruction.

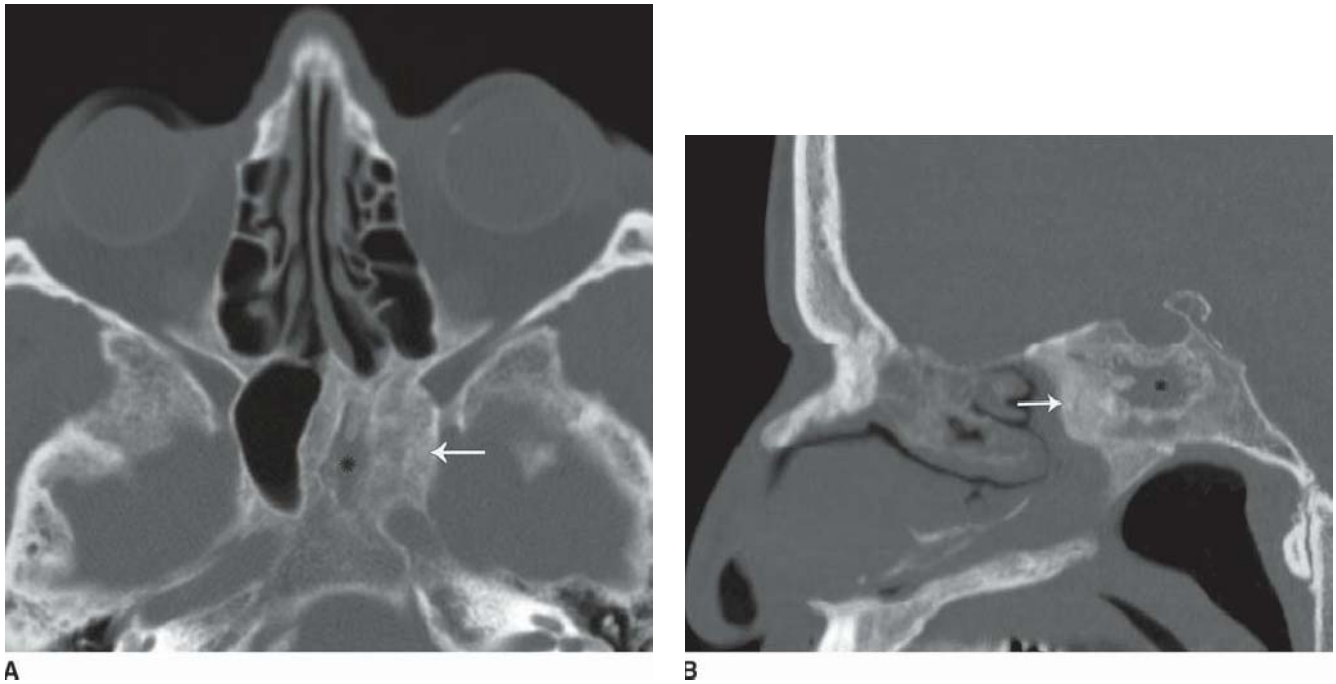

Figure 27.5 Chronic sinusitis. **A:** Axial and **B:** sagittal CT images show opacification of the left sphenoid sinus (asterisks) with bony sclerosis and wall thickening (*arrows*).

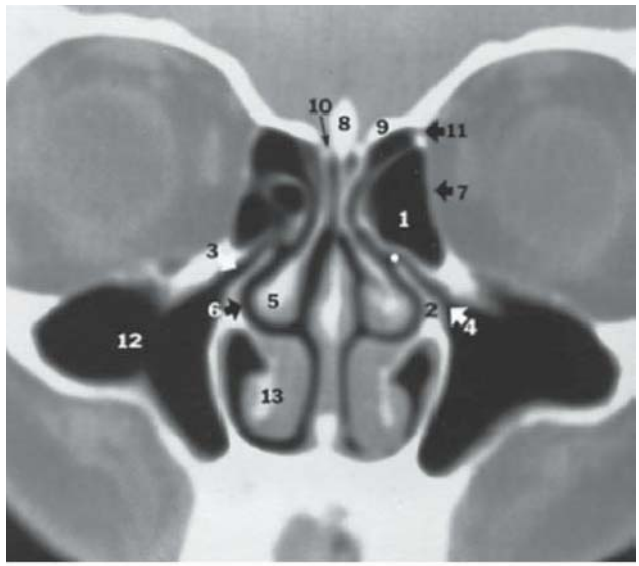

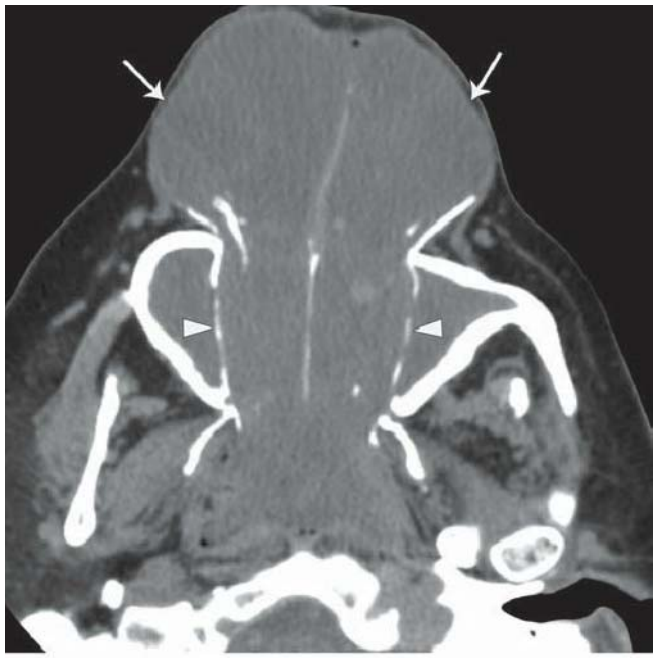

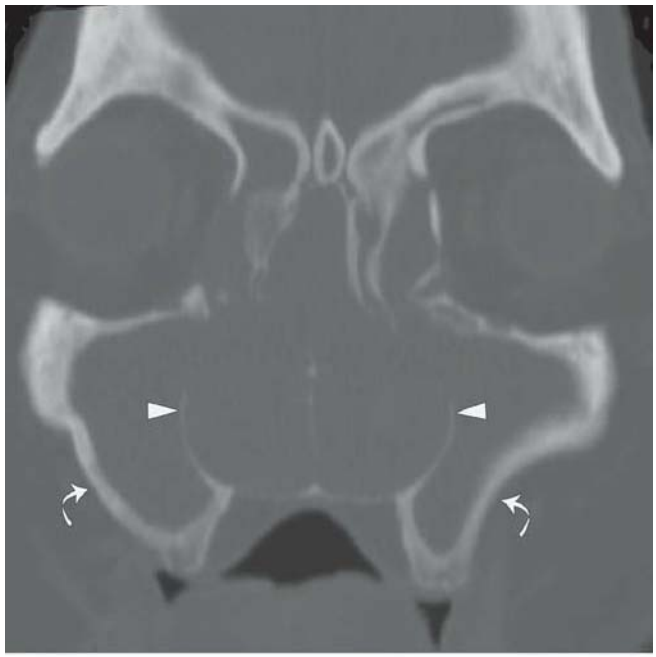

Figure 27.6 Normal paranasal sinus anatomy. **A:** Coronal CT image shows the normal OMC. Components of the ostiomeatal complex (OMC) are as follows: *1*, bulla ethmoidalis; *2*, uncinate plate; *3*, infundibulum; *4*, inner maxillary sinus ostium; *5*, middle turbinate; *6*, middle nasal meatus; *, hiatus semilunaris. The following are other important landmarks on this image: *7*, lamina papyracea; *8*, crista galli; *9*, fovea ethmoidalis; *10*, medial lamella; *11*, anterior ethmoidal foramen; *12*, maxillary antrum; *13*, inferior turbinate. **B:** Sagittal CT image shows the frontal recess. The frontal ostium (*arrows*) produces the waist of the classic hourglass configuration. Inferiorly, a large agger nasi cell bulges posteriorly to severely narrow and distort the recess. FS, frontal sinus; FR, frontal recess; AN, agger nasi; L, lacrimal bone; CB, concha bullosa; m, middle nasal meatus. **C:** Sagittal CT image shows the sphenoethmoidal recess (SER) (*arrowheads*). S, sphenoid sinus; PE, posterior ethmoidal sinus; A, anterior ethmoidal sinus; *arrowheads*, SER; *1*, inferior turbinate; *2*, middle turbinate; *3*, superior turbinate; *arrows*, basal lamella.

Figure 27.7 Sinonasal polyposis. **A:** Axial CT image shows complete opacification of the nasal cavity with soft tissue density masses projecting through the nostrils (*arrows*). There is bony thinning of the walls of the nasal cavity (*arrowheads*). **B:** Coronal CT image show nasal cavity opacification with thinning of the walls of the nasal cavity (*arrowheads*). There is also opacification of the maxillary sinuses with bony sclerosis and thickening (*curved arrows*). **C:** Photograph of polyps causing cosmetic deformity of the nose.

Other Inflammatory Sinus Lesions

Mucoceles are cysts lined by pseudostratified ciliated columnar epithelium (Fig. 27.8) and are most frequently observed in the frontal sinus followed by the ethmoidal, maxillary, and sphenoid sinuses. They are believed to form because of chronic obstruction of a sinus ostium, leading to accumulation of fluid within the sinus cavity and slow asymptomatic expansion of the sinus. Imaging typically demonstrates an enlarged completely opacified sinus with rounded contours and thinning of sinus walls. The density of the opacified sinus is usually low, representing fluid, but the sinus density can also be high as mucus becomes inspissated. Large mucoceles can lead to cosmetic deformities such as orbital proptosis and obstruct adjacent drainage pathways.

The less common complication of a chronically obstructed sinus is involution of the sinus, known as *atelectatic sinus* or silent sinus syndrome (Fig. 27.9). This forms because of negative intrasinus pressure and is most commonly seen in the maxillary sinus. The imaging findings are thinner sinus walls that are bowed or pulled inward to the center of the sinus. There may be cosmetic deformity or enophthalmos as the orbital floor bows down.

Retention cysts are common incidental findings in the maxillary and sphenoid sinuses. They are submucosal

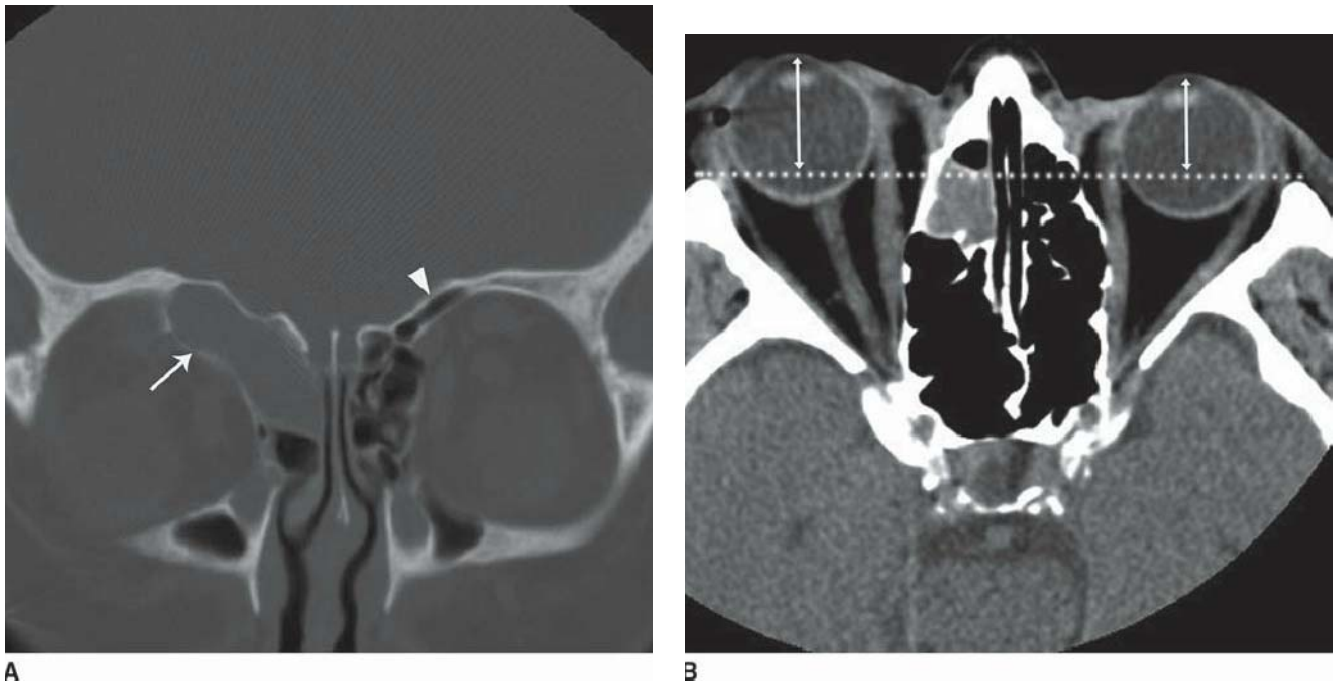

Figure 27.8 Frontal sinus mucocele with proptosis. **A:** Coronal CT image shows rounded expansion of the right frontal sinus with bony thinning (*arrow*) compared to the normal left frontal sinus (*arrowhead*). **B:** Axial CT image shows right proptosis due to mass effect from the mucocele. The dotted line is the interzygomatic line and allows comparison of the position of the right and left globe (*double arrowed lines*).

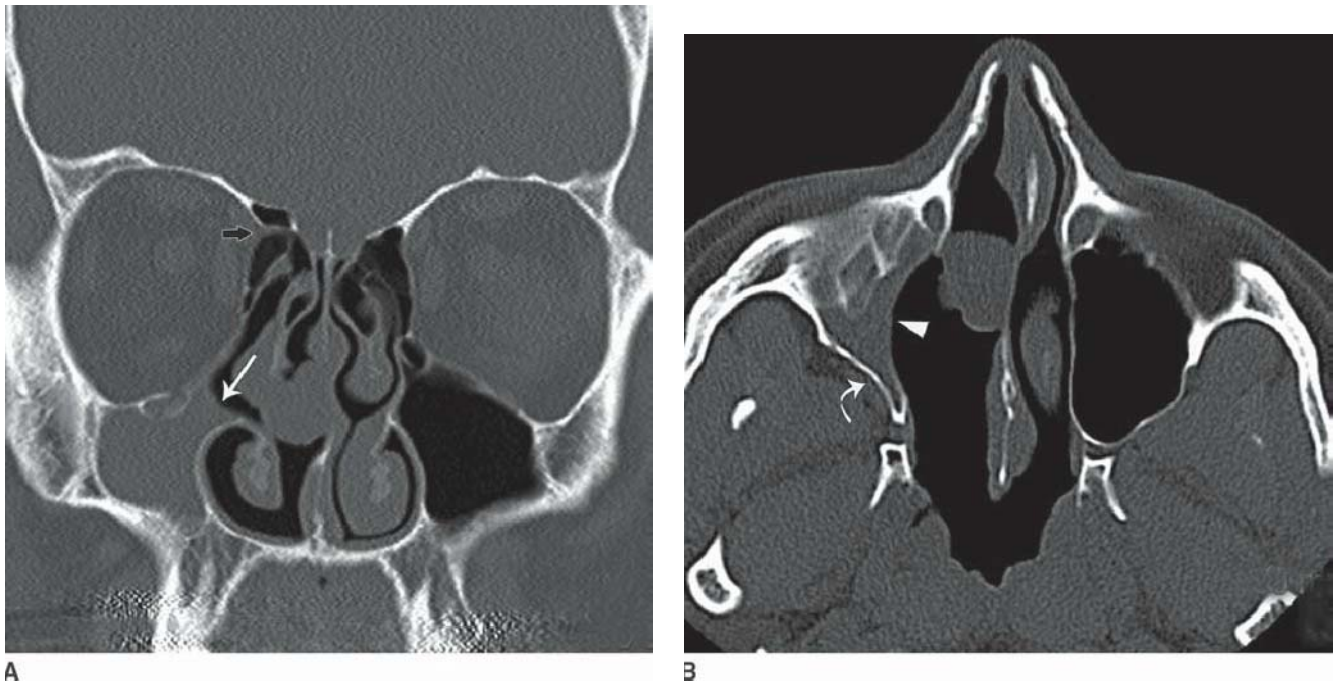

Figure 27.9 Atelectatic sinus. **A:** Coronal CT image shows a smaller right maxillary sinus. There is lateral rotation of the uncinate process (*white arrow*) that widens the space between the uncinate process and the middle turbinate. Note also the normal "nipple sign" indicating the anterior ethmoidal foramen (*black arrow*). **B:** Axial CT image shows smaller right maxillary sinus with inward bowing of the posterior (*curved arrow*) and medial walls (*arrowhead*) of the maxillary sinus. The atelectatic sinus predisposed the patient to complications during endoscopic sinus surgery (ESS).

C

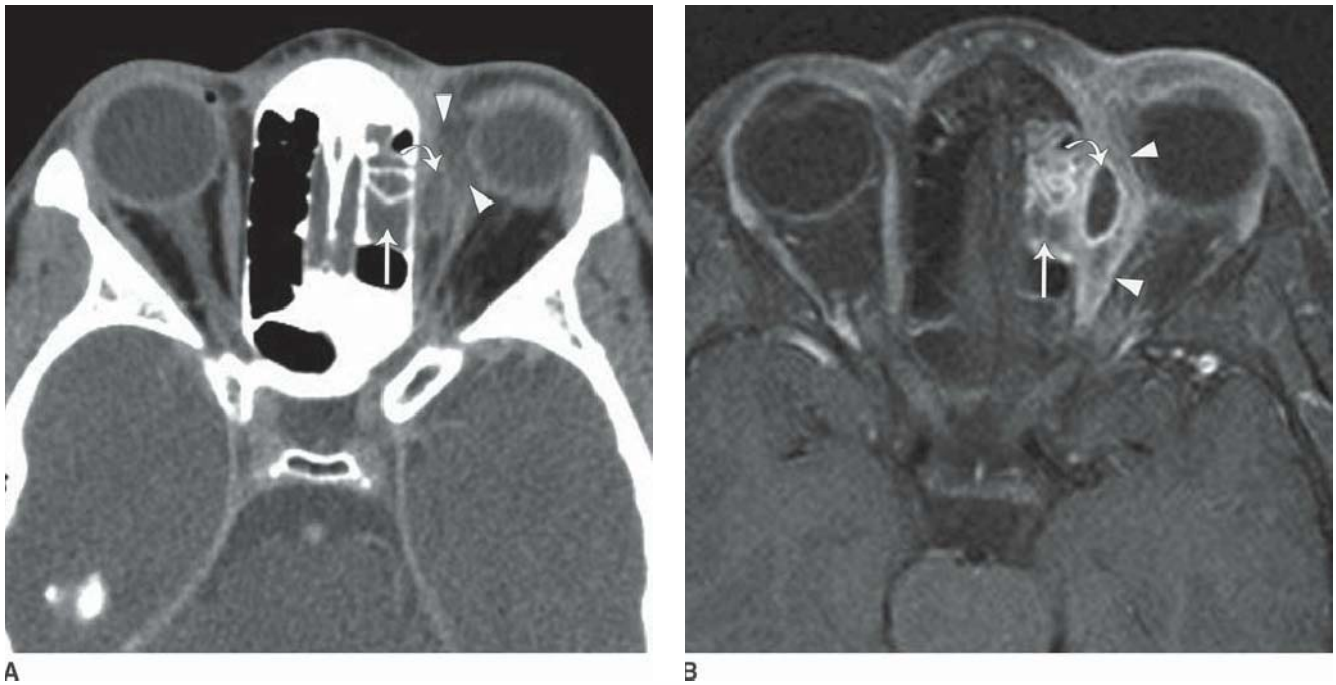

Figure 27.9 *(Continued)* **C:** Postoperative coronal CT image of patient in A and B demonstrating the ESS complication of a fracture to the floor of the orbit (*arrowhead*) and injury to the inferior rectus muscle with enlargement and fat stranding (*arrow*). Courtesy of MT Bhatti, MD, Duke University Medical Center.

collections of fluid (serous retention cysts) or collections from an obstructed seromucinous gland (mucous retention cysts). They most frequently occur in the maxillary antrum and appear as smooth, outwardly convex soft tissue density masses. On CT, it is difficult to differentiate a cyst from a polyp since both have soft tissue density. On MRI, a cyst does not enhance except for its mucosal surface. A polyp represents hyperplastic mucosa and will solidly enhance.

Evaluating Imaging for Complications and Obstructive Masses

Complications of sinusitis include spread of infection to the orbits, bone, and brain. CT or MRI can readily demonstrate an orbital subperiosteal abscess (Fig. 27.10) and deep extent of infection when there is clinically apparent periorbital cellulitis. Infection of the frontal bone can lead to a subperiosteal abscess known as *Pott puffy tumor* (6). If this is present, it is important to evaluate for intracranial complications (Fig. 27.11), which can occur with or without bony changes. MRI is more sensitive than CT for intracranial complications such as meningitis, subdural or epidural empyema (Fig. 27.12), brain abscess, and cavernous sinus thrombosis.

The most common cause of sinus drainage pathway obstruction is mucosal thickening, but occasionally the cause for obstruction may be due to anatomic variations and rarely there is an obstructing mass. The best sign of an underlying mass on CT is a soft tissue opacity with bony destruction (Fig. 27.13). In such cases, direct endoscopy and biopsy with or without preoperative MRI is the key to making a diagnosis. Prior to biopsy, it is important to consider whether the mass could be due to herniation of

A B

Figure 27.10 Orbital subperiosteal abscess complicating ethmoid sinusitis. **A:** Axial-enhanced CT image shows left ethmoid sinus opacification from acute sinusitis (*arrow*) and left orbit extraconal fat stranding (*arrowheads*). There is a small low attenuation collection (*curved arrow*) that is better seen on MRI. **B:** Axial-enhanced fat-saturated T1-weighted image shows left ethmoid sinus mucosal enhancement from acute sinusitis (*arrow*) and left orbit extraconal fat enhancement (*arrowheads*). There is a small ring-enhancing collection (*curved arrow*) representing an abscess.

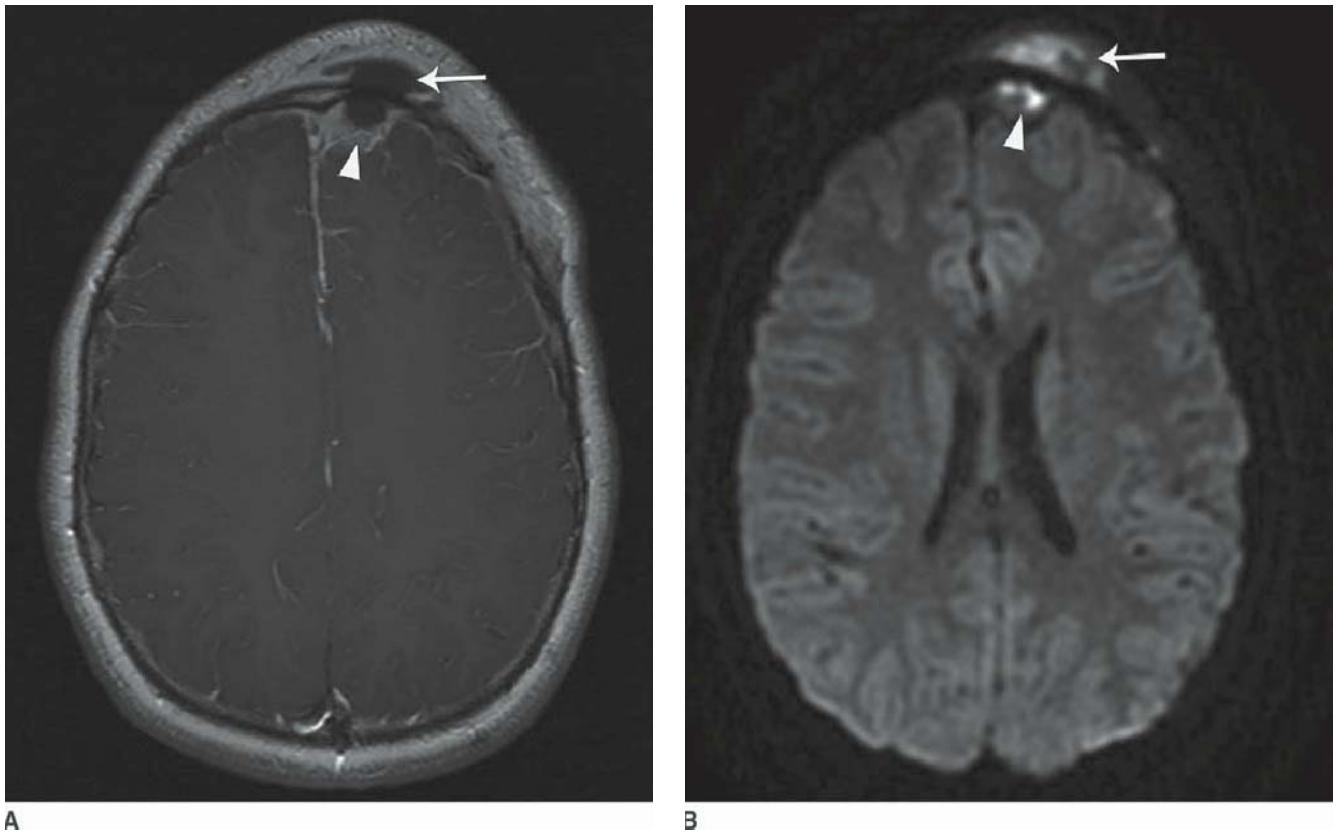

Figure 27.11 Pott puffy tumor with epidural empyema. **A:** Axial-enhanced T1-weighted image shows a hypointense collection overlying the left frontal bone (*arrow*) that is continuous with a rim enhancing extraaxial (outside brain parenchyma) collection overlying the left frontal lobe (*arrowhead*). **B:** Axial diffusion-weighted image shows bright signal in the collections indicating restricted diffusion. This supports the diagnosis of abscess.

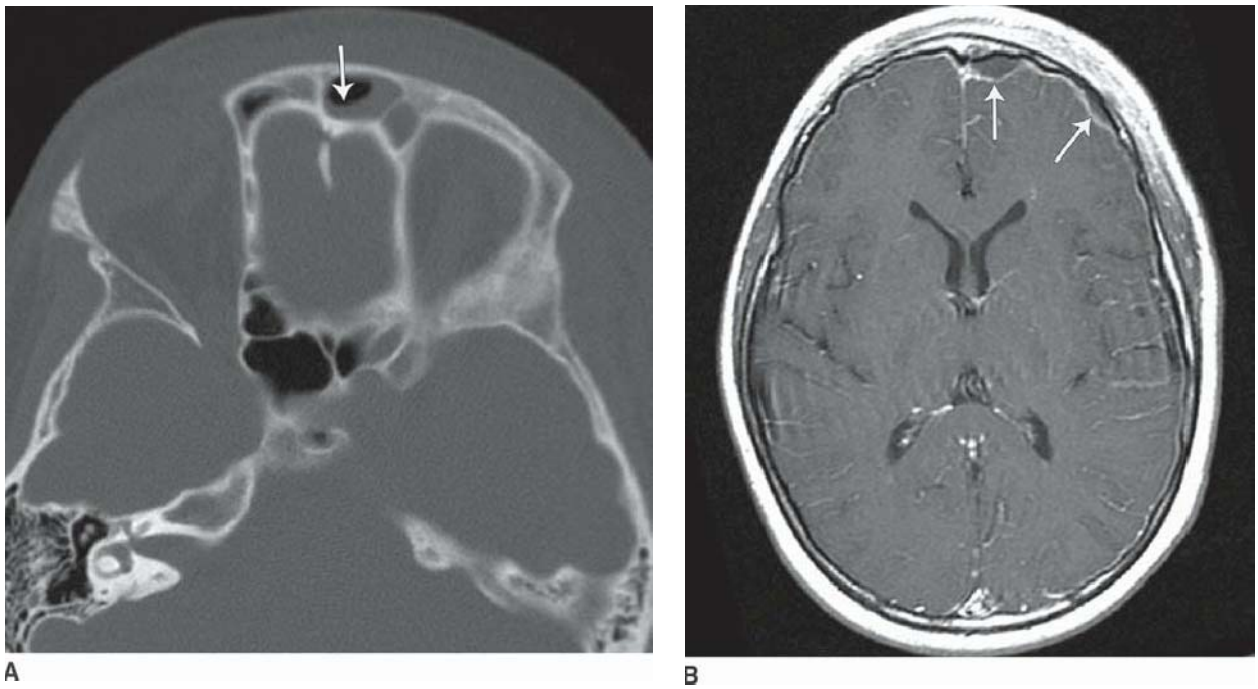

Figure 27.12 Subdural empyema complicating frontal sinusitis. **A:** Axial CT image shows left frontal sinus opacification with an air-fluid level (*arrow*) suggestive of acute sinusitis. **B:** Axial-enhanced T1-weighted MRI image of the brain shows a rim-enhancing crescentic extraaxial collection overlying the left frontal lobe consistent with a subdural empyema secondary to acute sinusitis.

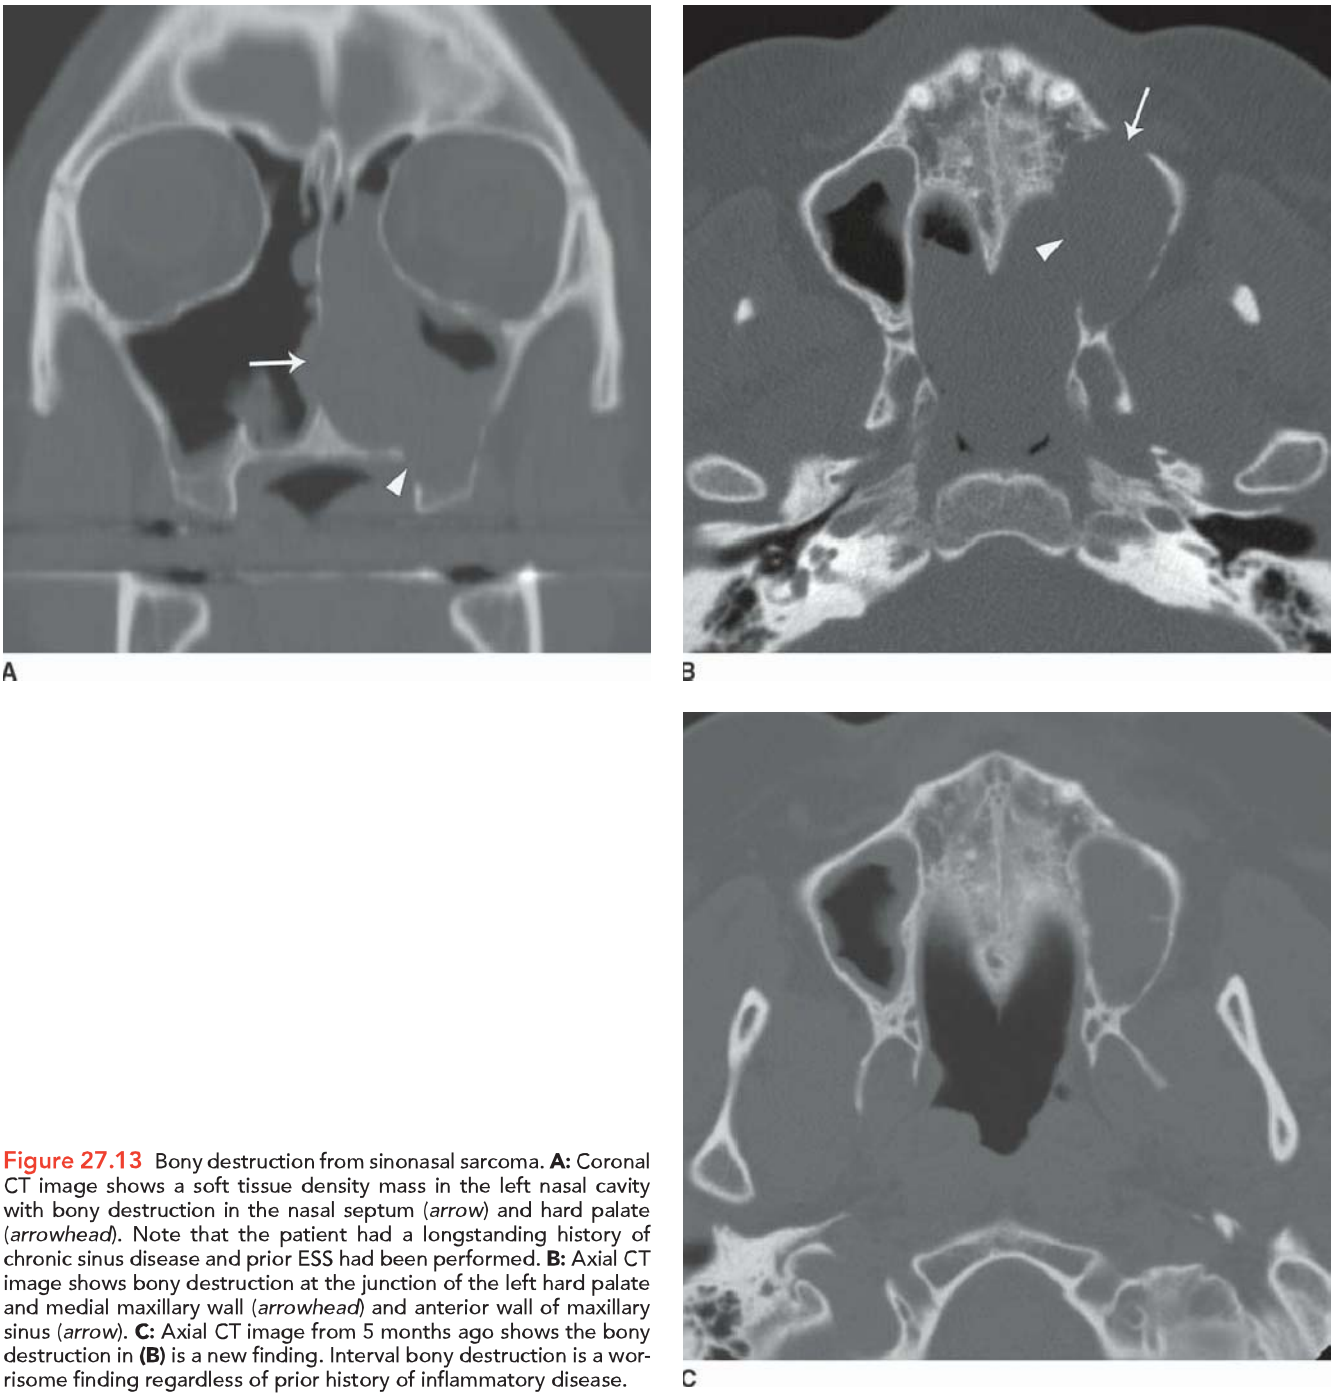

Figure 27.13 Bony destruction from sinonasal sarcoma. **A:** Coronal CT image shows a soft tissue density mass in the left nasal cavity with bony destruction in the nasal septum (*arrow*) and hard palate (*arrowhead*). Note that the patient had a longstanding history of chronic sinus disease and prior ESS had been performed. **B:** Axial CT image shows bony destruction at the junction of the left hard palate and medial maxillary wall (*arrowhead*) and anterior wall of maxillary sinus (*arrow*). **C:** Axial CT image from 5 months ago shows the bony destruction in **(B)** is a new finding. Interval bony destruction is a worrisome finding regardless of prior history of inflammatory disease.

intracranial contents. Meningoceles and encephaloceles appear on CT as a soft tissue mass abutting the skull base with focal bony dehiscence. The diagnosis is best confirmed with MRI. Meningoceles show T2 hyperintensity due to the presence of cerebrospinal fluid (CSF). Encephaloceles are characterized by a soft tissue mass with signal isointense to gray matter and contiguity to intracranial parenchyma (Fig. 27.14).

Finally, the sinus CT provides views of the brain, nasopharynx, and orbit which should be reviewed for incidental but significant findings or alternate nonsinus pathologies causing symptoms, such as mass or aneurysm.

Important Variants to Consider for Endoscopic Sinus Surgery

An important role of sinus CT prior to ESS is to detect anatomical variants that predispose to recurrent disease and affect operative technique, and critical variants that make surgery hazardous. The incidence of major ESS complications is 0.4% to 1.3% (7–9). Major complications include damage to the optic nerve, extraocular muscles, CSF leak,

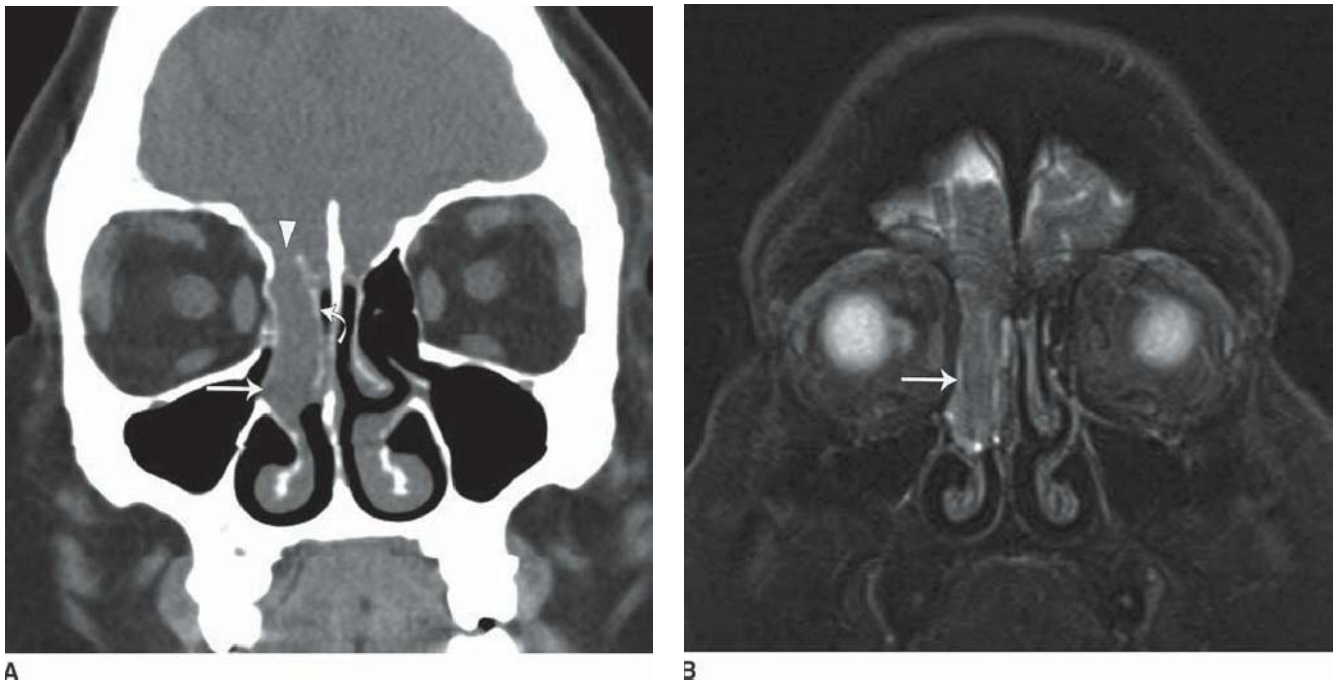

Figure 27.14 Encephalocele mimics a mass. **A:** Coronal CT image shows a soft tissue density mass in the right nasal cavity (*arrow*). There is a bony defect in the fovea ethmoidalis of the right cribriform plate (*arrowhead*) with widening of the space between the vertical lamella (*curved arrow*) and the roof of the orbit. **B:** Coronal T2-weighted MRI image shows the mass to be continuous with the right frontal lobe and to have the same signal characteristics.

meningitis, carotid vascular injury, orbital hematoma, and nasolacrimal duct stenosis.

Anatomical Variants

Nasal septal deflections and spurs are best visualized in the coronal plane (Fig. 27.15). Noting the direction of septal deviation is helpful for surgical planning as the patient may require septoplasty to facilitate ESS. Similarly, nasal turbinate reduction could be performed for an obstructing edematous inferior nasal turbinate. Another important variant is a laterally deviated uncinate process, with or without atelectatic sinus, which can increase the risk of medial orbital wall injury during uncinectomy (Fig. 27.9, see above text on *Other Inflammatory Sinus Lesions*).

Middle turbinate variations include paradoxical middle turbinates and concha bullosa. Paradoxical middle turbinates occur when the normal medial convex curvature is reversed. In some cases, this can lead to narrowing of the middle meatus and may contribute to the development of chronic rhinosinusitis. Concha bullosa occurs when there is pneumatization of the middle turbinate (Fig. 27.15). This may result in a very large turbinate that can compress the uncinate process laterally. The role of the concha bullosa in sinus disease is controversial when viewed across studies, with its size being more important than its mere presence with regard to sinus disease (10).

The Haller cell, or infraorbital ethmoid air cell, represents the most common variation in the maxillary sinus

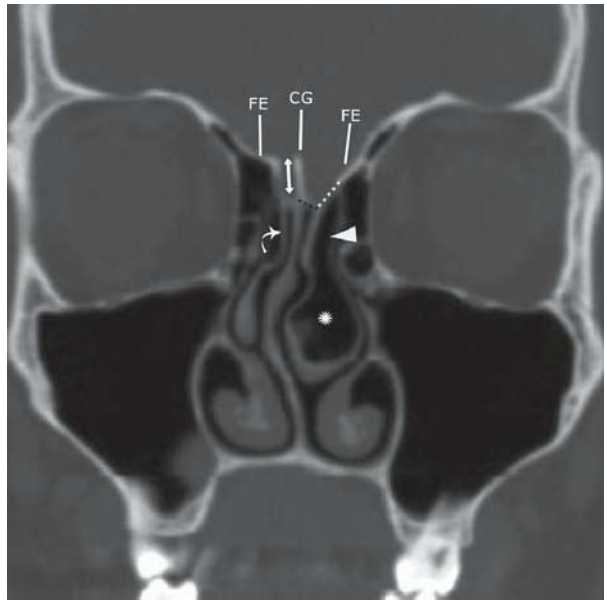

Figure 27.15 Anatomical and critical variants important for ESS. Coronal CT image shows anatomical variants of concha bullosa (*asterisk*) and concha lamella (*arrowhead*). The nasal septum is deviated to the right. There is a critical variant of asymmetry in the olfactory fossa, deeper on the right. The olfactory fossa (*double-headed arrow*) is formed by crista galli (CG) in midline, medial lamella (*black dotted line*) in the inferior aspect, and lateral lamella (*white dotted line*) in the lateral aspect. A deep olfactory fossa with long lateral lamellae as shown on the right can be complicated by fractures during ESS. Medial and lateral lamellae are separated by vertical lamella (*curved arrow*) of the middle turbinate. Fovea ethmoidalis (FE) is continuation of superior orbital roof to cribriform plate.

region. This is an ethmoidal cell that pneumatizes along the medial roof of the maxillary sinus and inferomedial portion of the lamina papyracea. It is present in up to 34% of patients and frequently encroaches on the infundibulum (10).

Anatomical variants of the frontal recess are best appreciated on coronal and sagittal imaging. The frontal recess can be narrowed by enlargement of the bordering agger nasi cell (anteriorly) (Fig. 27.6) and ethmoid bulla (posteriorly), or the presence of variant anterior ethmoid air cells in the frontal recess. Failure to resect these cells during frontal sinus endoscopic surgery can lead to recurrent disease (11).

Critical Variants

The lateral lamella is the thinnest part of the cribriform plate and at risk of fracture during ESS, especially when the olfactory fossae are deep or asymmetrical (Fig. 27.15). Fractures in the cribriform plate can result in defects in the bone and dura, leading to early complications of ascending meningitis and late complications of intracranial hypotension from CSF leaks, meningoceles, and meningoencephaloceles. In a classic study, Keros proposed a classification based upon the position of the cribriform plate in relation to the ethmoid roof. In type I olfactory fossa, the olfactory sulcus is 1 to 3 mm deep, and the corresponding lateral lamella is short. In type II olfactory fossa, the olfactory sulcus is 3 to 7 mm deep, and the corresponding lateral lamella forms a considerable portion of the medial ethmoid wall. In type III olfactory fossa, the olfactory sulcus is 7 to 16 mm deep and the ethmoid roof lies at a significant level above the cribriform plate.

Unrecognized congenital or posttraumatic dehiscence of the lamina papyracea may predispose to orbital injury (Fig. 27.16). The most common injuries are medial and inferior rectus muscle laceration that can lead to focal or global scarring and gaze dysfunction (12).

The anterior ethmoidal artery travels through a bony canal called the anterior ethmoidal foramen in the superior lamina papyracea and serves as a surgical landmark. Anatomic studies have shown that the anterior ethmoid artery is dehiscent in the nasal cavity between 16% and 30% of cases (13,14). When the artery courses below the skull base through the ethmoid air cells it can be inadvertently injured. Retraction of a severed artery into the orbit may produce an orbital hematoma, requiring urgent decompression. The anterior ethmoidal foramen is best visualized in the coronal section by identifying the so-called nipple sign, representing the site where the artery exits the orbit and traverses the skull base (Figs. 27.6 and 27.9).

Focal bony dehiscence of the sphenoid sinus in areas overlying the optic nerve, internal carotid artery, and the second (maxillary) division of the trigeminal nerve can result in injury to these neural and vascular structures. The optic nerve and internal carotid artery may also be at risk when there are Onodi cells, which occur when a posterior ethmoid air cell pneumatizes over the top of the sphenoid.

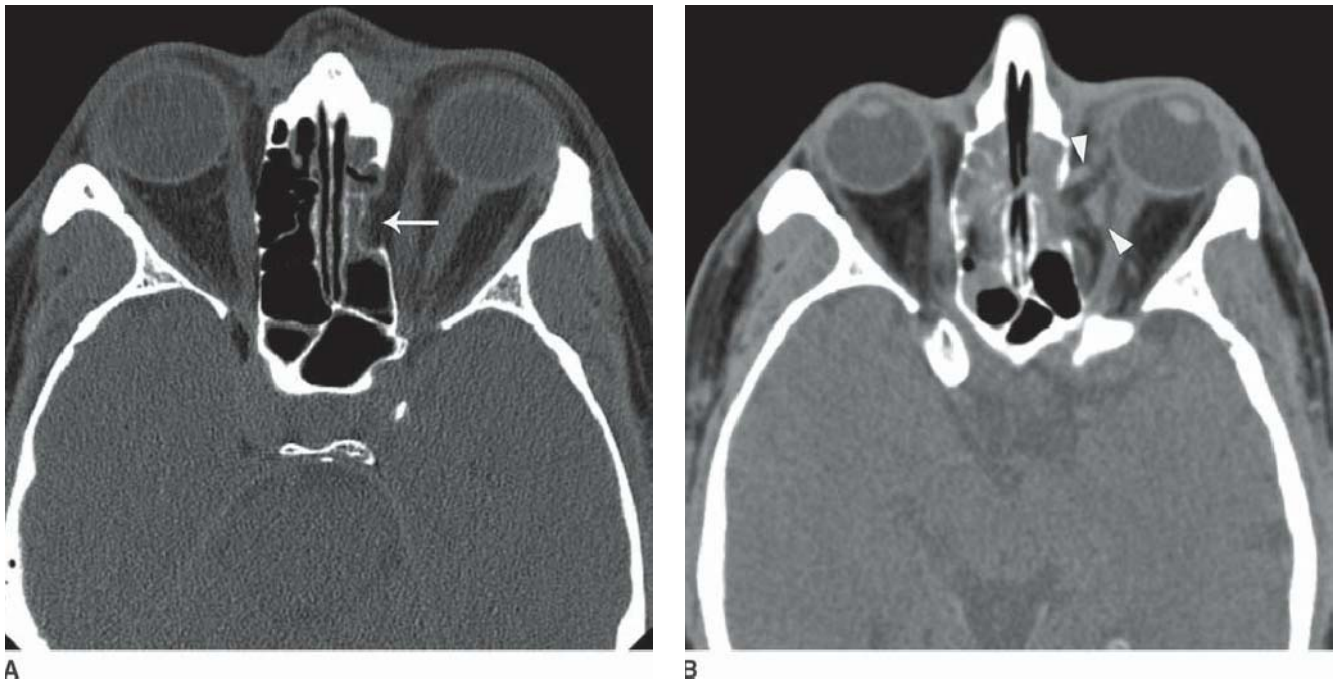

Figure 27.16 Orbital injury from lamina papyracea defect. **A:** Preoperative axial CT shows a defect in the left lamina papyracea (*arrow*) from an old orbital blow-out fracture. **B:** Postoperative axial CT shows loss of the normal left medial rectus muscle. Fat stranding and high-density blood products are present in the intraconal space (*arrowheads*). Courtesy of MT Bhatti, MD, Duke University Medical Center.

This places the optico–carotid recess within the posterior ethmoid cavity.

If technical difficulties are anticipated or if surgery involves the sphenoid sinus, the surgeon may choose to perform endoscopic surgery with a stereotactic CT image guidance system (6). This requires preoperative CT imaging with thin slice images.

FUNGAL AND GRANULOMATOUS SINUSITIS

Fungal sinusitis encompasses a wide variety of manifestations, from relatively innocuous to rapidly fatal. Invasive fungal infection should be considered in any patient with chronic rhinosinusitis, particularly when the patient is immunocompromised or has intractable symptoms despite adequate bacterial therapy. There are five forms of fungal sinusitis. Immunocompetent patients may develop allergic fungal sinusitis or a fungus ball. Invasive fungal sinusitis, which can be acute or chronic, most commonly occurs in immunocompromised patients but may also rarely develop in the immunocompetent population (15,16). The final form of fungal sinusitis is granulomatous invasive fungal sinusitis, a rare condition seen almost exclusively in northern Africa and which occurs in immunocompetent patients.

CT is the main imaging modality for evaluating fungal sinusitis with the exception of invasive fungal sinusitis where MRI can be more accurate in defining the presence and extent of orbital or intracranial involvement.

Imaging Findings of Noninvasive Fungal Sinusitis

Allergic fungal sinusitis typically presents with involvement of multiple sinuses and the nasal cavity, but can be present with incomplete opacification of sinuses, especially in postoperative recurrences (17). It is also possible for allergic fungal sinusitis to occur in just one sinus and even to occur in a sinus without nasal involvement. On CT, the sinuses are opacified by high-density allergic mucin. Characteristic bony changes are bony sinus expansion, remodeling, and thinning (Fig. 27.17). On MRI, there is low signal intensity or signal void on T2-weighted sequences.

Fungus ball is usually limited to one sinus, and most commonly the maxillary sinus. On CT, it appears as a high-density mass within the lumen of the sinus with or without punctate calcifications (Fig. 27.1). Associated bony changes can range from sclerotic thickening due to chronic obstruction to expansion and thinning from pressure necrosis. On MRI, the fungus ball is hypointense on T1- and T2-weighted sequences.

Imaging Findings of Invasive Fungal Sinusitis

Acute invasive fungal infection is due to organisms such as *Aspergillus* or Zygomycetes. In contrast to noninvasive fungal sinusitis that is limited to the lumen of the sinus, invasive fungal infection invades the mucosa to involve bone, blood vessels, and adjacent soft tissue. Invasive disease tends to be unilateral and most commonly beginning

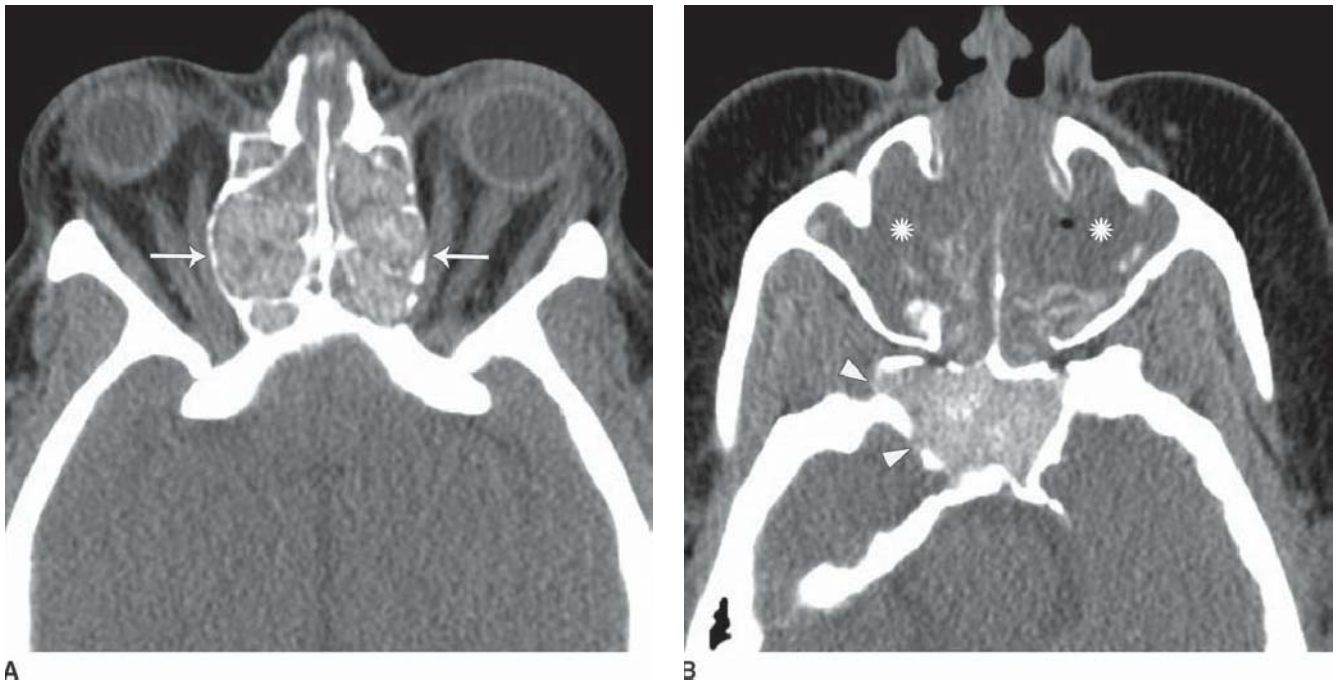

Figure 27.17 Allergic fungal sinusitis. **A:** Axial CT image shows bilateral ethmoid (*arrows*) opacification with high-density secretions and expansion. **B:** Axial CT image shows bilateral sphenoid sinus opacification with high-density secretions and focal areas of bony dehiscence (*arrowheads*). The high-density secretions in this case represent allergic mucin. A differential is inspissated secretions.

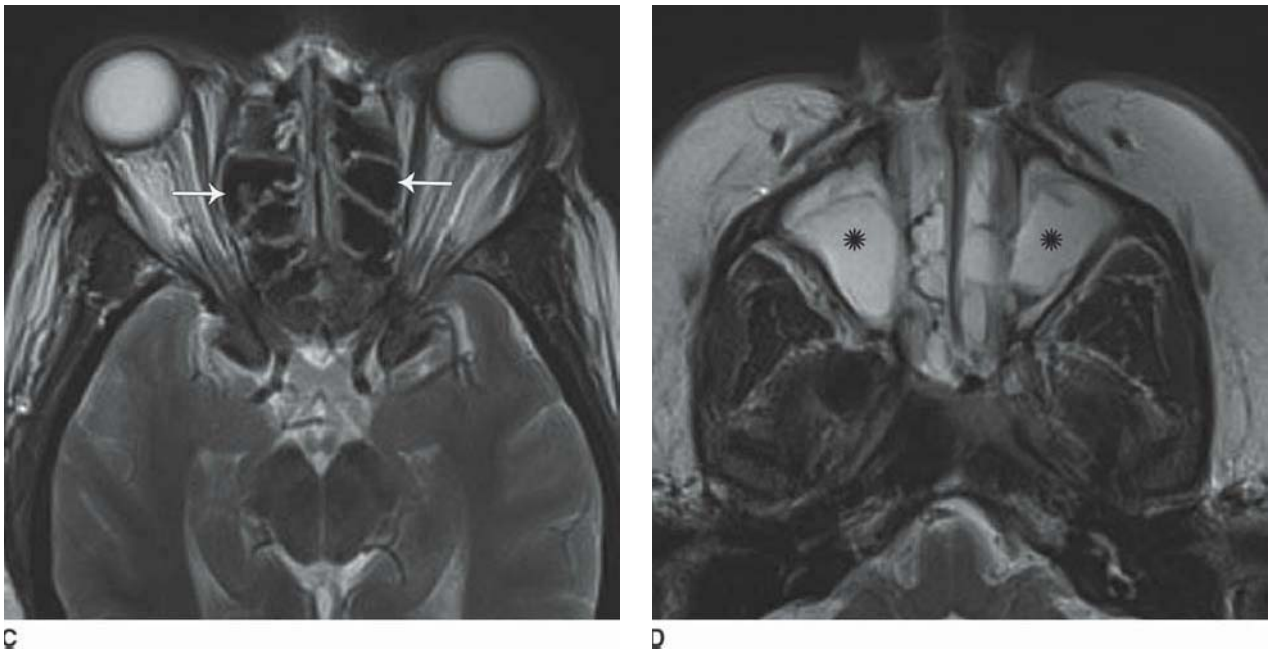

Figure 27.17 *(Continued)* **C:** Axial T2-weighted MRI image shows a signal void in the ethmoid sinuses also in keeping with allergic mucin. A pitfall is to mistake the signal void for air. **D:** Axial T2-weighted MRI image shows T2 hyperintense maxillary sinus opacification (*asterisk*) while on CT this is a soft tissue density (**B**, *asterisk*). This represents inflammatory fluid.

in the nasal cavity (18,19). Findings on CT are low attenuation or soft tissue density thickening in the sinus. On MRI, fungal elements can cause T2 hypointense signal. Spread of infection outside the sinus appears as T2 hyperintense signal and enhancement in the soft tissues (Fig. 27.18). Nonenhancement due to infarction of soft tissues may also be seen. Extension beyond the sinonasal cavity, orbital involvement, and bony erosion are signs of advanced

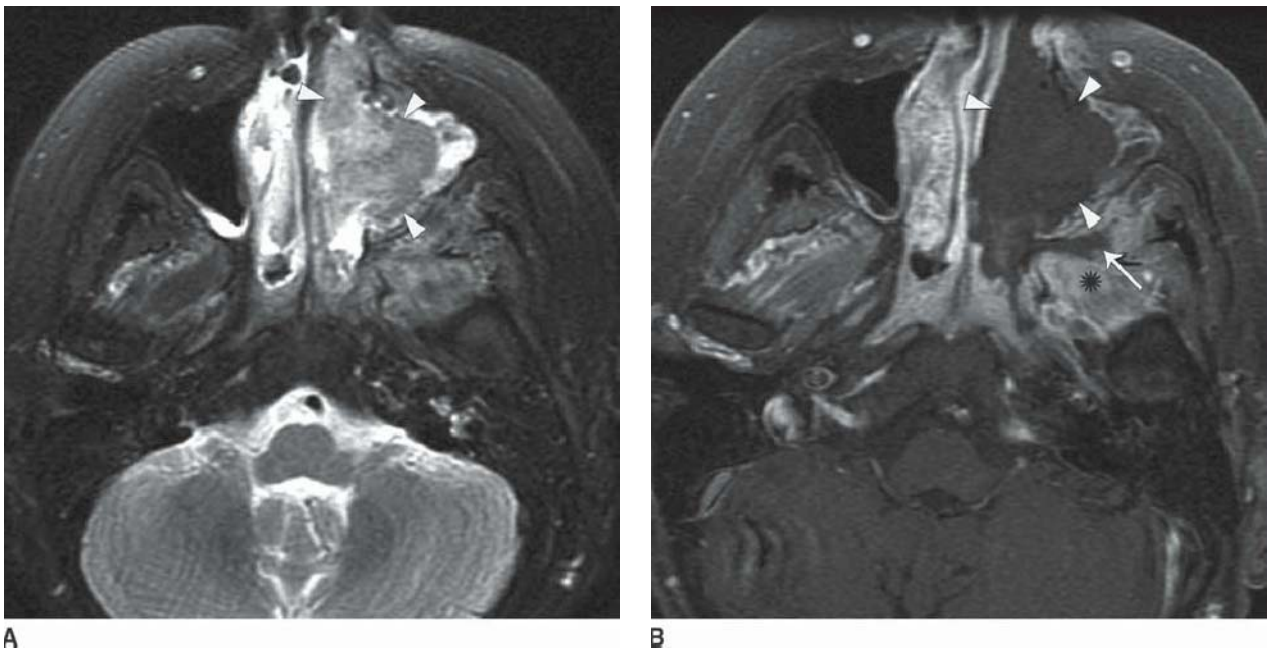

Figure 27.18 Invasive fungal sinusitis. **A:** Axial fat-saturated T2-weighted MRI image shows an isointense mass (*arrowheads*) in the left maxillary sinus and nasal cavity. There is also T2 hyperintense signal in left masticator space (infratemporal fossa). **B:** Axial-enhanced fat-saturated T1-weighted MRI image shows the maxillary sinus mass to have no enhancement (*arrowheads*). This is in keeping with necrotic eschar associated with invasive fungal infection. Note that similar nonenhancing tissue extends beyond the sinus to the masticator space (*arrow*). There is also enhancing tissue in the left masticator space (*asterisk*) in keeping with local fungal invasion.

disease that may be difficult to cure (19). In the absence of deep extension and bony changes, early findings in invasive fungal sinusitis are nonspecific and do not correlate well with surgical and pathologic findings.

Of note, orbital and intracranial fungal extension can occur even without bony destruction because of vascular invasion. Intraorbital invasion may appear as orbital fat stranding, extraocular muscle enlargement, and proptosis. Frank signs of intracranial invasion include the following: cavernous sinus thrombosis, carotid artery invasion leading to pseudoaneurysm or occlusion, leptomeningeal enhancement (meningitis), and brain parenchymal lesions from cerebritis, abscess, or granulomas.

Chronic invasive fungal sinusitis is also characterized by fungal hyphae in the mucosa and beyond, but the course of disease occurs over months and years and patients are usually immunocompetent. On CT, this entity can mimic tumor because of its mass-like appearance and extension outside the sinus. On MRI, the signal is most commonly T1 and T2 hypointense.

Imaging Findings of Granulomatous Sinusitis

The most common cause of granulomatous sinusitis is Wegener granulomatosis. On CT, early findings are nonspecific soft tissue nodules along the nasal septum with marked mucosal thickening. Later, there may be perforation of the cartilaginous nasal septum followed by destruction of the bony nasal septum and sinus walls as the disease progresses.

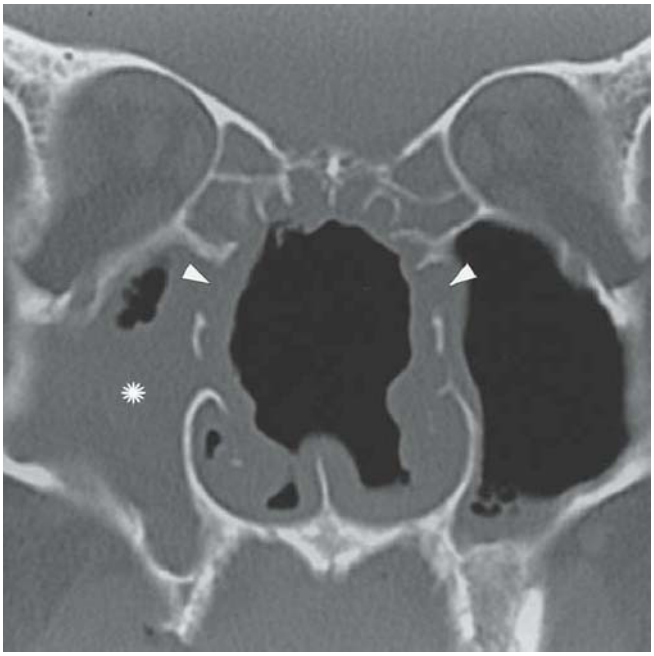

Figure 27.19 Granulomatous disease in cocaine user. Coronal CT image shows a large septal perforation that involves both bone and cartilage. The middle turbinates are eroded and there is circumferential soft tissue thickening throughout the nasal cavity. There is secondary obstruction of the OMCs bilaterally, with ethmoid opacification and right maxillary sinus fluid (*asterisk*).

Other causes of granulomatous sinusitis have the similar imaging findings and are classified as infectious or noninfectious. Noninfectious etiologies include sarcoidosis and foreign body reaction from beryllium, chromate salts, and cocaine (Fig. 27.19). Infectious diseases are uncommon in developed countries and include actinomycosis, nocardiosis, blastomycosis, tuberculosis, syphilis, rhinoscleroma, and leprosy. Histopathology is necessary to differentiate granulomatous invasive fungal sinusitis from chronic invasive fungal sinusitis, as there are no differences in radiologic features (20).

SINONASAL NEOPLASM

A variety of neoplasms can develop in the paranasal sinuses. The most common sinonasal tumor is squamous cell carcinoma (SCC), which accounts for nearly 80% of malignant tumors in the paranasal sinuses (21). Other neoplasms are classified as epithelial or nonepithelial. Epithelial tumors occur in the epithelial lining of the sinonasal cavities (adenocarcinoma, melanoma), accessory salivary tissue (adenoid cystic carcinoma, mucoepidermoid carcinoma), neuroendocrine tissue (sinonasal undifferentiated carcinoma, small cell carcinoma), and the olfactory mucosa (esthesioneuroblastoma) (22). Nonepithelial tumors include non-Hodgkin lymphoma and sarcomas.

CT and MRI are complementary in the diagnosis and workup of sinonasal neoplasm. A systematic approach to interpretation includes the following steps: (a) confirmation that a lesion is a mass, (b) identification of specific features suggestive of neoplasm, and (c) tumor staging for malignant disease.

Is It a Mass or Inflammation?

CT better demonstrates bony destruction, but MRI is extremely valuable for tumor imaging as it can distinguish mass from secretions and inflammatory mucosa. On MRI, the T2-weighted sequences are key: most sinonasal tumors have isointense to hypointense T2 signal while inflammatory secretions and mucosa are T2 hyperintense (Figs. 27.1, 27.20 and 27.21). Both tumors and inflammatory mucosal disease enhance with contrast, but fluid does not enhance. Being familiar with the characteristics of a mass helps to define the size and extent of tumor for biopsy and treatment planning.

Characterizing the Mass

CT imaging cannot reliably determine the histologic diagnosis of a tumor, but it does provide clues to whether the mass may be benign or malignant. Malignant tumors, such as SCC, lymphoma, and metastases, have focal and irregular bony destruction on CT (Figs. 27.1 and 27.21). In contrast, benign slow-growing tumors tend to cause sinus

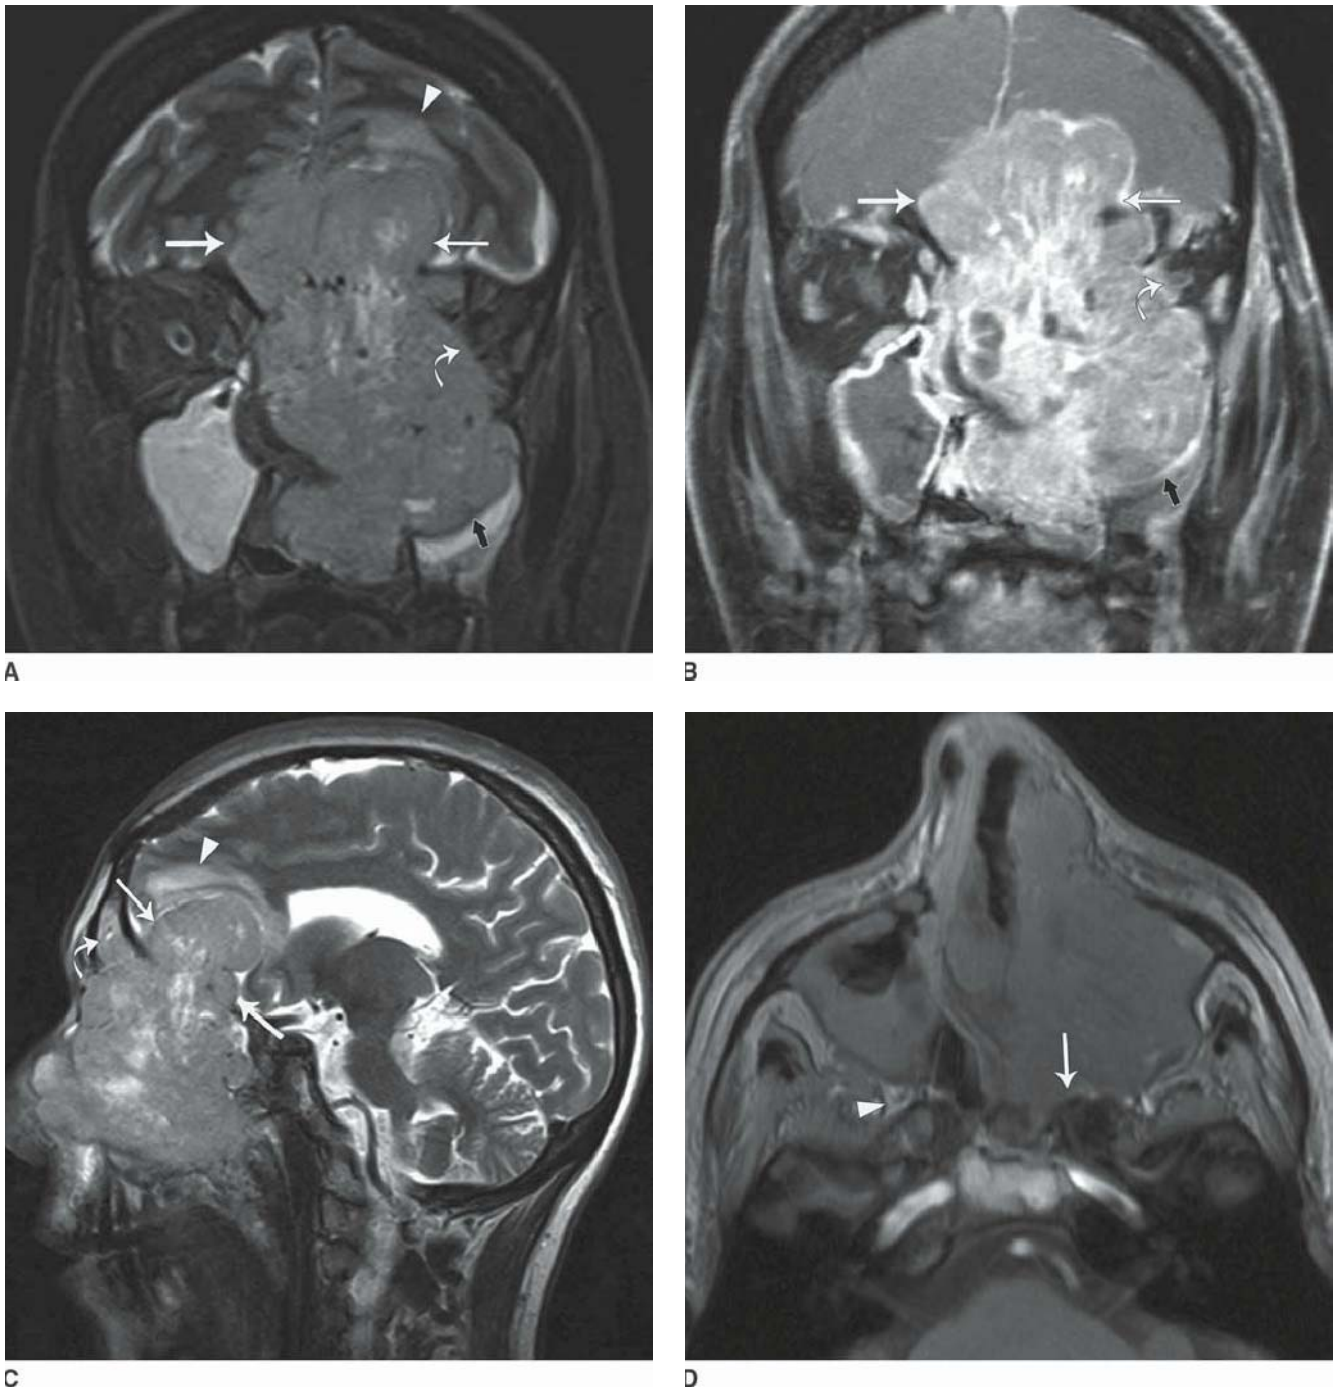

Figure 27.20 Sinonasal carcinoma with intracranial and orbital invasion. **A:** Coronal T2-weighted and **B:** enhanced T1-weighted fat-saturated MRI images show an isointense mass in the nasal cavity with intracranial extension (*arrows*). There is intraorbital tumor with irregular nodular contours suggestive of invasion through the periorbita (*curved arrows*). On the enhanced images **(B)**, there is also loss of normal appearance of the medial rectus, inferior rectus, and superior oblique muscles and tumor abutting the optic nerve (*curved arrow*). There is associated edema in the left frontal lobe from mass effect (*arrowhead*) and invasion into the left maxillary sinus (*black arrows*). **C:** Sagittal T2-weighted MRI image shows intracranial extension (*arrows*) and brain edema (*arrowhead*). There is also extension into the frontal sinus (*curved arrow*). **D:** Axial T1 MRI image shows tumor extension from the left maxillary sinus into the pterygopalatine fossa (*arrow*). Note the right pterygopalatine fossa containing normal fat (*arrowhead*).

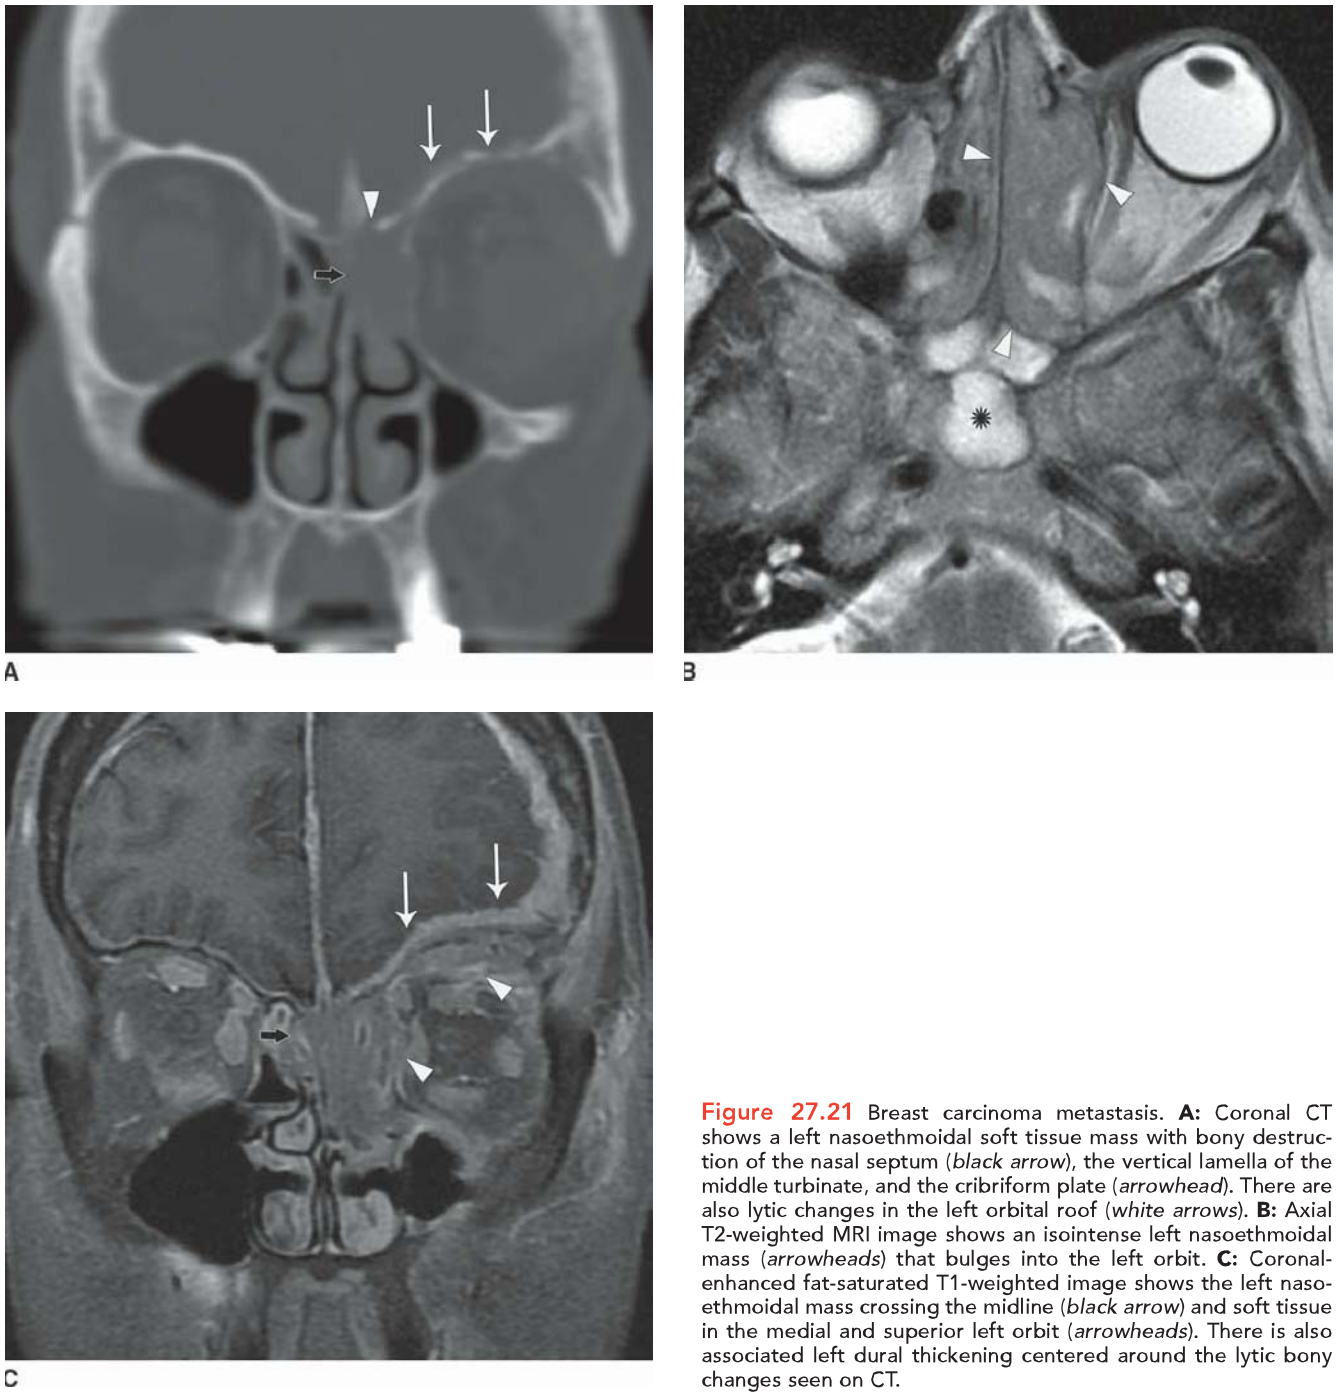

Figure 27.21 Breast carcinoma metastasis. **A:** Coronal CT shows a left nasoethmoidal soft tissue mass with bony destruction of the nasal septum (*black arrow*), the vertical lamella of the middle turbinate, and the cribriform plate (*arrowhead*). There are also lytic changes in the left orbital roof (*white arrows*). **B:** Axial T2-weighted MRI image shows an isointense left nasoethmoidal mass (*arrowheads*) that bulges into the left orbit. **C:** Coronal-enhanced fat-saturated T1-weighted image shows the left nasoethmoidal mass crossing the midline (*black arrow*) and soft tissue in the medial and superior left orbit (*arrowheads*). There is also associated left dural thickening centered around the lytic bony changes seen on CT.

expansion and bony remodeling (Fig. 27.22). Of note, an imaging trap is that bony remodeling and smooth expansion can be present in some malignant tumors, including adenoid cystic carcinoma, melanoma, and esthesioneuroblastoma. CT can also detect tumoral calcifications, but this is also not a specific sign. Intralesional calcifications can be present in SCC, adenocarcinoma, inverted papilloma, esthesioneuroblastoma, and mesenchymal tumors of bone or cartilaginous origin.

MRI is no better than CT for precise histologic diagnosis. Most malignant tumors have similar characteristics showing T1 and T2 isointense to hypointense signal. The exception is mucosal melanoma, which can be T1 hyperintense if it contains paramagnetic melanin or hemorrhage (23). There can also be distinguishing findings for esthesioneuroblastoma when there is intracranial invasion. This tumor can have cysts at the tumor interface with brain parenchyma (Fig. 27.23), and a dumbbell shape with a waist at the cribriform plate (24,25).

A notable benign tumor is the inverted papilloma. This epithelial tumor of the sinonasal cavity can mimic a malignant neoplasm with invasion into surrounding structures and recurrence after resection (26). Additionally, inverted papillomas can degenerate into or coexist with malignancy:

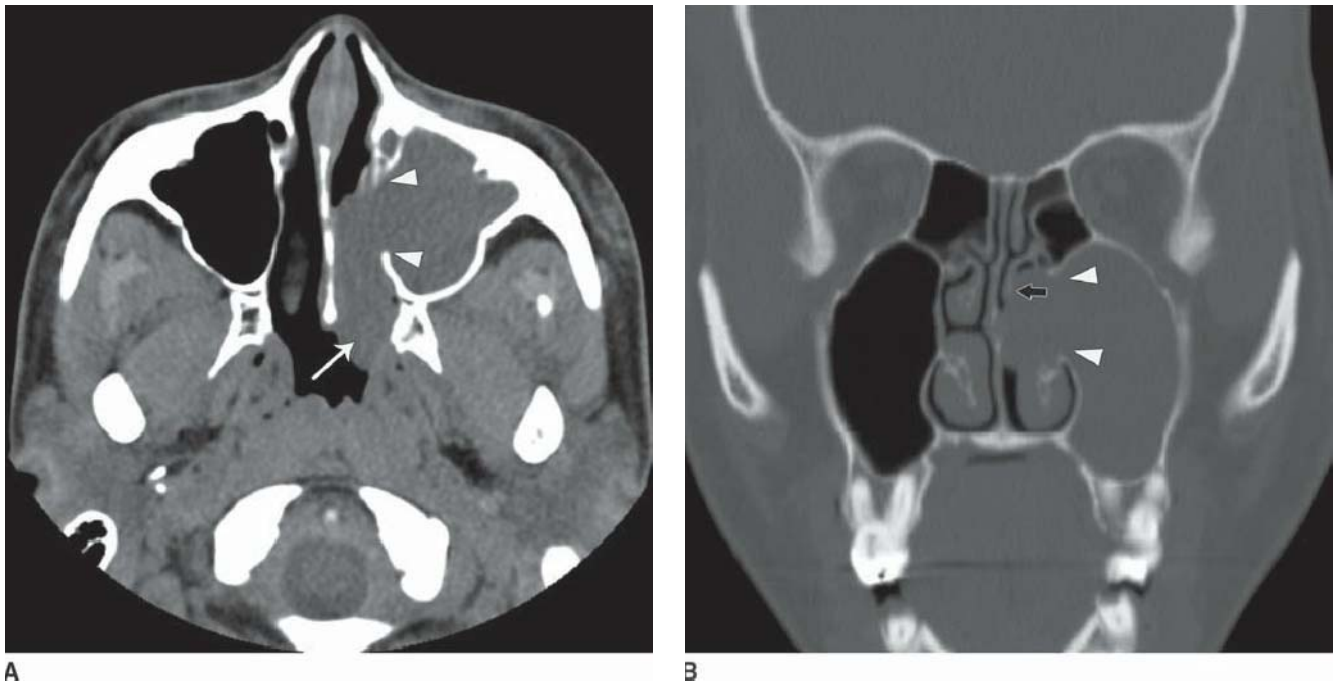

Figure 27.22 Antrochoanal polyp. **A:** Axial CT shows a mass in the left nasal cavity and maxillary sinus extending past the left nasal choana to the nasopharynx (*arrow*). There is bony remodeling with widening of the maxillary ostium (*arrowheads*). **B:** Coronal CT shows a mass in the left nasal cavity and maxillary sinus. Again there is bony remodeling with widening of the maxillary ostium (*arrowheads*) and truncation of the medial turbinate (*black arrow*).

up to 5% to 15% of resected cases are associated with SCC (26,27). Inverted papillomas typically arise from the lateral nasal wall at the level of the middle turbinate or less commonly within the maxillary sinus. On CT, they can have an aggressive appearance with bony destruction of the lateral nasal wall and extension into the maxillary antrum (Fig. 27.24). Alternatively, the adjacent bone can be sclerotic and mimic chronic sinusitis (28). There may also be curvilinear or irregular calcifications giving the tumor a cerebriform appearance. Other benign soft tissue tumors that occur around the paranasal sinuses are juvenile angiofibroma (Fig. 27.25) and neurogenic tumors.

Figure 27.23 Esthesioneuroblastoma. Coronal-enhanced fat-saturated T1-weighted image shows a bilateral nasoethmoidal mass (*arrowheads*) with intracranial extension. Peritumoral cysts (*arrows*) are noted at the junction of the tumor and brain parenchyma.

Since the sinus walls are bony, fibroosseous lesions can also involve the sinus and include osteomas, fibrous dysplasia, ossifying or nonossifying fibroma, chondromas, and malignant chondroid lesions. Another bony lesion that can mimic tumor is arrested skull base pneumatization (Fig. 27.26). This is a developmental variant that arises when early fatty marrow conversion occurs in preparation for sinus pneumatization, but pneumatization fails to occur. It is most commonly seen around the basisphenoid bone and is characterized on CT as a nonexpansile lesion with osteosclerotic borders and curvilinear calcifications (29). On MRI, the internal fat gives a characteristic pattern of T1 and T2 hyperintense signal.

Tumor Staging with Imaging

The most important role of imaging for malignancy is to define the extent of tumor for staging and treatment planning. The staging system for carcinoma is the American Joint Cancer Committee (AJCC) tumor, nodes, metastasis (TNM) classification (30). It applies only to the two most

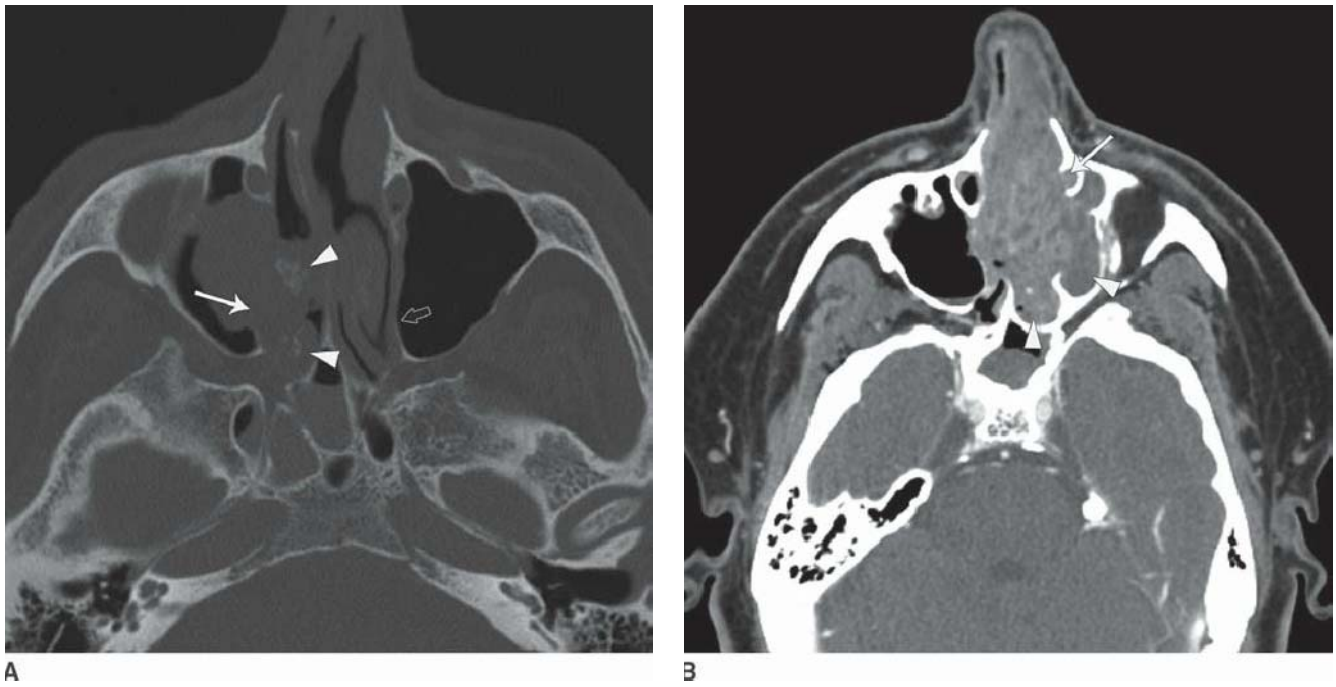

Figure 27.24 Inverted papilloma. **A:** Axial CT image shows a soft tissue mass in the right nasal cavity and maxillary antrum. There is bony erosion of the medial maxillary wall (*white arrow*) when compared to the left (*black arrow*). Intralesional calcifications are also seen (*arrowhead*). **B:** Axial CT image in a different patient shows a soft tissue mass in the left nasal cavity and maxillary antrum with scalloping of the maxillary sinus walls (*arrowhead*). This is characteristic of longstanding or recurrent inverted papilloma. There is also bony destruction of the nasal septum and possible invasion into the nasolacrimal duct (*arrow*). The surgical specimen in this case showed associated SCC.

Figure 27.25 Juvenile nasopharyngeal angiofibroma. Enhanced axial CT shows a large enhancing mass in the nasopharynx (*asterisk*), left nasal cavity (*arrow*), left maxillary sinus, and infratemporal fossa/masticator space (*arrowhead*). There is widening of the pterygomaxillary fissure (*double headed arrow*).

common sites for sinonasal tumors: the nasoethmoid complex and the maxillary antrum (Table 27.2). The components of the staging system are intrasinus tumor extent as defined by subsites, and deep invasion of critical structures such as the skull base, pterygopalatine fossae, orbits, and palate. CT and MRI have a complementary role. CT is preferred for evaluating bony invasion while MRI best delineates intracranial, perineural, and intraorbital disease.

Carcinoma, lymphoma, and esthesioneuroblastoma frequently invade the skull base. Early skull base invasion is best seen on coronal CT images (Fig. 27.21), but MRI surpasses CT in identifying dural enhancement (Fig. 27.21), and parenchymal edema and enhancement. Linear dural enhancement has lower specificity for dural invasion since reactive changes from adjacent tumor could also have this appearance. More specific signs for dural invasion are nodular dural enhancement, dural thickening greater than 5 mm, or associated leptomeningeal enhancement (31). Brain parenchymal invasion is characterized by intraparenchymal enhancement with edema. Brain edema may also be seen if there is mass effect from the tumor without parenchymal invasion (Fig. 27.20).

Orbital invasion can occur when tumor abuts the medial or inferior orbital wall and is best depicted on coronal imaging. CT shows bony invasion, which indicates a tumor stage of

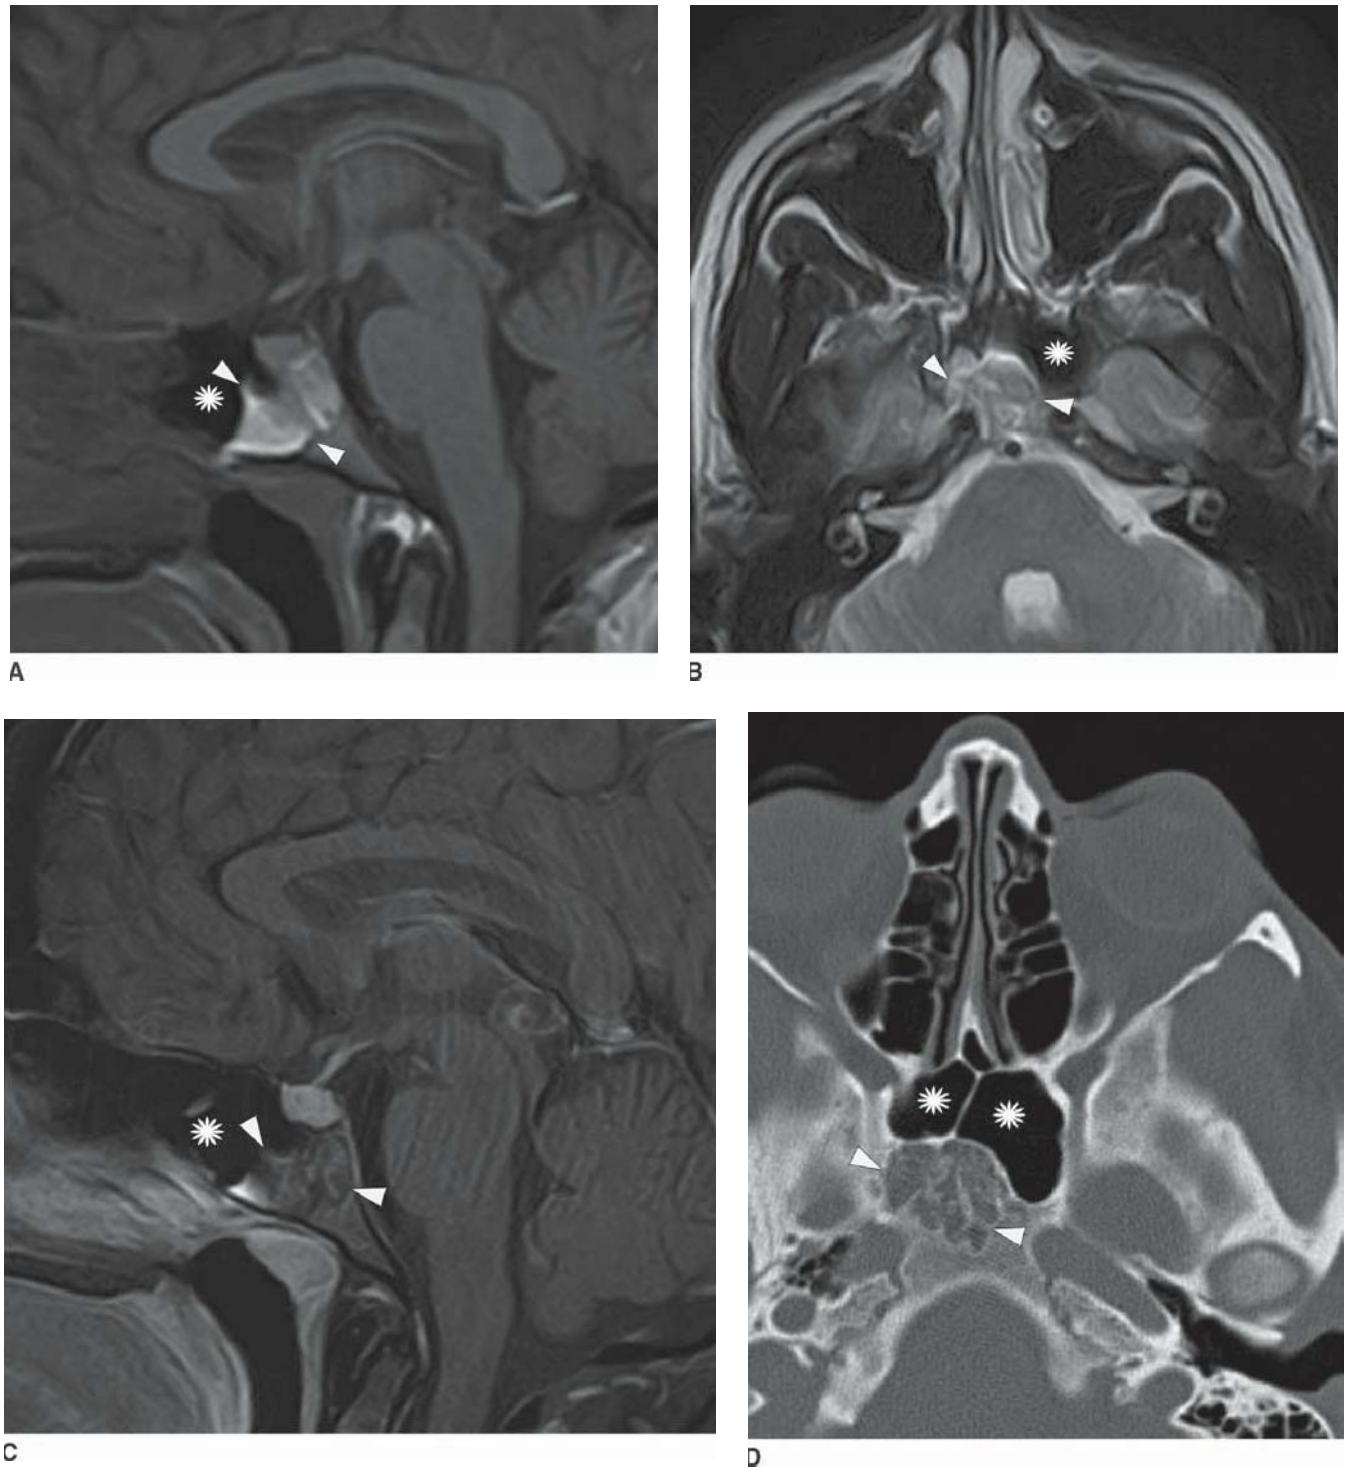

Figure 27.26 Arrested pneumatization of the basisphenoid, a developmental variant. **A:** Sagittal T1-weighted and **B:** axial T2-weighted images show a T1 and T2 hyperintense lesion in the basisphenoid bone (*arrowheads*). There is pneumatization of the sphenoid sinuses (*asterisk*), but the right sphenoid sinus is small. **C:** Sagittal-enhanced fat-saturated T1-weighted image shows that the lesion (*arrowhead*) does not enhance and signal suppresses in keeping with fat. **D:** Axial CT image shows a well-defined lesion (*arrowhead*) in the basisphenoid with sclerotic margins and central calcifications.

T3 (Fig. 27.2). Bone can be resected and this sign alone does not determine the need for orbital exenteration. Invasion of the periorbita, the orbital aspect of the periosteum, indicates stage T4 disease and is a crucial finding as this is a criterion for orbital exenteration. Signs of invasion through the periorbita are best seen on MRI with intraorbital fat stranding, a nodular interface with the orbit, and loss of the fat plane between the tumor and rectus muscles (Fig. 27.20) (32).

TABLE 27.2 AJCC 7TH EDITION NASAL CAVITY AND PARANASAL SINUS STAGING SYSTEM

	Maxillary Sinus	Nasal Cavity and Ethmoid Sinus
Primary tumor staging		
T1	Tumor limited to maxillary sinus mucosa with no erosion or destruction of bone.	Tumor restricted to any 1 subsite[a] +/− bony invasion.
T2	Tumor causing bone erosion or destruction including extension into the hard palate and/or middle nasal meatus (except extension into the posterior wall of the maxillary sinus and pterygoid plates).	Tumor invading two subsites[a] in a single region or extending to involve an adjacent region within the nasoethmoidal complex, with or without bony invasion.
T3	Tumor extends to invade the medial wall or floor of the orbit, maxillary sinus, palate, or cribriform plate.	
T4a (resectable)	Tumor invades any of the following: anterior orbital contents, skin of nose/cheek, minimal extension to anterior fossa, pterygoid plates, sphenoid or frontal sinuses.	
T4b (unresectable)	Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than V2, nasopharynx, or clivus.	
Regional lymph node staging		
N0	No evidence of cancer in the regional lymph nodes.	
N1	Metastasis to a single ipsilateral lymph node measuring ≤3 centimeters (cm).	
N2	**N2a:** Metastasis to a single ipsilateral lymph node measuring >3 cm, but ≤6 cm. **N2b:** Metastasis to multiple ipsilateral lymph nodes measuring ≤6 cm. **N2c:** Metastasis to bilateral or contralateral lymph nodes, which are ≤6 cm.	
N3	Nodal metastases >6 cm	

[a]The subsites of the nasal cavity are septum, floor, lateral wall, and vestibule. The subsites of the ethmoid sinus region are right ethmoid sinus and left ethmoid sinus.

MRI is also valuable for showing perineural spread of tumor. Signs of perineural tumor spread are nerve enhancement or thickening. Advanced cases may show widening or destruction of the neural foramen or canal at the skull base. The most commonly involved nerve in sinonasal carcinoma is the second division (V2) of the trigeminal nerve. Tumor can spread via small peripheral branches of V2 or there may be direct invasion of V2 via the pterygopalatine fossa that lies posterior to the maxillary sinus (Fig. 27.20). From the pterygopalatine fossa, tumor can spread in several directions: superiorly toward the superior or inferior orbital fissures, or posteriorly into the foramen rotundum. Perineural tumor spread is more common in cases of tumor recurrence and is associated with a decreased survival rate.

Correct preoperative evaluation of nodal disease with imaging provides important prognostic information (33). The nodal staging system comprises N0 to N3 and is shown on Table 27.2 (30). Nodal metastases occur in approximately 9% to 15% of patients with sinonasal malignancy and should be suspected if there is extension of tumor to involve the skin, gingivobuccal sulcus, or the pterygoid musculature (32,33). Levels I and II are the most frequently involved groups, and the signs worrisome for nodal metastases are size greater than 10 mm, central low attenuation regions representing necrosis, hyperenhancement, and loss of well-defined margins suggesting extracapsular spread. Of note, size is not the best criterion for malignancy as metastases can exist is subcentimeter lymph nodes, and enlarged hyperplastic benign nodes can also occur in the neck. Use of fluorodeoxyglucose positron emission tomography (FDG-PET) or diffusion-weighted MRI for nodal assessment may increase sensitivity and specificity.

CONCLUSION

CT and MRI are the main modalities for evaluating paranasal sinus diseases. Imaging of rhinosinusitis is dominated by CT. MRI is complementary to CT for complicated inflammatory disease and neoplasia. Evaluation of sinonasal disease with these modalities should be approached systematically in the context of the clinical scenario. One of the major roles of imaging is for preoperative planning

to evaluate extent of inflammatory and neoplastic disease and to identify anatomy that may make surgery more challenging or hazardous.

HIGHLIGHTS

- CT is valuable for evaluating all pathologies of the paranasal sinuses because of its high resolution of bony structures and the ability to reconstruct axially acquired images in coronal and sagittal planes.
- MRI is superior to CT for soft tissue characterization, and is thus complementary to CT when there is a sinonasal mass, and intracranial or orbital complications of inflammatory sinus disease.
- T2-weighted sequences are key for delineating sinonasal tumor. Most tumors have isointense to hypointense T2 signal while inflammatory secretions and mucosa are T2 hyperintense. Both tumors and inflammatory mucosal disease enhance with contrast, but fluid does not enhance.
- The presence of a fluid level and frothy or strandy secretions suggests acute sinusitis. Sclerosis of sinus walls indicates chronic sinusitis. In the absence of these findings, mucosal thickening is nonspecific and acute and chronic sinusitis cannot be differentiated on imaging.
- Identification of anatomical and critical variants on preoperative CT imaging is crucial to performing safe sinus surgery.
- Review of axial, coronal, and sagittal images is necessary to identify the natural sinus drainage pathways.
- High-density secretions on CT can represent inspissated secretions or allergic mucin. Allergic fungal sinusitis can be associated with sinus cavity expansion and thinning of the bony walls.
- In complicated bacterial sinusitis and invasive fungal sinusitis, bony destruction may be absent despite intracranial and intraorbital invasion if the route of spread is vascular.
- Imaging cannot reliably characterize the histology of tumor because of overlapping findings. The most important role of imaging malignancy is to define the extent of tumor for staging and treatment planning.

28 Diagnostic Tools for Sinonasal Disease and Role of Office Imaging

Luke Rudmik *Timothy L. Smith*

Due to the breadth of sinonasal pathologies, several diagnostic tools are available during rhinologic evaluation. Diagnostic evaluation always begins with a thorough history and physical exam. The importance of a complete history and physical cannot be over emphasized, as it narrows the differential diagnosis and focuses subsequent diagnostic tests. An incomplete history and exam may result in needless investigations and, worst-case scenario, lead to a misdiagnosis with a delay in treatment. A formal discussion on the rhinologic history and physical exam is beyond the scope of this chapter but should be performed on all patients. This chapter discusses the various rhinologic investigations used to evaluate patients with sinonasal pathology.

RIGID SINONASAL ENDOSCOPY

Rigid sinonasal endoscopy remains one of the most useful diagnostic tools used during the evaluation of sinonasal disease. Recent advancements in endoscopic technology have provided high-definition image detail with improved magnification. Most otolaryngologists will perform in-office rigid sinonasal endoscopy using a 4 mm 30-degree endoscope; however, a smaller 2.7 mm diameter endoscope and 0, 45, and 70-degree scopes are available, depending on surgeon preference. Utilizing a rigid, rather than flexible, endoscope enables the physician to scope with one hand and perform procedures, such as suctioning or debriding, with the other hand.

To improve patient comfort and optimize visualization, the procedure often begins with the application of a topical anesthetic and decongestant. Application can be achieved with either cotton pledgets or nebulized spray and commonly involves a mixture of 4% Xylocaine and xylometazoline.

A systematic approach to the endoscopic exam will provide a thorough evaluation and minimize missed information. A common approach to rigid sinonasal endoscopy involves a three-pass technique (Table 28.1). The first pass involves passing the scope medial to the inferior turbinate, along the floor of nose. Structures visualized include the inferior turbinate, inferior portion of the middle turbinate, nasopharynx, and eustachian tube. The second pass places the scope medial to the middle turbinate to visualize the sphenoethmoidal recess. The relationship of the septum to the middle turbinate may impair this step. A classification by Schaitkin et al. (1) describes the endoscopic turbinoseptal (TS) relationship following nasal decongesting: TS1—medial and lateral aspect of middle turbinate is visualized; TS2—anterior attachment of middle turbinate partially obscured by septum; TS3—anterior attachment of middle turbinate completely obscured by septum; and TS4—septum contacting the lateral nasal wall (Fig. 28.1). Patients with TS2, 3, and 4 often require a septoplasty for access during endoscopic sinus surgery (ESS). The third pass visualizes lateral to the middle turbinate, within the middle meatus. Anatomic abnormalities such as choncha bullosa and accessory fontanelles can be visualized. Noting the presence of the mucosal inflammation, mucopurulence, mucus recirculation, crusting, masses, or polyps are important information, which can guide the ordering of subsequent diagnostic tests (Fig. 28.2).

A thorough and complete endoscopic exam is critical in the evaluation of a patient with sinonasal disease. The objective information provided can improve diagnosis, guide therapy, and monitor therapeutic response during follow-up. A systematic approach, as mentioned above, can improve diagnostic yield and consistency.

RADIOLOGIC INVESTIGATIONS

Radiographic imaging of the paranasal sinuses has evolved over the last century. Early options were limited to plain films (roentgenographs), which were fraught with inaccuracy and provided minimal diagnostic yield. Several

TABLE 28.1 RIGID SINONASAL ENDOSCOPY 3-PASS TECHNIQUE

Endoscopic Pass	Structures Visualized
1st Pass Medial to the inferior turbinate (along floor of nose)	Inferior Turbinate Inferior aspect of Middle turbinate Nasopharynx Eustachian tube torus
2nd Pass Medial to the middle turbinate	Septal relationship with middle turbinate (TS1-4) Superior turbinate Sphenoethmoidal recess / sphenoid os
3rd Pass Medial to the middle turbinate (within the middle meatus)	Lateral portion of middle turbinate Accessory fontanelles

technologic innovations over the last 15 to 20 years have given otolaryngologists several new imaging modalities, which have subsequently advanced our understanding of sinonasal disease and improved patient care. Current options primarily include high-resolution computed tomography (CT) and magnetic resonance imaging (MRI). Although the majority of sinonasal pathology can be diagnosed with a thorough history, physical exam, and rigid sinonasal endoscopy, radiographic imaging has become a standard adjunct in the workup of sinonasal disease. The primary role of radiologic imaging is to improve the diagnosis, define extent of regional disease, and aid in surgical planning.

Plain Films (Roentgenographs)

Plain films have been the traditional sinus imaging modality; however, they have been made obsolete with the emergence of CT and MRI. The four most common sinus plain film views include: Waters', Caldwell, Lateral, and Submentovertex. The radiation exposure from these four views is 40 to 60 mSv (2). Although limited, these views were able to assess the size and opacification of the sinuses, as well as identify septal deviations (3).

The major limitations of plain films are their inability to provide accurate diagnostic information pertaining to the status of the ostiomeatal complex (OMC), surrounding soft tissue, and anatomic variations of the sinuses. Although demonstration of an air-fluid level may be helpful during the workup of acute rhinosinusitis, several studies have demonstrated limited accuracy rates (70% and 75%) (4,5)

when compared to a CT scan. With the advent of ESS, detailed preoperative anatomic assessment is necessary to optimize surgical dissection and minimize complications. Due to significant tissue and bony overlap, plain films cannot provide detailed anatomic information. Currently, the only indication for plain films of the sinuses is the inability to obtain other imaging modalities such as CT or MRI.

Computed Tomography

The emergence of high-resolution CT imaging has advanced our understanding of sinonasal anatomy and physiology, and was fundamental to the rise of ESS (6). The major advantage of CT imaging is the excellent anatomic bony detail it provides. As a result, it has become the gold standard imaging modality for inflammatory diseases of the paranasal sinuses and is essential for preoperative planning.

Imaging the sinuses in the coronal plane is preferred since it provides excellent detail of the OMC; however, significant neck extension during image acquisition makes this position difficult. Therefore, current sinus CT protocols acquire thin axial slice thicknesses, usually less than 3 mm (ideally 1 mm), which permits high-resolution multiplanar reconstruction in the coronal and sagittal planes. Slice thickness of 1 mm is often required for accurate image-guidance compatibility. Intravenous contrast is not used in standard sinus CT protocols; however, it may be utilized during cases when there is a suspected complication of inflammatory disease (such as abscess or thrombosis) or during the evaluation of a sinonasal neoplasm. New multidetector CT scanners allow for acquisition of up to 64 slices with one rotation of the tube. This significantly reduces acquisition times and minimizes motion artifact. Although the radiation dose from a high-resolution CT scan of the sinuses may vary depending on scanning protocol, most yield a dose of 0.96 mSv (7).

A sinus CT can provide helpful diagnostic information in a variety of sinonasal pathologies (Table 28.2). In order to optimize diagnostic yield, it is important to develop a systemic approach to the interpretation of a sinus CT. Although most information is obtained from the coronal plane, helpful information can be obtained from the axial and sagittal images (Table 28.3). Interpretation incorporates a combination of defining the extent of local disease, identifying anatomic variations, and when indicated, surgical planning (8). To optimize bony detail while preserving soft tissue definition, some authors have suggested viewing CT images on a width-level ratio of 2,000/200 (9). The bony contours should be assessed for expansion, erosion, and/or thickening. Bony expansion usually suggests a chronic disease process, while erosion implies a more aggressive, acute pathology. Bony thickening often suggests osteitis resulting from chronic inflammation. Mucosal thickening should be assessed for laterality and extent of sinuses involved. The characteristics of sinus opacification should be noted, as heterogeneity may imply a fungal rhinosinusitis.

TABLE 28.2 COMMON INDICATIONS FOR SINUS CT

Sinonasal Disease	Indication
Acute Rhinosinusitis	Suspected complication
	Severe illness
	Failure to improve with medical management
	Clinical deterioration on medical management
	Immunocompromised state
Chronic Rhinosinusitis	Failure of medical management
	Preoperative planning
Neoplasm	Defining extent of lesion (staging)
Trauma	Suspected frontal sinus fracture
	Suspected cerebrospinal fluid leak

TABLE 28.3 INFORMATION OBTAINED FROM THE DIFFERENT PLANES OF SINUS CT

Sinus CT Plane	Helpful Information
Coronal	Septal deviation
	OMC
	Uncinate attachment type (A,B,C)
	Middle turbinate variations
	Lamina papyracea anatomy
	Ethmoid anatomy
	Skull base anatomy/lateral lamella length
	Anterior ethmoid artery anatomy
	Sphenoid anatomy/sphenoethmoid cell (Onodi)
	Identify optic nerve and carotid artery dehiscence.
Sagittal	Frontal recess anatomy
	Slope of the skull base
	Sphenoid pneumatization pattern
Axial	Sphenoid anatomy/attachment of superior turbinate

Magnetic Resonance Imaging

The technique of MRI involves the application of a strong magnetic field to soft tissue, which results in atom magnetization. Once magnetized, a series of radiofrequency fields are applied, which induce the nuclei to emit a magnetic field specific to each tissue. The scanner detects these differences and produces an image. There are three common MRI sequences, which provide important information: T1-weighted, T2-weighted, and T1-weighted with contrast. Fat appears bright on T1 images, while water is bright on T2 images. Intravenous gadolinium provides an excellent contrast medium, which can provide information regarding the vascularity of tissue.

The major advantages of MRI include: improved soft tissue definition, differentiate between secretions and soft tissue, lack of radiation exposure, and multiplanar reconstruction. The major disadvantages of MRI include: the lack of bony definition, long acquisition time in a small confinement, higher costs, and contraindication with any metal implant (e.g., pacemaker, cochlear implant). Since cortical bone and air both fail to provide a magnetic signal,

TABLE 28.4 COMPARISON OF COMMON SINONASAL RADIOLOGIC MODALITIES

Radiologic Modality	Advantages	Disadvantages
Plain films	Fast acquisition time	Poor anatomic detail
	Low cost	Limited clinical value
CT	Excellent bony detail	Radiation exposure
	Multiplanar reconstruction	Limited soft tissue differentiation
	Surgical planning	
	Fast acquisition time	
MRI	Detailed soft tissue definition	Poor bony definition
	Differentiate secretions from soft tissue	Long acquisition times in confined space
	Lack of radiation exposure	Expensive
	Multiplanar reconstruction	Contraindicated with certain metal implants

MRI cannot differentiate between these two entities. The bony contours of the sinuses and the associated intricate bony lamellae are poorly represented.

Traditionally, MRI was thought to be overly sensitive when evaluating chronic rhinosinusitis (CRS); however, a recent study by Lin et al. (10) demonstrated that MRI and CT Lund-Mackay scores correlated very well ($r = 0.837$, $p < 0.001$). Although MRI may be comparable to CT CRS staging, the lack of bony definition makes surgical planning difficult, and thus precludes its routine use in CRS imaging. The most common indications for MRI include evaluation of: (a) sinonasal mass/neoplasm and (b) suspected intracranial complication of acute rhinosinusitis.

MRI is a useful adjunct during the evaluation of select sinonasal pathologies and is rarely indicated in isolation without obtaining a CT scan. The exquisite soft tissue imaging of MRI combined with the detailed bony anatomy of CT make these two radiographic modalities the ideal options in sinonasal pathology evaluation (Table 28.4).

LABORATORY INVESTIGATIONS

Although most patients with sinonasal pathology do not require routine lab testing, there are certain clinical scenarios whereby the information obtained from lab results can be imperative to the diagnosis and subsequent treatment success. A common scenario where lab testing is indicated is during the evaluation of a young patient with sinus disease and any patient with refractory CRS. Lab testing can identify an underlying congenital abnormality, such as cystic fibrosis (CF) or primary immunodeficiency, or acquired illnesses such as atypical infections and systemic inflammatory diseases.

Cystic Fibrosis Testing

The diagnostic criteria for CF requires the presence of clinical symptoms consistent with CF in at least one organ system, and objective evidence of cystic fibrosis transmembrane conductance regulator (CFTR) dysfunction on any of the following three tests: (a) elevated sweat chloride greater than 60 mmol/L (on two occasions), (b) presence of two disease-causing CFTR mutations on DNA testing, or (c) abnormal nasal potential difference (NPD).

The sweat chloride test remains the primary test used for laboratory confirmation of CF. Sweating is induced by a technique called pilocarpine iontophoresis. It involves placing a pilocarpine-soaked gauze on the skin and applying a gentle electrical current. The current draws pilocarpine into the skin and induces sweat gland secretion. The sweat is then collected and the chloride concentration is quantified (11). For infants older than 6 months, children, and adults, there are three groups of results: (a) Normal (CF very unlikely): ≤39 mmol/L, (b) Intermediate (Possible CF): 40 to 59 mmol/L, and (c) Abnormal (diagnosis of CF): ≥60 mmol/L. The accuracy of sweat chloride testing is operator-dependent and should be performed at experienced labs (12). Patients with an intermediate sweat chloride result should receive DNA analysis, using the multimutation method, to identify a CFTR gene mutation. Approximately 20% of patients with an intermediate sweat test will have an identifiable CFTR mutation on DNA analysis (13). If two CFTR mutations are not identified, then the sweat chloride test should be repeated. A false positive sweat test can occur in any of the following: (a) lab error, (b) malnutrition, (c) dehydration, (d) adrenal insufficiency, (e) hypothyroidism, (f) hypoparathyroidism, (g) mucopolysaccharidosis, and (h) nephrogenic diabetes insipidus. The two most common causes of a false negative sweat test are: (a) lab error and (b) skin edema.

Multimutation genetic testing involves screening at least 23 CF-causing CFTR mutations (14). This panel identifies approximately 90% of CF causing mutations. Molecular analysis should be ordered in cases with an intermediate sweat chloride test. An expanded CFTR mutation panel, deletion evaluation, and/or direct gene sequencing is available for cases when a genetic screen failed to identify

two CF-causing mutations and a repeat sweat test was intermediate (40 to 59 mmol/L).

The NPD measures CFTR function within the nasal respiratory epithelium. The technique involves the following three measurements of the potential difference across the nasal epithelium: (a) basal state, (b) after nasal perfusion with amiloride (blocks sodium transport—the major component of the NPD), and (c) after nasal perfusion with a chloride-free solution containing isoproterenol (a camp agonist—stimulates CFTR chloride transport). Patients with CF will demonstrate a high basal state potential difference, a large decline with amiloride, and minimal response to isoproterenol. Although not widely available, measuring the NPD is useful in cases where the sweat test and genetic analysis results are inconclusive but atypical CF is suspected due to clinical presentation in one or more organs.

Other rare tests for CF include pancreatic function analysis, such a 72-hour stool collection for fecal fat analysis. Pulmonary function tests and bronchoalveolar lavages can be helpful to define the extent of pulmonary disease.

Primary Immunodeficiency Testing

Immunologic testing can evaluate both the cellular and humoral immune systems. Immune dysfunction is common in patients with refractory CRS (15), therefore, knowledge of the available immune testing options is important.

Humoral immunity testing involves both quantifying immunoglobulin (Ig) levels and assessing for a functional immunoglobulin deficiency. Measurements of serum IgG, IgA, and IgM along with IgG subclasses are helpful to quantify a humoral deficiency. The significance of an IgG subclass deficiency remains controversial, while current recommendations state that it is not significant unless it is associated with an impaired specific antibody response. A functional immunoglobulin deficiency is evaluated by assessing the antibody response following administration of an unconjugated polysaccharide vaccine, such as pneumovax. For adults, a functional immunoglobulin deficiency is diagnosed if there was a lower than fourfold increase in antibody titers to 70% of the serotypes tested (16).

Cellular immunity is mediated by T cells and deficiencies with this system often result in severe infections. The complete blood count (CBC) is useful to identify a lymphopenia and other hematologic defects. Flow cytometry uses cell surface markers to evaluate lymphocyte subpopulations and provide subset quantitative information. The cutaneous delayed-type hypersensitivity test is an *in vivo* test measuring the recall response to an intradermal injection of an antigen, which the patient has previously been exposed.

Infectious Testing

Most cases of sinonasal infections can be diagnosed with a thorough history, physical exam, and rigid sinonasal endoscopic exam. However, resistant organisms or atypical infections must be considered in patients with persistent symptoms despite adequate antimicrobial therapy.

Sinus culture and sensitivities can be obtained by a variety of methods, including endoscopic middle meatal swabs, endoscopic suction sinus aspiration, or sinus puncture. Historically, the sinus puncture (either through the canine fossa or inferior antral window) was considered the gold standard sinus culture method; however, it has fallen out of favor due to the morbidity associated with significant patient discomfort. Recent evidence supports that endoscopic middle meatal swab is an accurate and less morbid culture method, with an 82% correlation rate to sinus puncture (17). Additionally, endoscopic sinus suction aspiration has an 88.5% correlation rate to sinus puncture (18). The endoscopic-directed culture methods are tolerated well by patients and can be obtained in the clinic.

When an atypical infection is suspected, tissue should be sent for fungal and mycobacterial culture and staining. The most common fungal stains available include: Gomori Methenamine Silver (GMS), Periodic acid-Schiff (PAS), Potassium Hydroxide (KOH), and Chitin-specific stain. Mycobacterial species can be identified by nucleic acid hybridization probes, polymerase chain reaction (PCR) analysis, or Ziehl-Neelsen staining. The Ziehl-Neelsen technique involves an initial stain with carbolfuchsin (red) and then rinsed with an acid (hydrochloric or sulfuric) and counterstained with methylene blue. Mycobacterial species will retain their red staining, and are thus called acid-fast bacilli.

Systemic Inflammatory Disease Testing

Evaluation of an underlying systemic inflammatory disease must be considered in patients with refractory CRS. Although most patients will already have a diagnosis of a systemic inflammatory disease, some cases may have isolated nasal cavity involvement and prompt a new diagnosis. Common diseases include Wegener granulomatosis, Sarcoidosis, Churg-Strauss, Sjogren syndrome, and Systemic Lupus Erythematosus.

General inflammatory markers include erythrocyte sedimentation rate (ESR) and c-reactive protein (CRP). Nonspecific autoantibody tests include antinuclear antibodies (ANA) and rheumatoid factor (RF). The antineutrophil cytoplasmic antibody (ANCA) is usually an IgG immunoglobulin against two neutrophil cytoplasmic antigens called proteinase-3 (PR-3) and myeloperoxidase (MPO).

Wegener granulomatosis is most commonly anti-PR-3 ANCA positive, while Churg-Strauss is usually anti-MPO ANCA positive. However, 20% of patients with Wegener granulomatosis may demonstrate anti-MPO ANCA. Additionally, negative ANCA results may occur in 52% of limited Wegener cases and in 10% of cases with multisystem involvement.

If sarcoidosis is considered, a serum angiotensin-converting enzyme (ACE) is elevated in 60% of patients and serum calcium levels commonly demonstrate hypercalcemia. If Sjogren syndrome is suspected, then serum

TABLE 28.5 SUMMARY OF COMMON SINONASAL LABORATORY TESTS

Sinonasal Disease	Lab Tests
CF	Sweat chloride test
	DNA testing
	NPD
Primary immunodeficiency	*Humoral*
	Serum immunoglobulin levels (IgA, IgG, IgM)
	IgG subclasses
	Antibody response
	Cellular
	CBC
	T-cell Flow cytometry
	Cutaneous delayed hypersensitivity
Bacterial infection	Middle meatal swab
	Endoscopic suction aspiration
	Sinus puncture
Atypical infection	Fungal stains—GMS, PAS, KOH, chitin-specific
	Mycobacterial—Ziehl-Neelsen stain
	Syphilis testing
Systemic inflammatory	ESR, CRP
	ANA
	RF
	ANCA (anti-PR3 and anti-MPO)
	ACE
	SS-Ro, SS-La

SSA-Ro and SSB-La antibody levels can provide helpful diagnostic information. SSA-Ro is positive in 75% of patients with primary Sjogren syndrome (SS) and 15% of patients with secondary SS. SSB-La is positive in 40% to 50% of patients with primary SS and 15% of patients with secondary SS. See Table 28.5 for a summary of common sinonasal lab testing options.

ALLERGY TESTING

Evaluating for the presence of allergy is an important step in the management of sinonasal disease. Allergy can be tested with either *in vivo* or *in vitro* methods. The term "sensitization" refers to a demonstrable IgE reaction to an allergen, whereas the term "allergy" refers to the presence of corresponding symptoms upon allergen exposure. Therefore, it is important to interpret sensitization in the context of the patient's clinical history, since a positive skin test in an asymptomatic patient is clinically irrelevant. Failure to recognize allergy as a contributory factor in sinonasal disease can result in misdiagnosis and treatment failure.

In vivo Allergy Testing

In vivo skin testing is the preferred method of allergy testing because it is fast, less expensive, and more sensitive than *in vitro* testing. A focused skin testing protocol may be employed if there is a single strong offending allergen in the history, such as a penicillin allergy. However, most cases require a broad skin testing protocol, since patients often describe seasonal or perennial allergy symptoms without a single offending allergen. In this scenario, an appropriate geographical panel of indoor and outdoor allergens would be evaluated for sensitization.

TABLE 28.6 INDICATIONS AND CONTRAINDICATIONS FOR *IN VIVO* (SKIN) ALLERGY TESTING

Indications	Allergic rhinitis
	Refractory chronic rhinosinusitis
	Allergic asthma
	Conjunctivitis
	Food allergies
	Some medication allergies (Penicillin)
	Venom allergies (Wasps, bees, yellow jackets, fire ants, and other)
	Latex allergies
Contraindications	High risk for anaphylaxis
	Recent anaphylactic reaction (within last month)
	On medications that interfere with the treatment of anaphylaxis
	Skin disease

There are several indications for *in vivo* skin testing (Table 28.6). The most common sinonasal indications include: (a) suspected allergic rhinitis and (b) refractory CRS. The four primary contraindications to skin testing include patients with any of the following: (a) high risk for an anaphylactic reaction to testing, (b) recent anaphylactic reaction (within the last month), (c) taking medications that interfere with the treatment of anaphylaxis, and (d) skin diseases. High-risk patients are considered those with poorly controlled asthma, clinical history of severe reactions to minimal allergen exposure, and significant cardiovascular disease. Recent anaphylaxis, within the last month, can render the skin unresponsive to allergen exposure, and therefore, a false negative skin test result can occur if tested too early. Medications such as beta-2-antagonists and ACE antagonists can impair the treatment of an anaphylactic reaction and should be avoided if skin testing is performed. Although skin testing is considered safe, systemic reactions occur in 33 patients per 100,000 (19). Therefore, all testing centers should have emergency anaphylactic equipment readily available. Due to a high false-positive test rate, skin conditions such as severe atopic dermatitis, dermographism, and mastocytosis should not receive *in vivo* testing. In cases where there is a contraindication to skin testing, *in vitro* allergy testing should be performed.

A full medication review needs to be performed prior to skin testing, since there are several medications that can affect testing results (Table 28.7). First generation H1-antihistamines should be stopped at least 3 days prior to testing, while second generation H1-antihistamines

TABLE 28.7 FACTORS AFFECTING SKIN TESTING RESULTS

Medications	*Reduced response in the following:*
	H1-receptor antagonists
	H2-receptor antagonists
	Systemic corticosteroids
	Omalizumab (anti-IgE antibody)
	Tricyclic antidepressants
	Tacrolimus
Physiologic	*Reduced response in the following:*
	Age (Infants and Age >50)
	Location (Forearm)

should be stopped 7 days prior to testing. H2-receptor antagonists should be stopped 48 hours prior to skin testing. The following medications have no affect on skin testing: Inhaled or intranasal topical steroids, decongestants, inhaled beta agonists, intranasal cromolyn, and leukotriene receptor antagonists. It is important to consider the age of the patient prior to testing, since infants and adults (older than 50 years of age) have reduced skin-testing responses.

There are two primary methods to *in vivo* testing: (a) skin prick/puncture, and (b) intradermal technique. The skin prick technique is very sensitive but has a poor specificity (e.g., higher rate of false positives). Therefore, a positive test is only considered an allergy if there are clinical symptoms upon exposure to that allergen. The intradermal technique has a higher sensitivity compared to skin prick; however, it carries a much lower specificity. Since the intradermal test is associated with a higher risk for an anaphylactic reaction, it should only be performed with allergens that resulted in a negative skin prick test.

During skin prick testing, both a positive and negative control should be used to evaluate the patient's skin for a normal response. Positive control usually involves a solution of histamine dichloride (10 mg/mL), while the negative control typically uses a saline solution, similar to the allergen extract. Skin prick wheals are measured at 15 to 20 minutes after the prick. A positive skin prick result is defined by one of two options: (a) wheal larger than 3 mm or (b) a wheal equal to or larger than the positive control.

Intradermal skin testing involves injecting 0.02 to 0.05 mL of allergen extract into the dermis, creating a small bleb. Since it is estimated to be 100 to 1,000-fold more sensitive, intradermal testing is only performed using allergens that created a negative response on skin prick testing. Due to a high rate of false positives and systemic reactions, food and latex allergies are not evaluated using the intradermal technique.

In vitro Allergy Testing

In vitro allergy testing involves the measurement of serum IgE, and can either be allergen-specific or total IgE. Although *in vivo* testing is the preferred method for allergy testing, there are several advantages of *in vitro* testing (Table 28.8). First, since it is a blood test, there is no risk of an allergic reaction to the patient. This is ideal for patients with a history of prior anaphylaxis or severe allergic reactions to minimal allergen exposure. Secondly, *in vitro* testing is not affected by current medication usage. Therefore, patients are not required to stop taking antihistamines, antidepressants, or systemic steroids prior to testing. Thirdly, *in vitro* testing is not affected by skin disease, while cutaneous conditions, such as atopic dermatitis or dermographism, often preclude the use of *in vivo* testing. Other advantages include being more convenient (single blood test) and may be more accurate for detecting food allergies.

TABLE 28.8 ADVANTAGES OF *IN VITRO* ALLERGY TESTING

No risk of allergic reaction during testing
Not affected by concurrent medications
Not affected by skin disease
Convenient
Accurate for food allergy testing

There are two primary forms of *in vitro* allergy testing: (a) immunoassays and (b) total IgE levels. Immunoassays identify the presence of "allergen-specific IgE" by evaluating the interaction between antigens and antigen-specific antibodies to provide both qualitative and quantitative information. There are three common types of immunoassays: (a) Enzyme-linked immunosorbent assays (ELISA), (b) Fluorescent enzyme immunoassay (FEIA), and (c) Radioallergosorbent test (RAST). Both the ELISA and FEIA involve anti-IgE antibodies that are coupled with an enzyme, that when mixed with a specific substrate, result in a change in color or give off a fluorescent signal. The RAST involves an antibody coupled to a radioactive tag.

Immunoassay technique involves placing patient serum (which contains several immunoglobulins, including IgE) onto a premade matrix with known antigens. After a period of incubation, excess immunoglobulins are washed off leaving only the antigen–antibody complex on the matrix. This complex is then incubated with anti-IgE antibodies, which are coupled with one of the above indicators (ELISA, FEIA, or RAST). After a substrate is added or radioactive detector is performed, the IgE-antigen complexes can be quantified. Since IgE from the patient's serum bind to the antigen on the matrix in direct proportion to their concentration in serum, a quantitative IgE value is provided. Immunoassay results are usually reported in units of kIU/L or ng/ml. The conversion rate is 1 kIU/L = 2.4 ng of IgE/mL. Results are reported as a grade between I and VI based on arbitrary cut-points (Table 28.9). Although there is limited clinical significance between immunoassay grades, allergen-specific IgE levels of grade III or higher

TABLE 28.9 GRADES OF IgE IMMUNOASSAY RESULTS

Immunoassay Class	IgE Concentration (kIU/L)
0	<0.35
1	0.35–0.7
2	0.7–3.5
3	3.5–17.5
4	17.5–50
5	50–100
6	>100

have a more consistent correlation with the presence of patient symptoms upon exposure to the allergen (20).

Measurement of total serum IgE must not be confused with measurement of allergen-specific IgE, which is performed by immunoassay techniques. Total serum IgE level does not provide information about which allergens the patient is sensitive to. Currently, total serum IgE has limited clinical value since it can be elevated in a number of different diseases such as: asthma, allergic rhinitis, atopic dermatitis, allergic fungal rhinosinusitis (AFRS), parasitic infections, allergic bronchopulmonary aspergillosis, and Wiskott-Aldrich syndrome. Although controversial, current uses of total serum IgE measurement may include differentiating between CRS and AFRS (21) or early prediction of an AFRS exacerbation (22).

It is important to remember that *in vitro* allergy testing must be evaluated in the context of the patient's clinical presentation and history. A negative immunoassay, in the setting of a strong allergy history, does not exclude the possibility of an allergy. If there is no contraindication, an *in vivo* allergy test should be performed in this scenario. Additionally, a high-grade immunoassay or elevated total IgE result in the setting of an asymptomatic patient has minimal clinical relevance.

OLFACTORY TESTING

The primary purpose of olfaction is to provide protection from potentially harmful agents in the environment, such as: spoiled foods, gas leaks, and smoke. Additionally, when olfaction is altered or lost, it significantly lowers the patient's health-related quality of life since the sense of smell provides a pleasurable component to life. An organized approach to olfactory testing is important since there are an estimated 2.7 million adults in the United States with olfactory dysfunction.

The majority of olfactory disorders can be diagnosed with a thorough history, physical exam, and rigid sinonasal endoscopic exam. Although rarely indicated, objective olfactory testing may be indicated to provide objective information pertaining to the degree of dysfunction. Quantitative olfactory testing can be organized into two categories: (a) Psychological, and (b) Electrophysiologic (Table 28.10). Since psychological tests are easier to administer, they are most commonly used in clinical practice. The electrophysiologic tests are primarily used for research purposes and have limited clinical utility. Although not discussed in this section, a CT scan of the sinuses and MRI of the olfactory cleft and brain should be considered during the evaluation of olfactory disorders. Additionally, a mini-mental exam should be considered when a neurodegenerative disease is suspected.

TABLE 28.10 LIST OF OBJECTIVE OLFACTORY TESTS

Quantitative Category	Olfactory Testing
Psychological	SIT
	Butanol Threshold test
	Sniffin' Sticks
Electrophysiologic	OERP
	EOG

Psychological Olfactory Tests

The Smell identification test (SIT) is a commonly used olfaction test that utilizes a scratch-and-sniff format. It has excellent test-retest reliability and has been validated in several different populations and disease states. It is composed of 40 odors with a selection of four corresponding answer options per odor (Fig. 28.3). Patients take the exam alone and are instructed to guess at the answer even if they cannot smell the odor. Anosmic patients should receive a score of approximately 10/40 since random answer selection should result in a score of 25%. Malingering patients will intentionally pick the wrong answer and often result in a score less than 10/40. The final scores are then compared to normal age-matched norms and the results are analyzed.

The butanol threshold test involves the identification of a solution containing butyl alcohol. The patient sniffs two bottles, one contains water and the other contains a specific concentration of butanol, with each nostril tested separately. After every incorrect identification response, the concentration of butanol is increased by a factor of 3 until one of the following is occurs: (a) the patient is able to correctly identify the butanol bottle five responses in a row or (b) until the concentration of butanol reaches 4%. The concentration threshold is then compared to age-matched norms and the results are analyzed.

Sniffin sticks testing use a series of reusable n-butanol pens, which contain different concentrations of odor. The test contains three parts and should be performed in the following order: (a) threshold test for butanol, (b) discrimination of odors, and (c) identification of odors. The

Figure 28.3 Smell identification test (Sensonics Quick-SIT, www.sensonics.com).

patient is blind folded and the odorant pens are presented 2 cm from an isolated nostril. For threshold testing, the pens are labeled from 1 (highest concentration) to 16 (lowest concentration) and the examiner begins by presenting pen 16 and continues to increase the concentration until the patient correctly identifies the butanol pen at least twice. During discrimination testing, patients are presented with a triplet of pens, with one of the three pens containing a unique odorant. The patient is asked to identify the unique odorant pen. Identification testing is similar to the SIT, whereby an odorant pen is provided and the patient is asked to provide the correct odor from a list of four responses.

Electrophysiologic Olfactory Tests

Olfactory-event related potentials (OERP) utilize the use of an electroencephalogram and electrooculogram and measure the responses after the delivery an odorant stimuli. Odors typically involve both a pure trigeminal stimulant as a control (i.e., carbon dioxide) and a pure olfactory stimulant (i.e., butanol or hydrogen sulfide). N1 is the first negative peak measured and P2 is the second positive trough. The peak amplitudes and latency between N1 and P2 are recorded and compared to age-appropriate norms. Although not clearly defined, olfactory dysfunction typically results in reduced wave amplitudes and prolonged latencies (23).

The electro-olfactogram (EOG) measures the electrical potentials of the olfactory epithelium in response to an odorant stimulus. Using endoscopic visualization, an electrode is placed onto the olfactory epithelium and a reference electrode is placed on the nasal dorsum. Due to difficulties in electrode placement and patient discomfort, combined with minimal human research, EOG has limited clinical utility and remains primarily a research tool (24).

NASAL AIRWAY PATENCY EVALUATION

Nasal obstruction is a commonly presenting sinonasal complaint and contributes to a reduced quality of life. Two objective tests, which have attempted to quantify nasal patency, include: (a) Acoustic rhinometry and (b) Rhinomanometry. The challenge remains that nasal obstruction is a subjective symptom, which is poorly correlated with objective nasal patency testing modalities. Despite limited clinical utility, acoustic rhinometry and rhinomanometry continue to be investigated and may play a role in certain clinical scenarios.

Acoustic Rhinometry

Acoustic rhinometry uses reflected sounds waves to measure the cross-sectional area (CSA) of the nasal cavity. A nosepiece containing a sound generator ("click") and microphone is placed within the nostril, ensuring it does not distort the nasal alae. A sound wave is generated that travels through the nasal cavity and becomes reflected at regions of anatomic narrowing. The reflected acoustic waves are recorded and the CSA is calculated. Two separate recordings are performed, before and after nasal decongestant, to determine the mucosal and structural components of the CSA. An acoustic rhinometry graph will have the distance (cm) on the x-axis and the CSA (cm^2) on the y-axis. According to a consensus report on acoustic rhinometry, the three minimal CSAs include: (a) CSA1: nasal valve area, (b) CSA2: anterior head of the inferior turbinate and/or middle turbinate, and (c) CSA3: mid-posterior aspect of the middle turbinate (25).

TABLE 28.11 THREE METHODS OF RHINOMANOMETRY TRANSNASAL PRESSURE MEASUREMENTS

Transnasal Pressure Measurement Method	Description
Anterior	Pressure detector is placed into the opening of a single nostril
Posterior	Pressure detector is placed within the oral cavity or oropharynx
Postnasal	Pressure detector is passed through one nostril into the nasopharynx

Dual-mode acoustic rhinometry is a variation of the standard technique whereby the nasal valve CSA is measured during apnea and during inspiration. The primary application of dual-mode acoustic rhinometry is during the diagnosis of nasal valve collapse. A normal patient should have an Inspiratory: Apnea CSA ratio equal to 1; while patients with nasal valve collapse have ratios less than 1 due to inspiration-related narrowing.

Rhinomanometry

Rhinomanometry simultaneously measures transnasal pressure (Pa) and airflow (cm^3/s), which is used to calculate the nasal resistance ($Pa/cm^3/s$). Rhinomanometry data is commonly presented using a pressure-flow curve with the change of transnasal pressure (ΔP) on the x-axis and airflow (V) on the y-axis. There are both passive and active methods of rhinomanometry. During the passive method, the patient holds their breath while air is pumped into the nasal cavity at a fixed rate. The active method involves the patient using his/her own nasal respiration as the source of airflow. The active method for rhinomanometry is the most commonly used technique since it is easier to perform and provides a variable pressure-flow curve rather than a fixed-flow curve.

Airflow is measured using a facemask while simultaneous transnasal pressure can be measured using one of three different methods: (a) Anterior, (b) Posterior, or (c) Postnasal (Table 28.11). Due to technical ease and improved patient comfort, anterior rhinomanometry is the most commonly used method of transnasal pressure measurement. The primary disadvantage of anterior rhinomanometry is that it cannot directly measure total airway values, since one side of the nose is plugged. Therefore, left and right values must be combined to calculate total nasal airway values.

CILIARY TESTING

Mucociliary clearance is an essential function for the development of healthy upper and lower airways. Normal human cilia have a basal cilia beat frequency of 9 to 15 Hz, which results in a normal mucus velocity between 3 and 25 mm/min. Although a full review of cilia structure is beyond the scope of this section, the essential components include nine microtubule doublets arranged in an outer circle around two central single microtubules (9 + 2 arrangement). Using adenosine triphosphate as an energy source, motility is accomplished by stimulation of the dyein arms, attached to the doublet microtubules.

Primary ciliary dyskinesia (PCD) is a rare hereditary disease, typically autosomal recessive, which results in abnormal mucociliary clearance. It commonly presents with neonatal respiratory distress, recurrent childhood pulmonary infections, chronic otitis media, and CRS. PCD in the presence of situs inversus, bronchiectasis, and CRS, is called Kartagener disease. Although most cases of PCD are identified in childhood, milder phenotypes may present in adulthood with male infertility and CRS. Testing for PCD often begins with screening tests (saccharin test or nasal nitric oxide [nNO] levels) followed by more definitive tests such as analysis for ciliary motility, structure, and genetic sequencing. The following section will discuss common methods for PCD evaluation.

Saccharin Test

The saccharin test is the traditional screening modality for PCD. It measures mucociliary clearance by placing a saccharin microtablet onto the anterior head of the inferior turbinate and quantifying the time it takes for the patient to taste the sugar. Although there are no standardized normal values for saccharin test results, values shorter than 20 minutes are considered in the normal range. The challenge remains that the saccharin test is unreliable in children (26), and therefore it is not commonly used during the diagnosis of PCD.

Nasal Nitric Oxide

nNO measurement has become the preferred screening modality for PCD. The technique involves placing a nasal catheter through a foam sleeve, which is used to seal the nostril from the atmosphere and measure the concentration of nitric oxide. During nNO measurements, the patient performs maneuvers designed to close the soft palate, which minimizes the contamination of nasal gases by pulmonary gases. Due to technical considerations surrounding the palate closure maneuvers, the youngest age for nNO measurements is 5 years old.

Several studies have demonstrated that patients with PCD will have low levels of nNO (27,28). False-positive low nNO can occur with CF, panbronchiolitis, and nasal polyposis. Therefore, screening results with a low nNO level, require other confirmatory tests, such as ciliary ultrastructure analysis or genetic analysis, before a definitive diagnosis of PCD can be made.

Ciliary Ultrastructure Analysis

Ciliary ultrastructure analysis, using transmission electron microscopy, remains an integral diagnostic modality during the evaluation of PCD. Fresh ciliated mucosal biopsies are performed and placed in glutaraldehyde. The preferred mucosal biopsy technique is a brushing from the bronchi and pharynx; however, other options include endoscopic bronchial tissue biopsy or inferior turbinate biopsy. Although several ciliary structural defects have been described, most common abnormalities include: (a) absence or shortening of dyein arms, (b) absence of radial spokes, and (c) loss of the central pair of microtubules with transposition of a peripheral doublet into the center (29).

Ciliary Motility Analysis

Ciliary motility analysis is a technically challenging diagnostic modality whereby fresh respiratory mucosal biopsies are placed in isotonic saline and rapidly transferred to a lab for high-speed video microscopy. Cilia are then evaluated for the following beat characteristics: (a) coordination, (b) frequency, and (c) pattern. The introduction of digital high-speed video microscopy has significantly improved the diagnostic utility of cilia motility analysis, as certain beat patterns have been correlated with specific ultrastructural defects. For example: (a) immotile or flickering cilia correlate with outer dyein arm defects, (b) low-amplitude stiff beats correlates with either an isolated inner dyein arm defects or radial spoke defect, and (c) a whip-like beat correlates with central microtubule defects, such as a peripheral doublet transposition (30).

Genetic Analysis

Genetic analysis for PCD can be challenging due to genetic heterogeneity and the extensive size of PCD-causing genes. The two most common genes mutated in PCD include DNAI1 (outer dyein arm intermediate chain) and DNAH5 (outer dyein arm heavy chain), both of which have been implicated in 30% to 38% of PCD patients (31). The other four genes with mutations implicated in ciliary dysfunction include: DNAI2, DNAH11, TXNDC3, and KTU. The KTU gene produces a cytoplasmic protein that is required for dyein arm assembly (32).

IN-OFFICE IMAGING

Over the last decade, point of care rhinologic imaging has been made possible with the development and refinement of in-office CT. Although the exact role of this imaging modality has not yet been defined, it is becoming a common diagnostic option and deserves discussion. There are four in-office CT scanners available on the market: (a) Xoran MiniCAT (Fig. 28.4), (b) Neurologica OTOscan, (c) J. Morita 3D Accuitomo 170, and (d) 3M/Imtec Iluma. These new in-office devices provide similar high-resolution CT image detail compared to traditional sinus CT scans

Figure 28.4 In-office CT scanner (Xoran Minicat, www.xorantech.com).

TABLE 28.12 RADIOLOGIC RADIATION EXPOSURE COMPARISONS (34)

CT Studies	Radiation Dose (mSv)
In-office Sinus CT	0.2
Abdomen and Pelvis CT	15
Chest CT (low dose)	1.5
Conventional Sinus CT	0.96
Mammogram	0.40
Chest x-ray PA and Lateral	0.10
Dental intraoral x-ray	0.005

and can be utilized in most image-guidance machines during ESS. Although some scanners can provide ultra high resolution 0.09 mm slice thicknesses, the most common clinically utilized thicknesses range between 0.625 and 1 mm. Acquisition time is usually less than 60 seconds for 600 frames.

The two primary advantages of in-office imaging is optimizing patient convenience and reducing patient radiation exposure. Eliminating both the need for a radiology appointment and the need for a second otolaryngology clinic visit to review the CT and plan management may optimize patient convenience. Patients with CRS often require multiple sinus CT scans throughout their life; therefore, minimizing radiation exposure is important. Compared to traditional sinus CT scans, in-office CT studies have been demonstrated to provide a lower radiation dose (Table 28.12). Another potential advantage would be to correlate current patient symptoms with immediate CT images; however, a recent article by Ryan et al. (33) demonstrated that symptoms correlated poorly with immediate in-office imaging, while endoscopy correlated well with CT images. This supports the literature whereby symptoms correlate poorly with CT stage and minimizes the importance of immediate sinus CT acquisition.

Despite several advantages for in-office CT scanning, there are several disadvantages that must be considered (Table 28.13). Although the radiation dose is low for the patient, the radiation exposure for in-office staff must be considered. Proper space and radiation protection must be implemented to ensure long-term safety for daily office personnel. Another important issue that must be addressed is overutilization and patient self-referral. Since in-office CT scanners are expensive, there is a danger that CT studies may be performed to help curtail some of the costs rather than for clinically indicated reasons. This is a controversial topic but must be considered during in-office imaging. Another concern is determining which medical specialty should interpret the in-office sinus CT scan. While most otolaryngologists are proficient in the interpretation of a sinus CT study, they may not be competent to identify nonrhinologic pathology. This raises the debate whether or not a radiologist needs to evaluate the in-office CT scan to protect against the medicolegal ramifications of missing nonrhinologic diseases, which may occur by an otolaryngologist interpretation.

In-office CT scanners have several advantages, which include improving patient convenience and reducing patient radiation exposure. However, there remain several areas of controversy, which must be elucidated before this novel technology can become widely implemented.

TABLE 28.13 CONSIDERATIONS OF IN-OFFICE CT

Advantages	Disadvantages
Improved patient convenience	Risk of radiation exposure to office staff
Immediate image viewing	Physician cost
Image-guidance capability	Risk of needless imaging
Reduced patient radiation exposure	Lack of optional IV contrast
	Liability for missed nonsinus pathology

HIGHLIGHTS

- Following the history and physical exam, a thorough rigid sinonasal endoscopy is an important first investigation during the evaluation of sinonasal pathology.
- Sinus CT imaging is considered the gold standard radiologic investigation for sinonasal inflammatory disease.
- MRI imaging is a useful adjunct during evaluation of a suspected sinonasal neoplasm or complication of acute rhinosinusitis.
- During cases of medically refractory chronic rhinosinusitis, consider obtaining tests to evaluate for a possible underlying allergy, systemic inflammatory disease, atypical infection, or congenital disease.
- Although there are several options for olfaction and nasal patency testing, they play a limited role in clinical practice, and remain primarily research tools.
- In-office CT imaging is an exciting new investigative tool; however, further research is required to define its exact role in sinonasal evaluation.

29 Allergic Rhinitis

James T. O'Neil *James W. Mims*

Allergic rhinitis, the second leading cause of chronic disease in the United States, affects up to 60 million Americans, approximately one person in every four households. Of those affected, more than half have experienced symptoms for longer than 10 years (1). Allergic rhinitis has a substantial effect on patient's quality of life, sleep, school performance, and productivity. Physicians should also be aware of the association of allergic rhinitis with other conditions such as asthma. Asthma is both underdiagnosed and suboptimally controlled in the United States (2). This chapter focuses on the epidemiology, diagnosis, and treatment of allergic rhinitis.

DEFINITION AND GENETICS

Allergic rhinitis is clinically defined in the 2008 Allergic Rhinitis and its Impact on Asthma (ARIA) Guidelines as "a symptomatic disorder of the nose induced after allergen exposure by an IgE-mediated inflammation" (3). Normally, harmless particles elicit an unnecessary immune response in patients with allergies. It is the inflammation that causes their symptoms. When harmless nonself substances cause inflammation, they are called hypersensitivity reactions. Atopy is the genetic predisposition to develop allergic hypersensitivity reactions. Examples of allergic disease are allergic rhinitis, allergic asthma, atopic dermatitis, and food allergies. One atopic condition tends to put individuals at risk for others.

Atopic conditions occur more frequently in children when parents are atopic, but do not follow simple Mendelian patterns of inheritance. The genetics of allergic rhinitis is complex and not well understood. Initial speculation was that the genetics of allergy was based in alterations of the inflammatory process. Single-nucleotide polymorphisms (SNPs) of inflammatory mediator genes were targeted. Some allergic individuals were found to have more SNPs in genes coding for allergic inflammation including interleukins IL-4, IL-13, and T-cell receptors than nonallergic controls (4). Many SNPs of inflammatory mediators have been found to be weakly associated with allergic patients, but these findings have been hard to reproduce (4). Broader studies such as the Genome Wide Association studies have identified gene candidates that were not directly linked to the allergic inflammatory cascade (5). It is likely that a combination of factors of innate immunity and variable changes in the regulation of inflammation may both contribute toward allergic hypersensitivity.

Allergic rhinitis is genetically a heterogeneous disease. As such, the predisposition for allergic rhinitis is influenced by multiple, perhaps hundreds, of genetic variables. An example of a gene affecting innate immunity influencing allergic disease can be seen in atopic dermatitis. A defect in the protein filaggrin has been identified in about one-third of those with atopic dermatitis (6). Filaggrin is a protein that helps connect or seal the outer layer of keratinocytes, and it is speculated that the genetic "loss of function" makes the skin barrier more porous. A filaggrin barrier defect may augment any genetic tendency toward promoting inflammation through increased allergen exposure through the more porous keratinocyte connections.

BASIC IMMUNOLOGY OF ALLERGY

IgE-mediated hypersensitivity (Gel and Coombs Type 1) defines allergic disease. An allergen is recognized by an antigen-presenting cell (APC) then processed and presented to a T-helper cell lymphocyte. Specific human leukocyte antigen receptors on the APC and a specific T-cell receptor are both necessary for this communication to take place. TH2 cells, a specific type of T-helper cell, are predisposed toward promoting allergic inflammation (7). TH2 cells present the allergen (or allergic epitope) to a B lymphocyte, which must also have a B-cell receptor for

that specific allergen. All of these specific receptors must be present to form an allergic response. IL-4 and other "allergic" cytokines can induce the B cell to change into an IgE-producing plasma cell. IgE can then travel via the circulatory system and bind to IgE receptors on basophils and mast cells throughout the body.

Reexposure to the specific allergen can cause an IgE-mediated degranulation of basophils and mast cells. This releases inflammatory mediators such as histamine. Histamine binds to histamine receptors on endothelial cells and vascular smooth muscle causing vasodilation and increased permeability (8). Patients then experience rhinorrhea, sneezing, and nasal congestion. Other proinflammatory mediators are released including IL-5, which recruit eosinophils and leukotrienes that promote "late phase" inflammation. The promotion of more inflammation is balanced by factors that down-regulate inflammation such as IL-10 and regulatory T cells (9).

EPIDEMIOLOGY

Allergic rhinitis is a common condition throughout the world, as well as in the United States. The prevalence of the disease is rising in developed countries (10). The widespread prevalence of allergic rhinitis places a significant burden on our health care system. There is evidence of an "allergic march" in which infant atopy leads to later problems with allergies. Also, the controversial "hygiene hypothesis" may explain the increase of allergies.

The prevalence of allergic rhinitis is difficult to precisely estimate for several reasons, including regional differences and how allergic rhinitis is diagnosed. Allergic rhinitis is frequently quoted to affect between 10% and 30% of adults, and up to 40% of children (11). In some countries, over 50% of adolescents report symptoms of rhinitis (1). However, larger epidemiologic studies suggest a lower prevalence. In the United States, the 2009 National Health Interview Survey conducted by the Centers for Disease Control reported that 17.7 million adults or 7.8% of those surveyed had been diagnosed with "hay fever" in the last 12 months (12). Over 7 million children were reported to have "hay fever" and 8.2 million (11%) were reported to have "respiratory allergy" in the last 12 months (13). There is often a difference in reported rates by questionnaire and by actual allergy testing. For example, in Sweden, by questionnaire alone 14.2% were allergic when compared to 9.1% who were positive by questionnaire and skin test (3).

The direct cost of allergic rhinitis includes physician charges and medications used to treat rhinitis, both prescription and over-the-counter. In 2011, Meltzer estimated the direct medical cost of allergic rhinitis at $3.4 billion in the United States (14). A 2002 study estimated direct and indirect costs related to rhinitis in the United States to be $11.58 billion (15). These costs, especially indirect costs, are hard to calculate. But given the prevalence of the disease, allergic rhinitis presents a significant burden in terms of cost.

The "atopic march" refers to the observation that young children with atopic dermatitis and food allergies are at risk of developing asthma and allergic rhinitis in later years (16). Identifying children at risk for allergic rhinitis and asthma can provide an opportunity for early detection and intervention. However, allergic rhinitis and asthma also commonly occur in individuals with no history of early childhood atopy.

The "hygiene hypothesis" is a controversial theory that may explain the increasing prevalence of allergic disease. It is postulated that exposure to infections early in life decreases the chance of atopy later in life. Different studies provide conflicting evidence to this theory (17,18). Evidence supporting the "hygiene hypothesis" includes decreased atopy associated with helminth eradication programs (19), measles vaccinations (20), day care attendance in the first 6 months of life (21), living on a farm during early life (22), and having multiple siblings (23). The controversy arises as published exceptions to the hygiene hypothesis are plentiful, including no observed change in atopic disease after an effective decrease in parasitic disease in Ecuador (24) or the increase in atopy observed after *Streptococcus pneumonia* vaccination in South Africa (25). One explanation for the hygiene hypothesis is that early infections shift the bias of T cells from allergic inflammation (TH2) at birth to a nonallergic bias (TH1) (18). If the TH2 (proallergic) bias persists, individuals are more likely to develop allergic hypersensitivity to otherwise harmless exposures.

DIAGNOSIS

History

Taking a thorough history is critical in the diagnosis of allergic rhinitis. The primary symptoms of allergic rhinitis are rhinorrhea, sneezing, and nasal obstruction (3). Determining if the symptoms are due to allergic rhinitis versus nonallergic rhinitis (discussed in detail in another chapter) can be challenging. In general, anterior rhinorrhea may be a more specific sign of allergic rhinitis than of postnasal drip, which is seen more commonly in rhinosinusitis (26).

The time and location that symptoms occur provide clues to differentiating allergic versus nonallergic rhinitis. Symptoms seen during certain seasons of the year can point the diagnosis toward pollen or mold allergy. Pollens tend to have seasonal peaks as discussed below. Patients sometimes observe that certain locations exacerbate their allergic symptoms, which may lead the physician to consider pet or mold pollen if the development of symptoms occurred after the patient moved to a certain geographic location. Most patients with allergies are polysensitized, which complicates pairing their history with pattern of exposure (3). Nonetheless, a history of allergic symptoms is necessary to diagnose allergic rhinitis as testing and physical findings independent of history are nonspecific. Table 29.1 summarizes reasonable topics to explore in taking an allergic history.

TABLE 29.1 TOPICS TO INVESTIGATE WHEN TAKING AN ALLERGIC HISTORY

- Nasal sneezing, itching, congestion, rhinorrhea
- Eye itching, watering, redness, swelling
- Wheezing, urticaria, eczema, ear pressure, cough
- Onset and duration of symptoms
- Episodic vs. perennial symptoms
- Changes in living conditions
- Length of time living in local area
- Symptom changes with travel or vacations
- Symptom changes with seasons
- Animal exposure at home, work, or school
- Medications tried to alleviate symptoms
- Childhood food allergy, asthma, atopic dermatitis
- Family members with allergy

TABLE 29.2 ARIA CLASSIFICATION OF ALLERGIC RHINITIS (3)

Intermittent	Symptoms are present <4 days a week or <4 consecutive weeks
Persistent	Symptoms are present >4 days per week and/or more than 4 consecutive weeks
Mild	None of the "Moderate/Severe" criteria present
Moderate/Severe	One or more of the following are present: Sleep disturbance Impairment of daily activities, leisure, and/or sport Impairment of school or work Troublesome symptoms

It is also important to be knowledgeable of the pollens common to the local geographic region and their seasonal variation. In the southern United States, pollination of trees occurs in the spring months, with peak levels occurring in March. In northern regions, the month of May tends to have the highest levels of tree pollen. Grass pollens are most often encountered in the summer months. Weed pollen levels are primarily high in the fall. Pollens are uncommon after the first frost. Fungal allergens may have seasonal peaks, but are much less predictable than other seasonal allergens (27).

Classically, allergic rhinitis has been divided as seasonal allergic rhinitis or perennial allergic rhinitis (PAR). However, recent ARIA guidelines recommend intermittent (IAR) and persistent (PAR) as there are too many exceptions to the seasonal model. For example, allergens such as molds and dust mites do not consistently fall into seasonal timeframes, but may cause symptoms intermittently (3). Persistent allergic rhinitis is defined by symptoms present for more than four consecutive days per week or for more than four consecutive weeks (28). Intermittent is defined as any timeframe less than persistent. Symptoms tend to be slightly different with the two groups, with intermittent rhinitis having more sneezing, itching, and rhinorrhea, while persistent patients complain more of nasal obstruction.

Rhinitis can be further classified by severity (Table 29.2) (3). Moderate to severe disease is associated with sleep disturbance, impairment of daily activities, or interference with work or school.

When the diagnosis of rhinitis is being considered, asking about asthma symptoms is also appropriate. Studies have shown that up to 80% of asthmatics have rhinitis, and that 10% to 40% of rhinitis patients have asthma (3). Food allergies and eczema in childhood can also point toward atopy. Family history is useful but far from exact. Allergic rhinitis does not follow Mendelian inheritance. A large study in Sweden showed that parental history of allergy had an odds ratio of 1.3 in predicting positive skin prick test in their children (10).

Physical Findings

Many organ systems can be associated with allergic rhinitis, so a thorough physical examination should be part of the allergic rhinitis workup. The examiner should carefully look for any signs of accompanying otitis, eustachian tube dysfunction, acute or chronic rhinitis, sinusitis, allergic conjunctivitis, and asthma. It is important to note that the asymptomatic patient might have minimal or no findings even with a history suggestive of allergic rhinitis.

In children, findings of dental malocclusion, a high-arched palate, and upper lip elevation may suggest long-standing disease (29). Children also wrinkle their face and frequently wipe their nose during acute attacks. This can cause a supranasal tip crease to develop from frequently lifting the nasal tip (30).

Anterior rhinoscopy is useful, but findings are often not specific for allergic rhinitis alone. Mucus tends to be more abundant in allergic rhinitis, and strands can often be seen between the septum and turbinates. Turbinates are often enlarged (Fig. 29.1), and the mucosa can be described as "pale" or "boggy." Polyps are also a sign of chronic nasal inflammation. Interestingly, they are not seen more frequently in allergic patients (31).

Eye findings include swelling of the lower eyelids due to venous congestion, thickening of the scleral surface, prominent conjunctival vessels, and increased mucous secretions (30). Increased vascularity of the lower eyelids can give the classic "allergic shiners," making the patient look bruised or tired.

Oral pharyngeal findings may include postnasal drip, which tends to drain on the sides. Erythema and edema of the posterior pharyngeal wall may also be observed. Cobblestoning of the posterior pharynx may also be seen.

Auscultation of the chest for wheezing is an important part of the exam due to the high concurrence of allergic rhinitis and asthma. Laryngeal edema and thick stranding mucus have also been observed in the allergic patient (32).

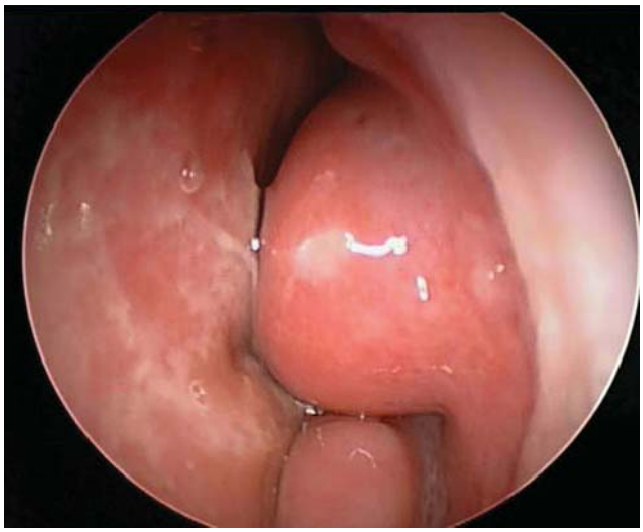

Figure 29.1 Left inferior turbinate hypertrophy. This turbinate was seen in a child with allergic rhinitis. While often seen in patients with allergies, turbinate hypertrophy is not specific for allergic rhinitis.

Testing

Allergy testing is covered in detail in another chapter. Allergy testing is not diagnostic alone, and the patient's history contains the most essential information for diagnosis. However, identification of hypersensitivity to specific allergens can be clinically useful in the management of the allergic patient. Testing is divided into three main categories.

Challenge testing exposes a patient to an allergen, and the subject reports their reaction. Placing allergen directly in the nose of the patient and placing a patient in a room with a circulating airborne allergen have both been used for allergic rhinitis challenges. The subjective nature of the tests along with difficulty in standardization has made it less than ideal for diagnosing allergic rhinitis (33). It is also difficult to test multiple allergens because of the time required between challenges.

Skin testing involves placing an allergen into a patient's skin. This can be accomplished via skin prick or intradermal injection. A wheal and flare are seen if an allergic reaction takes place and this response is compared to positive and negative controls. Physicians should be prepared for the small, but real risk that skin testing can evoke an anaphylactic reaction (34).

Serum-specific IgE levels can also be used to assess the allergic patient. Specific IgE tests assess the presence of IgE that binds to a specific allergen such as cat dander or ragweed. There are several differences between skin testing and specific IgE testing. Specific IgE testing requires only a single venipuncture and does cause local or systemic allergic reactions. Positive skin tests can be suppressed by medication, most commonly antihistamines, while specific IgE testing is unaffected. Skin testing is subject to technique and subjective interpretation, while specific IgE testing is subject to laboratory error. There continues to be some debate about whether allergy skin testing or specific IgE testing is "best," but both are widely accepted in the diagnosis of inhalant allergens (35).

Allergy testing is a valuable tool when combined with a thoughtful history and physical examination. The benefits of allergy testing include its usefulness in differentiating between allergic and nonallergic rhinitis and identifying which exposures may cause symptoms. Allergy testing is required when considering allergen-specific immunotherapy.

TREATMENT

Treatment of allergic rhinitis is traditionally divided into three categories: environmental control, pharmacotherapy, and immunotherapy all have a role. As otolaryngologists are surgeons, a fourth category of surgical interventions is also discussed.

Environmental Control

A logical approach to treat allergic rhinitis is to avoid allergen exposures. However, controlled studies looking at environmental modification for treatment of allergic rhinitis have shown inconsistent results. Varying degrees of environmental control have been attempted. Removing a patient completely from the environment that contains a known allergen has shown success. One study demonstrated improvement of allergic asthma symptoms when students were enrolled in a school located at a high altitude where dust mites could not survive (36). Many studies have evaluated whether measured allergen is decreased in an environment after a control measure is instituted. High-efficiency particulate air (HEPA) filtration (37), low humidity (38), hard surface flooring (removing carpets), hot water laundry (39), barrier protection on pillows and mattresses (40), and acaricides (41) have all been shown to be effective for decreasing allergen levels. These decreased levels do not consistently correlate with decreased symptoms. Studies have not been able to consistently demonstrate control of allergic rhinitis with single environmental control techniques. When multiple environmental control techniques are combined, studies have demonstrated moderate success (37). Avoidance of some allergens is more practical than others. Exposure to outdoor allergens may be decreased by showering and changing clothes after being outside, vacationing during a pollen season to a pollen-free area, sunglasses, or wearing a respiratory mask during activities that cannot be avoided such as mowing the grass. Indoor allergen symptoms may be reduced by combining interventions (42). For dust mite allergy, mattress covers, bedroom HEPA filters, frequent washing of linens, dehumidifiers, and removing carpet may reduce symptoms in a combined approach. Dust mite and cat allergen have

been consistently found in dust sampled from school and work environments (43), making avoidance more difficult. It takes months for the cat allergen levels to decrease after removing a cat from the home; however, some have advocated a pet-free bedroom albeit mixed evidence of efficacy (44). Removing allergenic pets that do not roam freely throughout homes, such as guinea pigs, seems to be effective in the author's experience.

Pharmacotherapy

Pharmacologic therapy is the mainstay treatment for the majority of allergic rhinitis patients. Billions of dollars are spent every year in the treatment of allergies.

Antihistamines have long been a mainstay in the treatment of allergic rhinitis. First-generation antihistamines such as diphenhydramine, clemastine, and chlorpheniramine are generally effective against sneezing, rhinorrhea, nasal itching, and eye symptoms, but are generally less effective on nasal congestion (45). First-generation antihistamines possess significant anticholinergic effects. While the anticholinergic action may help dry secretions, the sedation has been shown to impair school (46), driving (47), and cognitive performance (48). Second-generation antihistamines include cetirizine, levocetirizine, fexofenadine, loratadine, and desloratadine. Oral antihistamines have a quick onset, treat eye and nasal symptoms, and can be administered either daily or as needed. Given their poor efficacy in relieving nasal congestion, they are often combined with decongestants. They cause significantly less or no sedation and have little anticholinergic effect (45).

Intranasal antihistamines include azelastine and olopatadine. Benefits of intranasal antihistamines include a fast onset of action (49), some benefit in allergic and nonallergic rhinitis (50), and some improvement in nasal congestion (51). Intranasal antihistamines work better for allergic nasal symptoms than an oral antihistamine and there is not much benefit in nasal symptoms when oral and topical nasal antihistamines are combined (52). However, when intranasal antihistamines and intranasal corticosteroids are combined, there is an additive effect (53).

Intranasal corticosteroids (INCS) are the single most effective class of medications in the treatment of allergic rhinitis (54). There seems to be little difference in the clinical response between the available intranasal steroids in the United States (55). While nasal steroids can be beneficial when used intermittently (56), the maximal effect is usually seen in 7 to 10 days (57). When used at the recommended dose, INCS have shown to be relatively safe in both children (58) and adults. Studies with intranasal fluticasone propionate, mometasone furoate, and budesonide have indicated no effect on growth in children at recommended doses compared with placebo (58–60). One study indicated growth suppression when beclomethasone dipropionate was given for a year (60). Long-term studies of the effect of INCS on growth have not been published, so caution in children is warranted. Other complications reported with nasal steroids include epistaxis and nasal irritation, which may be exacerbated by the patient tilting the bottle toward their nasal septum during application. Nasal septal perforation is a rare complication. Systemic steroid effects are seen infrequently with INCS, but can occur.

Systemic steroids are effective at decreasing the inflammation from allergic rhinitis, but few studies have addressed their optimal role or dose. However, systemic steroids carry a significant complication profile. Other medications should be tried before using systemic steroids. For severe intermittent allergic rhinitis that is otherwise not well controlled, a short course of systemic steroids may be reasonable.

Leukotriene modifiers are effective for allergic rhinitis and control symptoms comparable to antihistamines (61). They have also been shown to have an added effect when combined with antihistamines similar to INCS (62). Monteleukast is currently the only leukotriene modifier in the United States that is FDA approved for the treatment of allergic rhinitis. There have been reported concerns with behavioral changes, depression, and suicidality with leukotriene modifiers (63). Leukotriene modifiers can be a good choice for patients who suffer from allergic rhinitis and asthma (64).

Cromolyn sodium is a mast cell stabilizer, decreasing the ability for mast cells to release proinflammatory mediators, including histamine. Cromolyn requires frequent dosing and has low efficacy. Ideally, cromolyn is optimally used just before allergen exposure for maximum effect. However, cromolyn has been shown to have an excellent safety profile (3).

Decongestants are most effective with nasal congestion. As such, they work well when combined with oral antihistamines. Side effects include hypertension and sleep disturbance. Decongestants seem to be best fit as an "as needed" medication for those patients with intermittent allergic rhinitis (3).

Selecting and combining allergy medication is based on frequency of use, needed onset of action, and which symptoms are targeted. Table 29.3 lists the relative benefits of the different classes of allergy medication.

Surgery

Inferior turbinate hypertrophy appears to be at least partially responsible for nasal congestion seen with allergic rhinitis. A recent study showed radiofrequency ablation of the inferior turbinate provided decreased nasal resistance and improved congestion when compared to intranasal mometasone spray (INCS) (65). A follow-up study showed that these results provide quality of life benefit at 5 years after turbinate reduction (66). Others have shown that allergic rhinitis patients refractory to medical therapy had improved symptoms at 1 year after radiofrequency turbinate reduction (67). This data underscores turbinate reduction playing a role in the treatment of allergic rhinitis in selected patients.

Other anatomic abnormalities can complicate allergic rhinitis. Surgically addressing nasal valve collapse, septal

TABLE 29.3 PHARMACOLOGIC OPTIONS FOR RHINITIS: EFFECTS ON SYMPTOMS

Medication	Strengths	Weaknesses
Oral antihistamines	Fast onset Sneezing, itching, rhinorrhea Ocular symptoms Safe	Nasal congestion Sedation with 1st Generation
Nasal antihistamines	Fast Onset Sneezing, itching, rhinorrhea Helps some with congestion Useful in Nonallergic rhinitis Safe	Taste Some sedation
Intranasal corticosteroids	Very effective for allergic rhinitis Nasal congestion, Sneezing, itching, rhinorrhea Useful in sinusitis	Nasal irritation Epistaxis Rare systemic steroid effects Slower onset
Leukotriene modifiers	Treats allergic rhinitis and asthma Lesser rhinitis efficacy	Behavioral changes Some require monitoring liver enzymes
Oral decongestants	Fast onset Nasal congestion, rhinorrhea	Sleep disturbance Hypertension
Mast cell stabilizers	Safety Few side effects	Frequent dosing Lesser efficacy
Topical anticholinergics	Watery rhinorrhea Helps with nonallergic rhinitis Helps in viral rhinitis	Nasal congestion Sneezing, itching

deviation, septal spurs, adenoid hypertrophy, nasal polyps, and chronic sinusitis may benefit the symptoms experienced by an allergic rhinitis patient. As surgical procedures are not thought to decrease allergic inflammation, it is appropriate to consider these procedures as adjuncts to other allergic therapy.

Immunotherapy

Immunotherapy, also known as allergy desensitization, promotes tolerance by regularly exposing a sensitized patient to the allergen(s) to which they are sensitized (68). Immunotherapy holds the most promise for patients to permanently decrease or eliminate their symptoms to an allergen. Immunotherapy can be given subcutaneously (shots), sublingually, intralymphatically (69), orally, or nasally. The two most common methods are subcutaneous immunotherapy (SCIT) and sublingual immunotherapy (SLIT), both of which are discussed in more detail below. Changes in T-helper cells and T-regulator cells that down-regulate inflammatory mediators is one proposed theory of how immunotherapy works, but a precise mechanism is not known.

Subcutaneous Immunotherapy

SCIT involves injecting allergens to which the patient is sensitized into the subcutaneous tissue. SCIT has been shown to be effective for allergic rhinitis in a Cochrane meta-analysis of placebo control single allergen trials (70). SCIT also decreases the development of new inhalant allergen sensitivities (71) and may decrease the incidence of developing allergic asthma in patients with allergic rhinitis (72). There are two phases of SCIT: escalation and maintenance. Escalation involves starting with a very dilute dose for safety, then gradually increasing the concentration of the allergen with each shot delivered once or twice weekly in most schedules. The concentration is escalated to an effective dose range. Maintenance therapy involves giving the same effective dose at regular intervals usually weekly to monthly. These intervals between shots are spaced out over time. The average patient continues the maintenance schedule for 3 to 5 years. Most patients can continue to see decreased allergic response even after stopping the scheduled shots. Occasionally, patients need to return to SCIT when allergic symptoms return (73).

Patients undergoing SCIT receive high levels of allergen. This poses the risk of anaphylaxis each time a shot is administered. Risk factors for either developing anaphylaxis or difficulty in managing anaphylaxis during allergen immunotherapy include poorly controlled asthma, escalation of the immunotherapy dose, prior episodes of anaphylaxis, and beta-blocker therapy (74,75). Offices giving SCIT must be prepared to handle anaphylaxis if allergy shots are administered. The time, expense, and anaphylactic risk indicate that immunotherapy should be reserved for patients with moderate to severe disease that is not well controlled with other measures (68).

Sublingual Immunotherapy

SLIT is performed by placing drops of allergen extract under the tongue. It is postulated that this method allows the allergen to be absorbed by the lymphatics draining the floor of mouth. Multiple studies using different techniques (spit or swallow), durations, frequencies, and doses have been published and meta-analysis has suggested effectiveness (76,77). Demonstrating efficacy in children has been inconsistent (78). Most studies have shown SLIT to be safe (77). However, some reports of systemic reactions have been presented, especially after the first dose (79). The combination of safety, efficacy, and convenience make SLIT a compelling option in the properly selected patient.

CONCLUSION

Allergic rhinitis is a common disease affecting patients who seek care from otolaryngologists and places a substantial burden on both quality of life and productivity. Otolaryngologists should develop an understanding of the diagnosis and treatment of allergic rhinitis. Although genetics plays a role in the disease, a simple Mendelian mode of inheritance is not seen. Allergic rhinitis is primarily a clinical diagnosis and allergy testing is complementary. Most individuals with allergic rhinitis are managed using a combination of environmental control, pharmacotherapy, and allergen immunotherapy. There may be a role for turbinate reduction in selected patients with allergic rhinitis refractory to other means of disease control.

HIGHLIGHTS

- Allergic rhinitis is a common disorder. Common symptoms include rhinorrhea, sneezing, and nasal congestion.
- The symptoms of allergic rhinitis impact quality of life, sleep, productivity, and school performance substantially.
- History of atopic dermatitis and food allergy in infancy and early childhood is a risk factor for allergic rhinitis and asthma later in life.
- Family history of allergy can help distinguish allergic rhinitis from other causes of nasal inflammation.
- The history of the patient's symptoms remains the primary tool for diagnosing allergic rhinitis.
- Allergic rhinitis and asthma are frequently concurrent. A patient with one should be considered for the other.
- Management options for allergic rhinitis include environmental control, pharmacotherapy, and immunotherapy.
- Turbinate reduction may be useful in selected patients with allergic rhinitis.

Nonallergic Rhinitis

30

Teresa V. Chan

Nonallergic rhinitis is a consortium of loosely related syndromes and diseases associated with symptoms of nasal inflammation in the absence of identifiable allergic triggers. Patients may present with varying degrees of nasal congestion, anterior or posterior rhinorrhea, sinus pressure, hyposmia, cognitive impairment, sleep disturbance, and fatigue. Sneezing and pruritus of the eyes, nose, or palate may also accompany these symptoms but less commonly than is seen with allergic rhinitis (1). Environmental irritants, medication side effects, autonomic dysfunction, autoimmune diseases, and hormonal influence are all potential etiologies.

Rhinitis is often divided into three main categories: allergic, nonallergic, and infectious. Nonallergic rhinitis can be further subdivided into idiopathic rhinitis (IR), nonallergic rhinitis with eosinophilia syndrome (NARES), autonomic rhinitis, work-related rhinitis, drug-induced rhinitis, hormonal rhinitis, atrophic rhinitis (AR), and systemic causes of rhinitis. This is largely a symptom-driven categorization as the underlying pathophysiology is multifaceted and incompletely understood.

Though it comprises a heterogeneous group, a few generalizations can be made about nonallergic rhinitis. It is more prevalent after age 20 (2,3). Overall, there is a slight female predominance (1,2). Patients tend to have a heightened sensitivity to irritants (2). Symptoms are typically perennial rather than seasonal, and nasal eosinophilia is present in 33% of patients (2).

EPIDEMIOLOGY AND SOCIAL IMPACT

Chronic rhinitis is one of the most common complaints in medical offices worldwide. While it is safe to say that everyone at some point in their lives has experienced symptoms of rhinitis, the true prevalence of chronic nonallergic rhinitis is not known and is difficult to study. The current classification system is in evolution. In its current state, it is imprecise and restricts a patient's disease process to a single designation. Mixed rhinitis (combined allergic and nonallergic rhinitis) is under recognized. It is more common than either pure allergic rhinitis or nonallergic rhinitis and occurs in approximately 44% to 87% of patients with allergic rhinitis (4,5).

There are also multiple biases in reporting. Firstly, patients with positive allergy testing results are assumed to have only allergic rhinitis, but as mentioned above, rhinitis in an individual patient may have multiple contributing factors. Secondly, patients who present with rhinitis symptoms and respond to a trial of empiric pharmacologic therapy are often presumptively given the default diagnosis of "allergic rhinitis" by their primary care providers without confirmatory testing. This empiric trial of pharmacotherapy is more cost-effective and efficient than allergy testing every patient with rhinitis symptoms but leads to problems when trying to quantify the prevalence of disease. Finally, most prevalence data are collected from physician reporting and retrospective data from the clinical offices of allergists and otorhinolaryngologists where specialty referral patterns may not represent the true prevalence of the general population.

According to extrapolation from population studies, the estimate for patients suffering from either pure nonallergic rhinitis or mixed rhinitis is 45 million persons in the United States (2,4). Twenty-five to thirty-three percent of patients presenting with rhinitis have nonallergic rhinitis (4,5).

The human cost of rhinitis is assessed in terms of symptoms, medication needs, interference with sleep, interference with activities of daily living, work impairment, absences from work and school, impaired learning efficiency, and interference with social activities. Comorbid conditions such as asthma, sleep apnea, sinusitis, and

otitis media contribute to the individual and societal burden of both nonallergic and allergic rhinitis. A recent study by Meltzer et al. compared sleep, productivity, and quality of life in subjects with allergic rhinitis, nonallergic rhinitis, and controls. Self-reported scores on all of these parameters indicate that allergic rhinitis and nonallergic patients perceive their symptoms to adversely impact sleep, quality of daily living, and productivity. Self-reported scores were significantly worse in allergic rhinitis patients (6).

PHYSIOLOGY

A brief review of relevant nasal physiology is discussed here. This is discussed in more detail in other chapters.

The functions of the nose and paranasal sinuses include filtration, conditioning, and humidification of inspired air; regulation of nasal airway resistance; and sensation of the environment through olfaction and general sensory nerves. A mucosa rich in blood vessels and secretory glands allows the relatively large surface area of the nose to adjust quickly to moment-to-moment changes in the environment. This rapid response can be easily appreciated when the paradoxical nasal vasculature expands with exposure to cold air and quickly produces nasal congestion and rhinorrhea in an attempt to warm and humidify the incoming air. Optimal nasal function depends on a working mucosa and a delicate balance between adrenergic, cholinergic, and sensory inputs. There is a marked α-adrenergic predominance in nasal blood vessels, so vasoconstriction generally prevails.

Norepinephrine and neuropeptide Y are the neurotransmitters responsible for regulation of sympathetic tone, which produces a vasoconstricted decongested state. The sympathetic nervous system has less control over the production of mucus than the parasympathetic system. The parasympathetic autonomic nervous system is largely responsible for rhinorrhea and congestion. Acetylcholine, vasoactive intestinal peptide, neuropeptide Y, nitric oxide, enkephalin, and somatostatin are the primary parasympathetic neurotransmitters. Sensory nerves from trigeminal nerve branches V_1 and V_2 can also regulate blood vessels in response to chemical and mechanical injury. Mucosal injury, inhalation of irritants, mast cell degranulation, substance P, and neurokinin A all cause nasal secretion and dilation of blood vessels. Nociceptive input also initiates systemic reflexes, such as the sneeze, and other autonomic reflexes.

The nose also performs the work of a sentry. It samples and traps particles entering the nares using the vibrissae and mucus. Cilia beat these trapped foreign particles at a rate of 3 to 35 mm/min to the natural sinus ostia and the pharynx. The nasal mucosal lining contains secretory IgA, proteins, and enzymes that help protect from infections. Disruption of any of these processes threatens to alter this delicate nasal homeostasis.

CLASSIFICATION

The term "nonallergic rhinitis" suffers from being too inclusive. For example, rhinitis of pregnancy and rhinitis symptoms related to Wegener granulomatosis both fall under the umbrella of nonallergic rhinitis but are clearly different disease processes. Only recently have we begun a concerted effort toward better classification and separation of these diseases through consensus definitions, deeper understanding of the pathophysiology of these diseases, and subcategorization by both pathophysiology and phenotype.

Classification of an individual patient's disease process is further complicated by the fact that many patients likely suffer from multiple underlying causes of rhinitis simultaneously. The prevalence of mixed rhinitis is likely underappreciated (2). Furthermore, there are, as of yet, no reliable biomarkers of disease or confirmatory tests like skin prick testing for allergic rhinitis. Differentiating between subcategories of nonallergic rhinitis, after allergic causes have been ruled out, relies largely on good history taking and exclusion of other potential diagnoses.

This chapter reviews the major subcategories of nonallergic rhinitis according to contemporary classification schemes and terminology.

IDIOPATHIC RHINITIS

IR is a diagnosis of exclusion but comprises roughly 60% of nonallergic rhinitis. Over the years, IR has been known by several terms, including noninfectious nonallergic rhinitis, nonallergic noninfective perennial rhinitis, perennial nonallergic rhinitis, intrinsic rhinitis, and vasomotor rhinitis. When allergy, mechanical obstruction, and infections have been excluded as the cause of rhinitis, a patient is given a diagnosis of nonallergic rhinitis. When occupational hazards, environmental irritations, hormonal contributions, nasal eosinophilia, medication effect, age-related changes, and autonomic disturbances have been ruled out, the remaining nonallergic diagnosis is IR. The fact that IR accounts for more than half of the constituency of nonallergic rhinitis reflects our incomplete understanding of the pathophysiology of rhinitis.

By definition, IR does not have a singular demonstrable etiology. Many theories continue to be investigated including: a chronic inflammatory state, an imbalance between sympathetic and parasympathetic input to the nasal mucosa, a nonadrenergic noncholinergic mechanism of stimulating nasal mucosa via peptides such as substance P and vasoactive intestinal peptide acting on sensory fibers, central nervous system sensory dysregulation, and nitric oxide synthase induction in vascular smooth muscle cells causing vasodilation (7). These are worth mentioning as currently outstanding theories. Likely it will be revealed that IR makes up a collection of heterogeneous diseases with equally heterogeneous pathophysiologies.

Patients presenting with IR will complain of refractory nasal congestion and rhinorrhea predominantly. Sneezing and pruritus are less common. Quantifying patient symptoms and impact of disease allow the physician to translate this constellation of symptoms into a treatable disease process. The workup reviewed here for IR applies to all of the following subcategories of nonallergic rhinitis.

The patient presenting with rhinitis symptoms should be asked not only how long the symptoms have been present but more specifically, "For how many hours per day are you affected by these symptoms." This will help to differentiate what is problematic disease from what may be a normal physiologic nasal reaction. A standardized daily record chart of symptom duration and intensity can be helpful for quantifying disease burden and is often discrepant from the verbal report at the first visit (7) (see Table 30.1). Impact of the symptoms on the individual and his/her daily activity is a crucial piece of information and can be ascertained with the simple question, "Which symptom is most bothersome to you?" Without this information, it is sometimes difficult to focus the treatment plan and measure improvement.

A thorough history should help the physician to rule out other causes of nonallergic rhinitis. Exacerbating and alleviating factors and where these factors occur (e.g., in the workplace) should be ascertained. It is important to clarify the patient's current and previous nasal regimens including what medications were/are being used, the frequency of use (i.e., compliance), what worked, and the reasons for cessation of the medication. Saline and over-the-counter medications are pertinent. Review of the patient's entire list of medications is also necessary to look for possible drug-induced rhinitis. Smoking history and other potential irritant exposures in the past 6 months should be sought. If the patient is a woman, recent and current pregnancy status should be asked.

TABLE 30.1 EXAMPLE OF A DAILY RECORD CHART FOR DEFINING NASAL SYMPTOMS IN IR PATIENTS

Daily Record Chart of Nasal Symptoms

Nasal blockage (not being able to breathe freely through the nose)	0—absent 1—between 0 and 1 h per half day 2—between 1 and 2 h per half day 3—more than 2 h per half day
Clear nasal discharge	0—absent 1—between 0 and 1 h per half day 2—between 1 and 2 h per half day 3—more than 2 h per half day
Sneezing	0—absent 1—<5 periods per half day 2—between 5–10 periods per half day 3—more than 10 periods per half day
Coughing	0—absent 1—<5 periods per half day 2—between 5–10 periods per half day 3 —more than 10 periods per half day
Green/Yellow mucus production	0—absent 1—present

From van Rijswijk JB, Blom HM, Fokkens WJ. Idiopathic rhinitis, the ongoing quest. *Allergy* 2005;60(12):1471–1481, modified and printed with permission.

Anterior rhinoscopy and nasal endoscopy should be performed to rule out structural contributions to the patient's complaints. A computerized tomography (CT) scan of the sinuses can be helpful to evaluate for evidence of chronic sinusitis or nasal masses not seen on exam; however, clinical suspicion should guide the pursuit of imaging studies. A CT scan is not required for the diagnosis of IR. Allergy testing either by skin prick or allergen-specific serum testing is important to rule in or out possible allergic rhinitis. In practice, however, an empiric trial of saline irrigations with either a topical antihistamine or topical steroid nasal spray is typically first initiated for 6 to 8 weeks. If symptoms persist, allergy testing should be pursued.

The cold dry air (CDA) provocation test may provide an additional objective test to differentiate between patients with IR and controls but is currently a research tool not yet in clinical use. Pulmonary CDA provocation of patients with asthma results in bronchial obstruction, and it has been found to be a suitable method for assessing bronchial hyperreactivity (8,9). Histamine and methacholine have been used to test nasal reactivity in allergic rhinitis patients. However, histamine could not differentiate controls and IR patients (10). Methacholine similarly could not differentiate IR patients with congestion as their primary complaint from control subjects (11). Braat et al. (12) demonstrated that IR patients had increased mucus production and nasal blockage in a dose-dependent manner to a standardized CDA challenge. CDA in their study proved less sensitive than histamine but more specific.

A wide variety of both pharmacologic and surgical therapies exist for symptom-directed treatment of IR. Azelastine is FDA approved for the treatment of nonallergic rhinitis. A recent randomized double-blind parallel-group multicenter trial showed efficacy of both available topical antihistamines (e.g., azelastine and olopatadine) for relief of nasal congestion, rhinorrhea, postnasal drip, and sneezing associated with IR (13). Two older placebo-controlled studies lend additional support to the use of intranasal antihistamines as first-line therapy for IR (14,15). Azelastine has been shown to have both antihistamine and anti-inflammatory effects *in vitro* and *in vivo* (16), which may explain its effectiveness in the treatment of both seasonal allergic rhinitis and nonallergic rhinitis (17). The most commonly reported side effect is taste disturbance.

Beclomethasone aqueous and fluticasone aqueous are FDA approved for the treatment of nonallergic rhinitis. It is reasonable to trial a topical nasal steroid alone or in conjunction with an intranasal antihistamine for treatment of IR. The combination of a nasal steroid with a topical antihistamine has not yet been shown to have added benefit

in IR though the combination has been shown to be beneficial in the treatment of patients with seasonal allergic rhinitis (18).

Ipratropium bromide aqueous is most effective for the rhinorrhea associated with nonallergic rhinitis and is a good pharmacologic option if this is the patient's primary complaint. It has also been shown to be effective at improving mood and quality of life scores in nonallergic rhinitis patients but was no better than placebo at relieving congestion, sneezing, or postnasal drip (19). The recommended starting dose is two sprays three to four times daily but once a therapeutic effect has been achieved, this can often be decreased to once or twice daily dosing.

Nasal saline spray or irrigation is often thought as an "active placebo" in clinical trials due to its reported effectiveness for nonallergic rhinitis patients. Saline irrigations have been shown in multiple studies and in a systematic Cochrane review to be well tolerated and beneficial in a majority of patients with rhinosinusitis (20). Daily isotonic nasal irrigations should be a component of the daily nasal regimen for any patient with IR.

Systemic antihistamines are a consideration if sneezing or pruritus is a major symptom, however, this is not as common with IR. Oral decongestants may be an adjunct for decongestion of a severely congested nose when starting topical therapies or for temporary symptom relief of episodic exacerbation of symptoms. Oral decongestant use should be limited in those with a history of hypertension or cardiac disease due to the potential to exacerbate these conditions. Topical decongestants play a very limited role in treatment of IR and patients should always be counseled to avoid these medications for any longer than 3 days at a time.

Capsaicin is a substance found in hot peppers that induces rhinorrhea and congestion when ingesting spicy foods. Nasal capsaicin provocation results in rhinorrhea, nasal blockage, and sneezing via stimulation of the unmyelinated sensory C fibers or pain receptors. Repeated intranasal applications of capsaicin in some individuals, however, lead to desensitization by prolonged stimulation of an ion channel receptor which is sensitive to physical and chemical nociceptive stimuli. This ion channel receptor, called Transient Receptor Potential Vanilloid type 1 or TRPV1, is found on epithelial cells, vascular endothelial cells, submucosal glands, and nerves in human nasal mucosa and is capable of regulating nasal secretion and congestion (21).

One recent randomized double-blind placebo-controlled trial demonstrates that capsaicin is effective for relief of symptoms in patients with IR without significant side effects or rebound (22). This supports the findings of several previous randomized trials (23,24). The onset of the relief occurred within 60 seconds and was present for at least 9 months without change in cellular mediators or neural tissue density (22,24). Capsaicin has not reliably shown this same benefit in allergic rhinitis patients (25,26).

Capsaicin spray is currently available under the brand name *Sinus Buster* in the United States. There is no current consensus regarding the dose and frequency of administration but all recent studies have demonstrated that less than 2 weeks of treatment is adequate for relief and can be repeated when symptoms recur (22–24). In one study, one spray given every 2 to 3 days over 2 weeks was found to be as efficacious as a single day treatment during which one spray was given each hour for 5 hours (24). From its initial studies, capsaicin seems to be an appealing potential option for treatment of IR. It has a quick onset of action, a short course of treatment, and aside from a slight burning sensation upon administration, has minimal reported side effects. However, larger clinical trials are needed before formal recommendations can be made regarding its safety and use intranasally. Caution should be used in patients with concomitant lung disease. Inhaled capsaicin is a well-documented stimulator of the cough reflex and severe, fatal asthma attacks have been reported with inhalation of capsaicin when used as an incapacitating agent (i.e., pepper spray) in asthmatics (27).

Surgical options for refractory symptoms of rhinitis include various methods of inferior turbinate reduction and vidian neurectomy. A myriad of approaches to turbinate reduction have been described including steroid injection, electrocautery, cryotherapy, coblation, laser reduction, microdebrider-assisted partial turbinectomy, complete inferior turbinectomy, and simple out-fracture (28). In general methods that are destructive or disruptive to mucociliary function such as complete turbinectomy and electrocautery should be avoided. Submucosal methods prevail over extramucosal approaches (29). Steroid injection into the turbinate can be temporarily effective but topical decongestion for 5 minutes prior to a slow steady injection is paramount as there are remote case reports of blindness after steroid injection. From a recent review of techniques, microdebrider-assisted partial turbinoplasty and holmium-YAG laser turbinate reduction demonstrated the most durable improvement in nasal patency lasting for at least 3 years (28,30–32).

Vidian neurectomy was introduced in the 1960s as a means of reducing severe rhinorrhea related to "vasomotor (autonomic) rhinitis" from presumed overstimulation of the parasympathetic system. This was initially described through a transantral approach to the pterygoid canal. Initial reports demonstrated lasting efficacy (33) but subsequent studies showed recurrence of symptoms in 71% of patients at 1 year postprocedure (34). Over the years, the original transantral approach to vidian neurectomy has evolved into an endoscopic approach that carries less surgical morbidity. A recent study showed long-term effectiveness of endoscopic vidian neurectomy at controlling rhinorrhea and nasal congestion up to 7 years (35).

The aim of the vidian neurectomy is to cut the efferent pathway of the parasympathetic reflex, which causes rhinorrhea from irritation of the nasal mucosa. Dry eye is a

common side effect of the procedure as there are preganglionic parasympathetic fibers from the greater superficial petrosal nerve which pass through the pterygoid canal as part of the vidian nerve to supply to lacrimal gland. However, in a recent study of the endoscopic approach most patients eventually recovered from xerophthalmia within months (35). This may be due to the fact the nerve was addressed with bipolar cautery or laser without removal of a segment of nerve as originally described.

Studies from Japan report a modification of vidian neurectomy that affords the same relief of rhinitis symptoms as vidian neurectomy with theoretically less risk of xerophthalmia (36–38). In the posterior nasal neurectomy technique, sensory and autonomic branches are ligated distal to the pterygoid canal just after exiting the sphenopalatine foramen as they travel alongside the sphenopalatine artery. Endoscopic vidian neurectomy and posterior nasal neurectomy are ultimate surgical options for patients with intractable rhinitis refractory to other management strategies.

NONALLERGIC RHINITIS WITH EOSINOPHILIA SYNDROME

NARES is a clinical syndrome in which symptoms such as sneezing, pruritus, and profuse watery rhinorrhea seem decidedly allergic, however, there is (a) an absence of demonstrable systemic atopy and (b) marked eosinophilia on nasal smear. Nasal smear must show greater than 20% eosinophils to be diagnostic. Nasal symptoms in patients with NARES are often more severe than in their allergic rhinitis counterparts (39) and anosmia is present more frequently (2).

NARES represents roughly 15% to 33% of adults with nonallergic rhinitis (39,40). There is an association of NARES with aspirin-exacerbated respiratory disease (AERD) and a number of these patients go on to experience aspirin sensitivity and polyposis in the future. Some reports have suggested that NARES is an early manifestation of AERD and the presence of eosinophilia should be interpreted as a marker for future aspirin intolerance and polyps (39).

The pathophysiology of NARES is not yet understood. Eosinophils and activated mast cells seem to play an important role. Eosinophils have been shown to release toxic substances such as major basic protein and eosinophilic cationic protein into the nasal mucosa (41). Physiologic studies on patients with nonallergic rhinitis have shown a correlation between eosinophilia and prolonged mucociliary clearance on saccharin clearance tests (42). Stasis from prolonged mucociliary clearance may set up a predilection for infection and further exacerbate the cycle of inflammation. Mast cells and chronic histamine release also appear to be relevant to this disease process though their roles have not been fully elucidated (41).

The symptoms of allergic rhinitis and NARES are quite similar yet these conditions are categorized separately solely based on results of systemic allergy testing. Interestingly, though nonallergic rhinitis patients test negative on systemic tests for allergy, nasal provocation challenge studies have been positive in 10% to 65% of nonallergic rhinitis patients (43–46). The concept of a localized allergic reaction in the nasal mucosa or "entopy" (as opposed to "atopy") was formally introduced by Powe et al. in 2003 and remains an area of debate and continued study (47,48).

Powe et al. proposed that on a cellular level the inflammatory reaction that occurs in the nasal mucosa in nonallergic rhinitis patients is akin to the systemic allergic reaction in atopic patients (47). This theory is further supported by the following:

1. Antigen-specific IgE antibodies are detectable in the nasal mucosa of some nonallergic rhinitis patients as well as allergic rhinitis patients but not normal controls (45,47).
2. A similar pattern of localized Th2-driven, IgE-mediated cellular infiltrate is seen in the nasal mucosa and secretions from allergic rhinitis and nonallergic rhinitis patients (49,50). Specifically mast cells, eosinophils, IgE-positive cells, and similar T-cell subpopulations are present in both subgroups (50). Released mediators from these cells such as eosinophilic basic protein and tryptase have been found in all studied forms of chronic nasal inflammation including allergic rhinitis, nonallergic rhinitis, and nasal polyposis (though in notably varying degrees) (41).
3. Nasal provocation studies are positive in the absence of systemic atopy as previously mentioned above (43–46).

Despite our reliance on skin and serum testing for detection of atopy, the association between systemic atopy and localized nasal symptoms is not well understood. In patients with a history suggestive of allergy with negative tests for systemic allergy, nasal smear and nasal provocation challenge testing should be performed to look for evidence of local nasal reactivity.

Intranasal corticosteroids are the mainstay of treatment for NARES and the presence of significant eosinophilia on nasal smear signals a favorable response to these medications (51). Oral steroids are more effective than topical steroids in alleviating the symptom of anosmia in NARES patients (52). Antihistamines in one study provided added benefit in conjunction with topical steroids (53). Presumably leukotriene antagonists would be effective given the association of NARES with AERD and polyposis; however, no randomized controlled studies to date have corroborated this (54). Immunotherapy similarly may be an effective choice for patients who test positive on nasal provocation challenges though this remains to be studied (54). In patients who test positive on nasal provocation, it is reasonable to counsel avoidance of provocative substances. More directed therapies will likely emerge as the pathophysiology of NARES is better understood. Anti-IgE and a monoclonal antibody to IL-5 are two areas of potential research in pharmacologic solutions (54).

WORK-RELATED RHINITIS (OCCUPATIONAL RHINITIS)

Work-related rhinitis or occupational rhinitis (OR) is nasal irritation and inflammation due to workplace exposures. In addition to primary nasal symptoms, ocular irritation, ocular pruritus, and cough are common symptoms of OR. Over the past 10 to 15 years, renewed research in this area has revealed that classification and confirmation of this diagnosis is more complex than previously appreciated and there is currently no accepted consensus definition of OR. The 2008 position paper from the European Academy of Allergy and Clinical Immunology (EAACI) Task Force on OR proposes this definition: "OR is an inflammatory disease of the nose, which is characterized by intermittent or persistent symptoms (i.e., nasal congestion, sneezing, rhinorrhea, itching), and/or variable nasal airflow limitation and/or hypersecretion due to causes and conditions attributable to a particular work environment and not to stimuli encountered outside the workplace" (55).

The prevalence of work-related rhinitis has not been well established as this number is largely dependent on the criteria used to define the disease. OR is not an uncommon disease and likely occurs more frequently than is currently appreciated. OR is a part of a continuum of airway disease brought on in the workplace and is known to be two to four times more common than occupational asthma (56–58). Development of occupation rhinitis may be a herald sign of development of lower airway symptoms in 2 to 5 years (56–58).

Causes of rhinitis in the workplace can be either allergic, irritative, or a combination of both. Agents that cause OR are divided into high molecular weight compounds (HMWCs) and low molecular weight compounds (LMWCs). HMWCs can be thought of as plant- or animal-derived proteins. For almost all of these HMWCs an IgE-mediated mechanism has been proven causative of OR (58). Examples of HMWCs include animal dander, latex, grain dust, flour, dust mites, and biologic enzymes (see Table 30.2 for a listing of HMWC and LMWC). LMWCs are typically too small to be immunogenic on their own. They must be coupled with a protein as a hapten–protein complex in order to elicit an IgE-mediated hypersensitivity response. For this reason it is often difficult to isolate LMWC for skin and serum IgE-mediated allergy testing. The few LMWCs that have demonstrated IgE-mediated OR include platinum salts, acid anhydrides, and reactive dyes. Aerosolized agents such as tobacco smoke, perfumes, air fresheners, and solvents are examples of irritative causes of OR.

According to data from the Finnish Register of Occupational Diseases from 1986 to 1991, patients in the following fields have a higher risk for developing OR: fur

TABLE 30.2 PREVALENCE AND ETIOLOGIC AGENTS IN OR

Agents	Occupation	Prevalence (%)
High molecular weight agents		
Laboratory animals	Laboratory workers	6–33
Other animal-derived allergens	Swine confinement workers	8–23
Insects and mites	Laboratory workers, farm workers	2–60
Grain dust	Grain elevators	28–64
Flour	Bakers	18–29
Latex	Hospital workers, textile factory workers	9–20
Other plant allergens	Tobacco, carpet, hot pepper, tea, coffee, cocoa, dried fruit, and saffron workers	5–36
Biologic enzymes	Pharmaceutical and detergent industries workers	3–87
Fish and seafood proteins	Trout, prawn, shrimp, crab and clam workers, aquarists and fish-food factory workers	5–24
Low molecular weight agents		
Diisocyanates	Painters, urethane mould workers	36–42
Anhydrides	Epoxy resin production, chemical workers, electrical condensers workers	10–48
Wood dust	Carpentry and furniture making workers	16–36
Metals (platinum)	Platinum refinery workers	43
Drugs (psyllium, spiramycin, piperacillin)	Health care and pharmaceutical workers	9–41
Chemicals	Reactive dye, synthetic fiber, cotton, persulfate, hairdressing, pulp and papers, shoe manufacturing workers	3–30

From EAACI Task Force on Occupational Rhinitis; Moscato G, Vandenplas O, Gerth Van Wijk R, et al. Occupational rhinitis. *Allergy* 2008;63: 969–980, printed with permission.

industry workers; bakers; livestock breeders; food-processing workers; veterinarians; farmers; assemblers of electrical, electronic, and telecommunication products; and boat builders (57). A separate population-based study in Sweden found that workers whose employment involved exposure to wood dust, textile dust, fire fumes, quick-drying glues, paint hardeners, or paper dust were at increased risk for developing rhinitis (59).

Patients with OR often have a coexisting history of atopy which predisposes them to additional nasal mucosal inflammation from agents encountered in the workplace. This phenomenon was illustrated by Shusterman et al. (60) in a study which challenged allergic rhinitis patients and nonallergic patients with inhaled intranasal chlorine. He found that patients with preexisting allergic rhinitis were more prone to non-mast-cell-mediated nasal inflammation measured by acoustic rhinometry. In a related positive control study, rye-grass provocation caused the seasonal allergic rhinitis patients to develop both objective nasal inflammation and mast cell degranulation. The relationship of cigarette smoking and risk for developing OR, interestingly, is still unclear; results from various studies have been contradictory.

The diagnosis of OR requires both (a) documentation of rhinitis and (b) causation by a workplace exposure. Documentation of rhinitis is accomplished by a careful medical history, occupational history, and exam. Medical history should include preexisting nasal symptoms, onset of symptoms, exacerbation and relief of symptoms in and out of the workplace, severity of symptoms, and impact of symptoms on work productivity, and the individual's well-being. Pertinent occupational history includes: duration of employment (latency) prior to onset of symptoms, length and frequency of exposure to potential rhinitis triggers or other irritant exposures. The nasal exam can be accomplished with anterior rhinoscopy and nasal endoscopy but findings are typically consistent with nonspecific mucosal irritation or inflammation. The nasal exam can be helpful in ruling out additional causes of the patient's nasal symptoms such as deviated nasal septum or nasal polyposis.

There are two main options for establishing causation by a workplace exposure. The first is immunologic testing either by skin-prick testing or by serum allergen-specific IgE antibodies. Immunologic testing is widely available and likely adequate for confirmation of suspected allergic reactions due to HMWCs. However, immunologic testing has limitations in evaluation of OR caused by LMWCs. Commercially available, standardized extracts of these LMWCs are not readily available. LMWCs are also prone to a high false-positive rate in skin testing due to nonspecific interactions with histamine (61).

Nasal provocation challenge remains the standard of care for establishing a diagnosis of OR. This can be conducted in the office or in the natural setting of the workplace. It can be used to confirm both IgE-mediated and non-IgE–mediated OR. Reproduction of nasal symptoms has been used as acceptable proof for diagnosis of OR but increasingly physiologic measurements like rhinomanometry, acoustic rhinometry, and peak nasal inspiratory flow are being utilized for objective documentation of nasal patency before and after provocation (62,63). These physiologic measurements do not have interindividual consistency and data obtained from these measurements cannot be compared between individuals or to standardized norms. Nasal lavage and volume of mucus production have been used in some studies as measures of inflammation but similarly there are no standardized norms for comparison (64,65).

There are three primary tenets to treatment of the individual with OR (a) limit the impact of disease on the individual's well-being, (b) limit untoward effects on work productivity, and (c) prevent additional adverse health sequelae (e.g., occupational asthma) from continued occupational exposure. Avoidance of causative exposures is the first line of defense in OR. When complete avoidance of one's workplace or specific work-related tasks is not possible, limited exposure with medications for symptom control is acceptable. Treatment with saline irrigations, steroid nasal sprays, decongestants, and antihistamines is guided by similar principles as in allergic rhinitis. Immunotherapy has a role if specific allergic triggers have been identified and avoidance and pharmacotherapy are not sufficient.

Though OR shares many similarities with other causes of rhinitis, one major difference is the ability to effect change on a system-wide scale. Whereas all other forms of rhinitis focus on the individual, OR provides the opportunity to identify a potential organizational problem and effect change for the entire system. Diagnosis of the affected patient can be likened to a sentinel event. This initial diagnosis should ideally prompt internal analysis and system-wide action to limit future workplace morbidity.

DRUG-INDUCED RHINITIS

Drug-induced rhinitis is divided into three categories (a) neurogenic, (b) inflammatory, and (c) idiopathic. There are a number of medications that list rhinitis in their side-effect profiles. The most widely used and notable of these are antihypertensive medications, erectile dysfunction medications, and some psychiatric medications. Topical decongestants, when overused, notoriously lead to rhinitis medicamentosa by a different mechanism. (A list of common rhinitis-inducing medications and their mechanisms of action can be found on Table 30.3. A list of common topical agents, which can cause rhinitis medicamentosa is found in Table 30.4.)

Systemic anti-hypertensive medications are examples of drugs that cause rhinitis through neurogenic mechanisms. They tip the balance between sympathetic and parasympathetic regulation of the nasal mucosa toward parasympathetic dominance through direct or indirect inhibition of

TABLE 30.3 SYSTEMIC MEDICATIONS ASSOCIATED WITH RHINITIS

Drug or Drug Class	Examples	Mechanism of Action
Neurogenic		
Beta-blockers (antihypertensive)	Atenolol Propanolol Pindolol Carvedilol	Blocks EPI and NE-mediated stimulation of the sympathetic nervous system
Alpha-adrenergic antagonists (antihypertensive, BPH)	Phenoxybenzamine Phentolamine Prazosin Doxazosin Tamsulosin Yohimbine	Blocks EPI and NE-mediated stimulation of the sympathetic nervous system
Hydralazine (antihypertensive)	Apresoline (brand name)	Increases GMP levels, decreasing the action of the IP_3, limiting calcium release in the smooth muscle resulting in vessel relaxation. Dilates arterioles more than that of veins
Guanethidine (antihypertensive)	Ismelin (brand name)	Inhibits NE release from sympathetic nerve ending; gradually depletes NE stores in the nerve ending
Reserpine (antipsychotic/ antihypertensive)	Serpasil (brand name)	Blocks the vesicular monoamine transporter which normally transports free NE, 5-HT, and DA from the cytoplasm of the presynaptic nerve terminal into storage vesicles for subsequent release at synaptic cleft
Methyldopa (Alpha-adrenergic agonist antihypertensive)	Aldomet	Two mechanisms: (a) Competitively inhibits the enzyme DOPA decarboxylase, which converts L-DOPA into DA. DA is a precursor for NE and subsequently EPI (b) Its metabolite, α-methylnorepinephrine, is stored in neurosecretory vesicles in place of NE and is a potent $\alpha 2$ agonist causing negative feedback on NE release
Tricyclic antidepressants	Amitriptyline	Binds NE reuptake receptors on the presynaptic side to keep NE circulating, but also depletes NE stores over time
Some antipsychotics (typical and atypical)	Thioridazine Chlorpromazine Perphenazine Risperidone	Blocks central adrenergic receptors, blocks DA-blocking, and has minor anticholinergic activity. DA is the precursor for NE. Rhinitis listed as a minor side effect, possibly worse with newer antipsychotics
Clonidine (antihypertensive/pain control/antistimulant)	Catapres	Alpha 2 agonist, inhibits NE release, functions primarily in the CNS but has peripheral effects
Phosphodiesterase type-5 inhibitors (erectile dysfunction)	Sildenafil Vardenafil Tadalafil	Inhibits enzyme PDE5 which breaks down of cGMP in smooth muscle cells. Increased cGMP causes relaxation of smooth muscle and vasodilation
Inflammatory		
Aspirin and COX-1 inhibiting nonsteroidal anti-inflammatory (anti-inflammatory)	Aspirin Ibuprofen	Exacerbates excessive production of leukotrienes and prostaglandins due to anomaly in the arachidonic acid cascade
Angiotensin-converting enzyme inhibitors (antihypertensive)	Enalapril Lisinopril	(Proposed) Decreases angiotensin II, increases bradykinin resulting in reduced vasoconstriction and increased vasodilation
Idiopathic		
Hypnotic + Benzodiazepine	Chlordiazepoxide	Unknown
Nonbenzodiazepine, nonbarbiturate hypnosedative	Zolpidem tartrate, zaleplon	Not well understood but reported. Acts on central GABA receptors
Amiloride(potassium sparing diuretic)	Midamor (Brand name)	Partial effect of drug is inhibition of cGMP-gated ion channels
Apomorphine	Apokyn (Brand name) (Injectable dopamine)	Nonselective DA agonist used in the treatment of Parkinson disease and erectile dysfunction

Key: NE, norepinephrine; EPI, epinephrine; 5-HT, serotonin; DA, dopamine; IP_3, inositol triphosphate; cGMP, cyclic guanosine monophosphate; GABA, Gamma-Aminobutyric acid.

TABLE 30.4 TOPICAL MEDICATIONS THAT CAN CAUSE RHINITIS MEDICAMENTOSA

Topical Agent	Alias
Imidazolines	
Oxymetazoline	Afrin
Xylometazoline	Otrivin
Naphazoline	Clear eyes
	Naphcon eye drops
Sympathomimetics	
Ephedrine	Ma-Huang
Levomethamphetamine	Vicks Vapor Inhaler
Phenylephrine	Neosynephrine
Tramazoline	(Not available in US)
Amphetamine	Benzedrine
Cocaine	Coke[a]

[a]An exhaustive list of aliases for cocaine is beyond the scope of this table.

norepinephrine. Many antipsychotics and antidepressants similarly alter the availability of norepinephrine by their interference with norepinephrine and dopamine reuptake pathways at the synaptic cleft. Treatment in the case of neurogenic rhinitis consists of identification of the offending medication and substitution with alternatives if possible.

Some of the rhinologic effects of psychiatric medications such as hypnosedatives (e.g., zolpidem) are less well understood. These act centrally on gamma-aminobutyric acid (GABA) receptors yet have effects in the peripheral nasal mucosa. These are examples of idiopathic drug-induced rhinitis.

Aspirin Exacerbated Respiratory Disease

Aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs) can exacerbate an inflammatory rhinitis in a susceptible subset of the population with altered arachidonic acid metabolism. This rhinitis is a part of a larger constellation of symptoms collectively recognized as AERD. Though AERD is colloquially referred to as *Samter's triad*, it is in fact a tetrad consisting of (a) sensitivity to aspirin and other cyclooxygenase isoenzyme 1 (COX-1) inhibiting nonsteroidal anti-inflammatory medications, (b) asthma, (c) nasal polyposis, and (d) chronic eosinophilic rhinosinusitis. The underlying medication sensitivity is sometimes referred to as an "aspirin allergy"; however, this is incorrect as no IgE-mediated allergic mechanism is responsible. The most accurate description of AERD is a *nonallergic hypersensitivity reaction* (66).

AERD occurs most commonly in early adulthood between 20 and 40 years old with a 3:2 female to male predilection (67). It affects roughly 1% of the general population (68), but the prevalence rises to 21% in asthmatics (69). In asthmatics with nasal polyposis, up to 30% to 40% are affected (70).

Symptoms of rhinitis often precede the onset of asthma (71). Some patients will present with a self-recognized history of aspirin or NSAID-induced asthma attack or worsening of rhinitis symptoms after using these medications. Onset of upper or lower airway symptoms typically occurs within 90 minutes of ingestion of the COX-1 inhibiting medication. It is important to note that ingestion of aspirin or NSAIDs does not initiate the disease, but can exacerbate symptoms once the disease process is underway (72).

Diffuse nasal polyps filling the nasal cavity and quick recurrence of polyps after surgical resection are hallmarks of AERD. A CT scan of the sinuses often shows pansinusitis with near-total opacification of the sinuses. There may be lateral bowing of the lateral walls of the nasal cavity or bony thinning of the intersinus septa from the mass-effect of polyps on the confined space of the nasal cavity. Polyps contribute to the severe nasal congestion, anosmia, and sleep disturbance often seen in these patients (73).

The pathophysiology of this disease is well studied but only partially understood. An underlying anomaly in arachidonic acid metabolism leads to overproduction of eicosanoids, namely leukotrienes and prostaglandins (74–76). Eicosanoids are lipid-based local signaling molecules that function much as neurotransmitters do to activate membrane-bound G-proteins and induce signal transduction and cellular responses. However, because they are lipid-based they cannot be stored in vesicles like neurotransmitters and are instead produced on demand.

Both leukotrienes and prostaglandins are proinflammatory. They work via receptors on target cells to contract bronchial and vascular smooth muscle; increase permeability of blood vessels; enhance secretion of mucus in the airway and gut; and recruit leukocytes such as mast cells, eosinophils, and neutrophils to sites of inflammation. Leukotrienes LTC4, LTD4, and LTE4 make up the slow-reacting substance of anaphylaxis. Compared to histamine, this mixture of leukotrienes is more potent and has a slower onset but longer duration of action.

In addition to increased production of leukotrienes, upregulation of leukotriene receptors have been demonstrated in the respiratory mucosa of AERD patients (77). Proinflammatory cytokines IL-2, IL-3, IL-4, IL-5, IL-13, GM-CSF, and eotaxin are also present and facilitate the production, recruitment, and longevity of eosinophils and mast cells (78–81). Biopsy of the upper and lower respiratory mucosa of AERD patients demonstrates this abundance of eosinophils and activated mast cells (82,83).

The eosinophils release toxic substances such as eosinophilic cationic protein, major basic protein, eosinophil-derived neurotoxin, and eosinophil peroxidase furthering the cycle of tissue damage and inflammation (72). Mast cells release preformed mediators such as histamine and tryptase; synthesize prostaglandins and leukotrienes; and participate in bronchoconstriction, vasodilation, and ongoing chemotaxis of eosinophils (72). What is not known is what triggers this cascade of inflammation and how to specifically

interpret this data in patients with AERD given the fact that some aspirin-tolerant patients with polyps or asthma have shown activation of the exact same proinflammatory leukocytes and mediators, albeit to a lesser degree.

This underlying overproduction of leukotrienes and prostaglandins is exacerbated by the ingestion of COX-1 inhibiting medications. Inhibition of COX-1 shifts arachidonic acid metabolism toward leukotriene production. Specifically diminished COX-1 leads to decreased production of prostaglandin E2 (PGE2), an anti-inflammatory mediator and inhibitor of leukotriene production. Less PGE2 also translates into decreased mast cell stability and release of histamine and tryptase. This manifests clinically as varying degrees of rhinitis, conjunctivitis, laryngospasm, and bronchospasm.

Not all cyclooxygenase inhibiting medications exacerbate respiratory disease by this mechanism. Multiple separate studies have shown that selective COX-2 inhibiting medications (e.g., celecoxib/Celebrex) do not worsen airway symptoms in AERD patients (84–86). Separate studies also demonstrated that AERD patients can tolerate partial COX-2 inhibitors (e.g., meloxicam/Mobic), which have some COX-1 activity at high doses and the poor COX-1 inhibitors such as acetaminophen in low doses (87–92) (see Table 30.5). However, caution is still advised when prescribing *any* COX-2 inhibiting medications to a patient with confirmed AERD. Rare case reports of severe adverse reactions with selective COX-2 and partial COX-2 inhibitor medications do exist and continue to arise (93). The first reaction is typically the most severe and if a COX-2 inhibiting medication is medically necessary for an individual patient, it would be prudent to trial this first in the office under medical observation.

The prevalence of AERD is both overestimated and underestimated by self-reported patient history alone (94). Currently there is no reliable *in vitro* test for aspirin/NSAID hypersensitivity and aspirin challenge remains the gold standard for diagnosing AERD. There are four routes available for provocation challenges: oral, bronchial inhalation, nasal inhalation, and intravenous. In the United States, oral aspirin challenges are performed. According to one study, 45 or 60 mg of aspirin was the typical provoking dose for naso-ocular and bronchial reactions in patients undergoing oral aspirin challenge (95).

Treatment for AERD falls into two categories—emergency management of acute exacerbations and long-term control. Acute respiratory reactions caused by accidental aspirin or NSAID ingestion are treated with inhaled β-agonists, systemic antihistamines, and systemic corticosteroids. Management follows the principles and protocols for acute airway management, which can be found in other chapters. If hypotension, urticaria, or other signs of systemic

Universally elicit reactions in AERD patients	Reactions occur with higher doses of these NSAIDs	No reactions occur in multiple controlled studies; however, case reports of severe reactions still exist

histamine release are present, intramuscular epinephrine should be given. For ocular or nasal reactions only, oral antihistamines may be sufficient. The patient should be observed for several hours as aspirin-induced reactions can last for several hours.

Multimodality therapy is required for the long-term management of AERD. Daily leukotriene inhibitors, intranasal steroids, and saline along with avoidance of aspirin and other NSAIDs are the foundations of medical treatment. Patients with simultaneous allergic rhinitis should be identified and treated accordingly. Treatment of lower airway disease should be managed in conjunction with a pulmonologist. Endoscopic sinus surgery is a necessary adjunct and follows principles of sinus surgery found in other dedicated chapters. Patients should be counseled regarding the recurrent and recalcitrant nature of their disease and forewarned of the potential need for multiple sinus surgeries.

Aspirin desensitization can be considered in anyone with respiratory symptoms of confirmed AERD. Those who would benefit most include (a) patients with refractory airway symptoms despite daily compliance with intranasal steroids and leukotriene inhibitors, (b) those who require aspirin or other NSAIDs for antiplatelet activity long-term (e.g., cardiac stent patients), (c) those whose polyposis is so severe as to require frequent sinus surgeries, or (d) those who require unacceptably high doses of systemic steroids to control symptoms. Aspirin desensitization is very effective for airway symptoms associated with AERD but not as reliable for cutaneous manifestations of aspirin sensitivity.

The most commonly used aspirin desensitization protocol was devised by physicians at Scripps Clinic and Research Institute. This consists of an oral ingestion of aspirin starting in the early morning at 30 mg and proceeding at 3-hour intervals through 45, 60, 100, 150, and 325 mg up to a final dose of 650 mg over a 2- or 3-day period. Doses are repeated if a naso-ocular or bronchial reaction occurs (95,96). Pulmonary function and symptoms are followed with each dose escalation. After desensitization, patients are maintained on 325 to 650 mg twice daily indefinitely. Multiple permutations on this protocol exist regarding dosage and timing of escalation (97). Data suggests that this is a safe protocol when performed in an experienced clinic with long-term improvement in symptoms and reduction of medication use over 5 years (98).

Rhinitis Medicamentosa

Rhinitis medicamentosa is a special category of drug-induced rhinitis that occurs by a different mechanism than the drug-induced rhinitis described above. Overuse of topical nasal vasoconstrictors induces a rapid tolerance, or tachyphylaxis, with a severe rebound rhinitis. These rebound symptoms encourage an on-going dependence on the offending agent. Topical nasal decongestants containing oxymetazoline hydrochloride and phenylephrine hydrochloride are by far the most popular culprits. Similar rebound rhinitis can also be caused by use of cocaine topically in the nose.

The primary complaint is of severe nasal congestion. There is usually a paucity of actual rhinorrhea though there is the sensation of rhinorrhea and chronic sniffling. Pruritus and sneezing are notably absent. On exam, the nasal mucosa is typically described as edematous, "beefy red," and dry. These findings are by no means pathognomonic or specific for rhinitis medicamentosa but are noted in contrast to the bland, nonspecific exam findings seen in other cases of drug-induced rhinitis. There is a poor response to application of topical decongestants in the office.

Oxymetazoline and phenylephrine are categorized as imidazole derivatives and sympathomimetic amines, respectively. Their mechanism of action is α- and β-adrenergic stimulation of the sympathetic nervous system. In the nasal mucosa, the predominant adrenergic receptor is the α_1 receptor. This is located on the smooth muscle and stimulation causes release of norepinephrine and vasoconstriction. The α_2 receptor is located on the presynaptic neuron and induces negative feedback on the release of norepinephrine (see Fig. 30.1). There is also a less pronounced but possibly longer lasting β-adrenergic effect of the sympathomimetic amines, which leads to smooth muscle relaxation in the airway mucosa.

Tachyphylaxis has been proposed to occur by many mechanisms including (99):

1. Exhaustion of the presynaptic supplies of norepinephrine from continued stimulation.
2. Decease in sensitivity and number of the α_1 receptors on the postsynaptic side due to the inhibitory effects of α_2 receptor on the presynaptic neuron.
3. Prolonged β-adrenergic vasodilation outlasting the α-adrenergic effects.

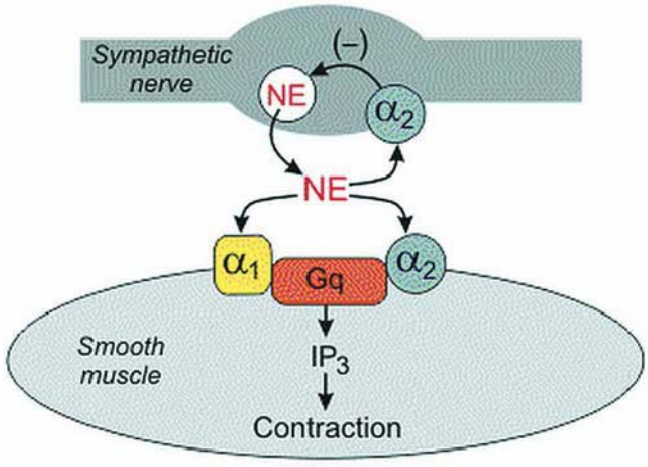

Figure 30.1 Mechanism and feedback of α-adrenergic receptors.

4. Tissue hypoxia from prolonged vasoconstriction leading to eventual rebound vasodilation either from vascular fatigue or need to resupply nutrients to these hypoxic tissues.
5. Increased parasympathetic tone leading to vascular permeability and increased edema.

None of these theories has been proven definitively. Histologically, the changes seen in rhinitis medicamentosa include nasociliary loss, squamous cell metaplasia, epithelial cell denudation, increased intercellular widening, increased vascularity, fibrosis, edema of the epithelial cell layer, goblet cell hyperplasia, increased expression of the epidermal growth factor receptor, and inflammatory cell infiltration (100).

Topical nasal decongestants can be found under common trade names such as Afrin, Neosynephrine, and Sinex but there are a myriad of other brand names on pharmacy shelves. The best way to elicit a salient history is to ask directly, "What over-counter nasal sprays are you using and how often?" At times, patients will not list these nonprescribed medications and will not offer up this portion of the history unless specifically asked. Patients who have been using these medications chronically often develop a psychological as well as physiologic dependence on these medications and need first to be educated about the hazards of prolonged topical decongestant use.

Treatment of rhinitis medicamentosa is directed at cessation of the offending agent, replacement with more therapeutic pharmacologic options, and identifying possible underlying causes of rhinitis. Patients should be weaned quickly off these medications within a matter of days and may be helped by replacement with nasal saline sprays and topical nasal steroids. Consideration must be given to the fact that a disease process often underlies the initiation and chronic use of these medications. It is important to investigate other medical causes of rhinitis such as allergic rhinitis, nasal polyposis, or deviated nasal septum and treat these accordingly. Patients should be counseled to be off topical decongestants for at least 1 to 2 months prior to any endonasal surgery.

There are instances when the short-term use of topical decongestants is warranted. For instance, if a patient's turbinate congestion is so severe as to preclude application of other topical therapies, a short course of topical decongestants serves as a necessary adjunct. Patients who are advised to use these medications acutely must always be counseled against prolonged use longer than 3 days at a time. Patients with poorly controlled hypertension or a cardiac history should be given topical and oral decongestants cautiously due to potential to exacerbate these conditions.

HORMONE-INDUCED RHINITIS

Nasal congestion is thought to occur secondary to elevated estrogen and progesterone levels. This is a well-recognized phenomenon in pregnancy; however, it is less clear whether this occurs in other states of endogenous or exogenous hormone excess. There is some evidence to suggest increased nasal congestion occurs during the preovulatory peak of estrogen during menses (101–104). However, studies have failed to show a consistent correlation between sources of exogenous female hormones (e.g., modern lower-dose oral contraceptives, hormone replacement therapy, or fertility treatment) and rhinitis (105–107). This may be because current doses of estrogen in oral contraceptives and hormone replacement therapy are quite low (50 to 300 units pmol/L) compared to pregnancy (70 to 150,000 units pmol/L).

About one-third of pregnant women have symptomatic nasal congestion during pregnancy defined by Ellegård and Karlsson as "a nasal congestion present in the last 6 or more weeks of pregnancy without other signs of respiratory tract infection and with no known allergic cause, disappearing completely within 2 weeks after delivery" (108,109). Up to 65% of women self-report nasal congestion at some time during their pregnancy (110). This typically becomes more pronounced in the second trimester of pregnancy and abates soon after delivery. It is more common in multiparous women compared to nulliparous women and is not influenced by age, smoking habits, or body mass index (110).

Though an association between pregnancy and rhinitis seems to exist, the mechanism of hormone-influenced rhinitis is still under debate. Clearly hormone-induced rhinitis is not just a dose–response phenomenon. It appears that either a cyclical pattern of hormone delivery or slowly increasing plasma levels is required to elicit a nasal mucosal effect (111). The decrease in estrogen and progesterone after delivery is known to correlate well with the rapid resolution of rhinitis symptoms after delivery. However, studies to date have failed to show consistent difference in levels of estrogen and progesterone between symptomatic pregnant women and asymptomatic pregnant women or even nonpregnant women (111). Similarly equivocal results have come out of histologic and physiologic studies comparing these groups of women.

Treatment is focused on a balance between symptom relief for the mother and consideration for the developing fetus. Medications are safety rated for use in pregnancy based on animal and human studies. Only Category D and Category X are based on existing human studies that have demonstrated harm to the fetus. Categories B and C are based on extrapolation from animal reproduction studies only without clear evidence from human studies. The FDA requires a relatively large amount of high-quality data on a pharmaceutical for it to be defined as Pregnancy Category A.

Saline irrigations are very effective for rhinitis of pregnancy and should be the first-line agent before trying pharmaceuticals. Nasal cromolyn sodium is a Category B medication, which is effective for symptoms of

rhinorrhea, sneezing, and itching. The first- and second-generation oral antihistamines are listed as Category B except for fenofexadine and desloratadine, which are designated as Category C. Ipratropium bromide is Category B but it is typically more effective for rhinorrhea and less so for the primary complaint of congestion. Nasal steroids are all Category C except budesonide aqua, which was recently upgraded to Category B. Intranasal antihistamines, oral decongestants, and intranasal decongestants are all considered Category C and should be used sparingly as second-line therapies if symptoms are severe and unresponsive to other agents. Leukotriene inhibitors are Category B and have been proven to be well-tolerated in pregnancy without major malformations to the developing fetus (112). However, the effectiveness of leukotriene inhibitors in the rhinitis of pregnancy has not been specifically studied and would largely depend on the underlying pathophysiology of rhinitis of pregnancy (see Table 30.6 for a listing of pregnancy safety classification of common medications used in the treatment of rhinitis). In pregnant patients for whom a component of allergic rhinitis contributes to their symptoms during pregnancy, maintenance subcutaneous immunotherapy may continue if it is providing benefit without causing systemic reactions but injections should not be started or escalated (113).

Hypothyroidism is an infrequent cause of rhinitis symptoms. If not previously diagnosed, a thorough review of systems should elicit positive responses such as fatigue, cold intolerance, nonvolitional weight gain, brittle hair, and skin changes, which would prompt initial laboratory testing with TSH and T4 levels. Replacement with exogenous thyroid hormone relieves symptoms of rhinitis caused by hypothyroidism (114).

TABLE 30.6 SAFETY IN PREGNANCY OF MEDICATIONS COMMONLY USED TO TREAT RHINITIS

Medication Class	Pregnancy Class B	Pregnancy Class C
Systemic antihistamines, first generation	Chlorpheniramine (Chlortrimeton) Clemastine (Tavist) Dimenhydrinate[a] (Dramamine) Diphenhydramine (Benadryl) Hydroxyzine (Vistaril)	Pheniramine (Avil) Promethazine [a](Phenergan)
Systemic antihistamines, second generation	Cetirizine (Zyrtec) Levocetirizine (Xyzal) Loratadine (Claritin)	Desloratidine (Clarinex) Fenofexidine (Allegra)
Systemic decongestants		Phenylephrine Pseudoephedrine
Leukotriene inhibitors	Montelekast (Singulair) Zafirlukast (Accolate)	
Nasal anticholinergics	Ipratropium bromide (Atrovent)	
Nasal antihistamines		Azelastine (Astelin, Astepro) Olopatadine (Pataday)
Nasal decongestants		Oxymetazoline (Afrin) Phenylephrine (Neosyneprhine) Xylometazoline (Otrivin)
Nasal Mast Cell Stabilizers	Cromolyn Sodium (Nasylcrom)	
Nasal Steroids	Budesonide Aqua (Rhinocort Aqua)	Beclomethasone (Beconase, Vancenase) Ciclesonide (Omnaris) Fluticasone furoate (Veramyst) Fluticasone propionate (Flonase) Mometasone furoate (Nasonex) Triamcinolone acetonide (Nasacort)
Pregnancy Category B	Animal reproduction studies have failed to demonstrate a risk to the fetus and there are no adequate and well-controlled studies in pregnant women OR. Animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester	
Pregnancy Category C	Animal reproduction studies have shown an adverse effect on the fetus and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks	

[a]Primarily used as antiemetic.

AUTONOMIC RHINITIS (VASOMOTOR RHINITIS)*

Autonomic nervous system dysfunction has long been thought to play a role in chronic nasal inflammation and rhinitis. This was first demonstrated quantitatively by abnormal tilt table testing in patients with autonomic rhinitis (115). More recently, studies have shown that it is likely a hypoactive sympathetic nervous system rather than a hyperactive parasympathetic system that drives symptoms of autonomic rhinitis (116,117).

The symptoms of autonomic rhinitis may occur in response to physical, emotional, or gustatory stimuli. Some common provocative stimuli include cold air, changes in humidity, exercise, sexual arousal, alcohol, emotional stress, spicy foods, and direct manipulation of the nasal mucosa. The patient typically complains of profuse watery rhinorrhea elicited by one of these factors. Nasal congestion may also be present but often to a lesser degree. Pruritus is rare but the sneeze reflex is an autonomic host defense mechanism and may be present.

Autonomic rhinitis is unique among other causes of rhinitis in the fact that it responds particularly well to ipratropium bromide nasal sprays two to four times daily (117). Intranasal topical corticosteroids and intranasal antihistamines have also been found to be effective agents for autonomic rhinitis (118,119).

ATROPHIC RHINITIS

AR is a disease of paradoxical nasal congestion and mucociliary stasis. Patients present with the primary symptom of chronic severe nasal obstruction and on exam the nasal cavities are often remarkably patent or even widened. There are primary and secondary forms of AR that differ in their epidemiology and etiology. Characteristic findings in both forms include nasal crusting, enlarged nasal cavities, mucosal atrophy, and paradoxical nasal congestion. It may be that primary and secondary AR are similar clinical manifestations of disparate inciting factors.

Some terms that have been used interchangeably with AR include *rhinitis sicca*, *empty nose syndrome*, and *ozena*. These may be diseases along a spectrum or different diseases altogether (120,121). The loose use of nomenclature has contributed to confusion in categorization and study of this disease.

The primary form of AR is seen most often in underdeveloped countries. Children and young adults seem predominantly affected though some studies have shown an average age of 50 in their study populations (121). There is a slight female predilection. These patients often present with chronic nasal obstruction accompanied by significant nasal crusting and cacosmia consistent with the triad originally described by Fraenkel of fetor, crusting, and atrophy of the nasal structures. The patients themselves may complain of anosmia but the fetor is often so severe that it is perceived by others. Clinical depression is not uncommon in these patients due to the social stigma of a chronically odiferous nose (121). Prior to the onset of symptoms, a significant history of sinonasal disease is absent in the primary form.

The secondary form of AR presents similarly with paradoxical chronic nasal obstruction; however, the presence of a fetid odor is less common or less pungent. Nasal crusting also tends to be more limited than in the primary form and resorption of turbinates and bone is seen less frequently (121,122). Secondary AR occurs more often in later adulthood and is the predominant form seen in the United States and developed countries. Aggressive sinus surgery with overzealous resection of the turbinates accounts for the great majority of cases of secondary AR. Other causes include: chronic granulomatous diseases such as Wegener granulomatosis, severe nasal trauma, history of radiation to the head and infections such as leprosy, tuberculosis, syphilis, or rhinoscleroma.

The sense of paradoxical nasal obstruction in both primary and secondary AR is not completely understood. Several theories exist (122–124):

1. The turbinates normally direct and eddy inspired air. Atrophy of these areas leads to disruption of normal airflow, which is perceived as obstruction.
2. Some degree of resistance is likely an important factor in the sense of a satisfying breath. The nose contributes 50% of the airway resistance and this is lost with a widely patent nose.
3. Though the nasal cavity is abnormally patent, an atrophic nose has less mucosa surface area for hydration and conditioning of inspired air.
4. There is a general loss of sensory and olfactory input including the perception of inspired air.

The unremitting dry nasal airflow leads to chronic changes to the respiratory epithelium. Histologically, this is reflected in the transformation of the nasal mucosa from normally stratified squamous respiratory epithelium to keratinizing squamous epithelium. There is loss of cilia, goblet cells, serous and mucous glands, and a diffuse endarteritis obliterans (121).

Many possible cofactors have been proposed for the underlying pathophysiology of AR including infection, nutritional deficiency, hormonal imbalance, poor hygiene, vasculitis, autoimmune processes, and hereditary factors. The most often reported of these possible factors is *Klebsiella ozaenae* infection.

*The term vasomotor rhinitis has often been used to describe rhinitis secondary to presumed autonomic dysfunction. It has also been used synonymously with what is now more appropriately called idiopathic rhinitis. Because it has been so ubiquitously applied to multiple categories of nonallergic rhinitis, continued use of the term here adds confusion to the discussion. In this chapter, as in the 2008 ARIA consensus statement, the term vasomotor rhinitis will not be used primarily.

K. ozaenae is the most frequent organism cultured from the crusts of patients with AR (121,125). This occurs more often in primary AR than secondary. In the largest case series to date, out of 242 patients with AR, 45 out of 45 patients with primary AR were culture-positive for *K. ozaenae* whereas only 1.5% of secondary AR patients were positive (121). Whether the presence of *K. ozaenae* is the inciting event in AR or simply an opportunistic superinfection is uncertain, but this organism likely contributes in some part to the ongoing disease process in primary AR. Ciliary beat studies have shown that *K. ozaenae* has ciliostatic properties, which may help in the establishment of chronic colonization and infection (126).

Further implications for an infectious etiology in primary AR comes from a natural correlate which exists in swine called progressive AR. In swine the bacteria *Pasteurella multocida*, alone or in combination with *Bordetella bronchiseptica*, has been established as the causative organism of progressive AR. Vaccines against *P. multocida* are protective against symptoms and signs of progressive AR in swine (127).

AR is a clinical diagnosis. On exam, the nasal mucosa is pale, shiny, and dry. It may appear thinned or cobblestoned. Once the extensive yellow-green crusts are removed, there is a widely patent nasal cavity with loss of normal intranasal landmarks.

Distinguishing between primary and secondary forms in the studies to date has been based on consensus. Patients with *de novo* sinonasal symptoms in the absence of history of nasal trauma, sinonasal surgery, granulomatous disease, or radiation are designated primary AR whereas all others are deemed secondary. The country of origin and recent immigration status of a patient, severity of cacosmia, and radiographic presence of turbinate regression may also be distinguishing characteristics between primary and secondary forms though this has yet to be studied in a case-controlled fashion. In a study by Ly and deShazo, the diagnosis of secondary AR was made with a specificity 0.95 and a specificity of 0.77 if two or more of the following clinical findings were present: epistaxis, anosmia, nasal purulence, nasal crusting, chronic inflammatory disease of the upper airway for 6 months, or two or more sinus surgeries (128).

The extent of bony destruction is often best appreciated on CT scan, which demonstrates a cavernous nasal cavity with loss of normal nasal structures (Fig. 30.2). Pace-Balzan et al. and Moore separately noted the following findings to be consistent with AR: (a) mucosal thickening of the paranasal sinuses, (b) loss of definition of the ostiomeatal complex secondary to destruction of the ethmoid bulla and uncinate process, (c) hypoplasia of the maxillary sinus, (d) enlargement of the nasal cavities with destruction of the lateral nasal wall, and (e) bony destruction of the inferior and middle turbinates (121,129).

Laboratory studies including a complete blood count, basic metabolic profile, rapid plasma reagin, HIV, angiotensin converting enzyme level, calcium level, antineutrophil cytoplasmic antibodies (c-ANCA, p-ANCA, myeloperoxidase, and proteinase 3) are recommended as part of the initial evaluation of a patient with suspected secondary AR. A chest x-ray is an effective and low-cost method to evaluate for coexisting pulmonary disease.

Figure 30.2 Coronal CT scan at the level of the right anterior ethmoid artery shows abnormally patent sinuses with resection of major endonasal structures including bilateral inferior and middle turbinates, bilateral uncinates, bilateral total ethmoids.

Positive nasal cultures can help support the diagnosis and direct antibiotic therapies but are not required for the diagnosis. Nasal biopsy should be performed whenever granulomatous causes of secondary AR are under question. If there is associated weight loss, chronic dyspnea, or other symptoms of coexisting pulmonary disease, a nasal biopsy is warranted. Similarly, if a septal perforation is present without history of iatrogenic intervention or intranasal drug abuse, clinical suspicion should be raised for an underlying vasculitis and a biopsy should be taken. A primary etiology for AR should always be sought first and treated accordingly.

The mainstay of treatment for AR is moisture and debridement. Debridement should initially occur in the office at 4- to 6-week intervals followed by isotonic nasal saline irrigations of at least 200 mL 2 to 4 times a day. A non–petroleum-based salve should be used twice daily in between irrigations to improve nasal moisture. Once the patient is improved from the standpoint of excessive crusts and foul smelling rhinorrhea, nasal surveillance and debridement in the office can be performed less frequently but the patient must be counseled regarding the persistence of this disease and the importance of daily compliant therapy. Occasionally topical antibiotic solutions in addition to saline for 2 to 4 weeks are helpful in eradicating the chronic infection and foul-smelling crusts. Some commonly used topical antibiotic preparations include 200 mL of gentamycin (80 to 160 mg/1,000 mL) twice daily or mupirocin (22 mg of 2% in 1,000 mL) twice daily. A systemic quinolone or tetracycline can be considered if patients remain refractory despite daily compliant therapy.

Decongestants and antihistamines should be avoided as these will exacerbate the dried mucosa.

Surgical options are aimed at improving nasal humidity and/or nasal resistance. A modified Young's procedure develops anterior mucosal flaps to close off one naris at a time and allows for rehumidification of the nasal mucosa. Periodic nasal endoscopy is facilitated by leaving a small 3 mm orifice. A subsequent recanalization procedure is required. Limited studies have shown a decrease in nasal crusting at 6 months and increase in length but not number of cilia (130).

There are a number of different removable nasal stents that are available for narrowing the diameter of the nares to increase nasal resistance. There are a variety of methods for surgical vestibuloplasty in the literature. These involve the development of mucosal flaps or injection of various autografts or allograft implants at the internal nasal valve. Results of all surgical options have been varied at best and should be pursued with caution after exhausting all conservative options over a prolonged period of time.

SYSTEMIC CAUSES OF NONALLERGIC RHINITIS

Systemic diseases may present with clinical symptoms of chronic rhinitis and must be considered in the differential of refractory chronic nonallergic rhinitis. Autoimmune and granulomatous diseases such as Wegener granulomatosis and sarcoidosis are the most common considerations. Exam findings may be nonspecific but a review of systems may reveal positive constitutional, pulmonary symptoms, or musculoskeletal symptoms which should raise one's clinical suspicion for an underlying systemic process. Infectious agents such as tuberculosis, rhinoscleroma, and chronic fungal infections may also incite granulomatous reactions in the nose and chronic rhinitis. "Snuffles" is a term used to describe the persistent and at times blood-tinged rhinorrhea that is a manifestation of congenital syphilis. Directed serum studies and intranasal biopsy are indicated to rule out infectious and autoimmune causes of refractory rhinitis. A chest x-ray is an efficient, low-cost modality that should also be employed when investigating the potential of coexisting pulmonary disease.

Extraesophageal reflux (EER) is recognized as a common cause of refractory rhinitis in children (131) and is increasingly recognized as a contributor to chronic rhinosinusitis in adults (132). EER has also been associated with autonomic rhinitis in adults and may be a manifestation of generalized autonomic dysfunction (116). Chronic phlegm, excessive throat clearing, globus, cough, and throat irritation are symptoms that could be equally attributable to refluxed stomach contents from below or inflammatory mediators in nasal discharge from above. A history of heartburn, regurgitation, sour brash, or dyspepsia is important to seek from patients with chronic rhinitis symptoms; however, the absence of these symptoms does not exclude the diagnosis of EER. Koufman (133) demonstrated that even trace amounts of reflux, three times a week, are enough to cause mucosa trauma to the larynx. A specialized dual pH probe with separate esophageal and nasopharyngeal arms can detect events of acid reflux into the nasopharynx but there is currently no standardized data to delineate what is normal or what is significant. An empiric trial of antireflux medication may be warranted for patients with refractory rhinitis symptoms.

Both hematogenous and solid organ malignancies may mimic nonallergic rhinitis symptoms. Nasal neoplasms should always be investigated with nasal endoscopy and CT scan of the sinuses. NK/T-cell lymphoma, formerly called lethal midline granuloma, can cause an aggressive erosion of intranasal structures consistent with AR. Chronic lymphocytic leukemia has also been reported to masquerade as chronic rhinitis (134).

Patients with Parkinson Disease demonstrate a fivefold increased incidence of rhinorrhea against age-matched controls in self-reported studies (135). This appears predominantly autonomic in description and responds to ipratropium bromide. This may be due to the sympathetic dysregulation seen in Parkinson Disease. (See Table 30.7 for a listing of potential systemic and structural causes of chronic rhinitis.) These disease processes are discussed in more detail in separate chapters.

TABLE 30.7 SYSTEMIC AND STRUCTURAL CAUSES OF RHINITIS

Inflammatory or immunologic conditions
- Wegener Granulomatosis
- Sarcoidosis
- Systemic lupus erythematous
- Churg–Strauss
- Relapsing polychondritis
- Amyloidosis
- Immunodeficiency (e.g., Selective IgA deficiency)
- NK/T-cell lymphoma
- Chronic lymphocytic leukemia

Structural or mechanical conditions
- Choanal atresia
- Deviated septum
- Enlarged adenoids
- Foreign bodies
- Nasal polyps
- Nasal tumors
- Ciliary dyskinesia (e.g., Primary ciliary dyskinesia, CF, Kartagener syndrome)
- CSF leak

Other
- EER
- Parkinson disease

AGING AND RHINITIS

Rhinitis in children is predominantly infectious and allergic. After age 20, nonallergic rhinitis is more common. After the sixth and seventh decades of life, changes in the nasal mucosa, weakening of the cartilaginous nasal structure, and polypharmacy predispose older adults to a condition, which some have dubbed "geriatric rhinitis" or "senile rhinitis" (136).

With aging, the nasal mucosa becomes more atrophic with a loss of submucous serous glands and goblet cells and a decrease in microvascular flow. Laxity in the cartilaginous support of the nose with age-related loss in collagen may also accentuate symptoms of nasal airflow obstruction. The aged population is also likely to be on chronic medications such as diuretics, beta-blockers, anxiolytics, and antivertigo drugs with known side effects of nasal dryness and congestion.

Patients may present with complaints of thickened nasal secretions and crusting, excessive postnasal drip and phlegm, excessive throat clearing, nasal congestion, and occasionally decreased sense of smell and taste. Alternatively elderly patients may report watery rhinorrhea and exacerbation with meals, temperature changes, or exercise that is more consistent with autonomic rhinitis. The differential for new-onset geriatric rhinitis includes allergic rhinitis, vasomotor rhinitis, atrophic rhinitis, chronic sinusitis, EER disease, benign and malignant nasal masses, and CSF leak. It is paramount to investigate and eliminate more morbid conditions prior to commencing presumptive therapy.

The goals in the treatment of geriatric rhinitis focus on increasing nasal moisture and mucociliary clearance. To this end, saline nasal sprays and irrigations are the mainstay of treatment. Addition of a mucolytic such as guaifenesin can also help to thin nasal secretions. There is some debate about the role of topical nasal steroids in geriatric rhinitis. Some have cautioned to use these sparingly as they may exacerbate nasal dryness but in many patients the combination of saline and a topical nasal steroid is effective. A trial of nasal steroids is reasonable with close monitoring for local side effects. Nasal steroids should be used with caution in patients with narrow angle glaucoma as steroids can raise intraocular pressures. If treatment with steroids is necessary in a patient with a history of narrow-angle glaucoma, the patient should have frequent intraocular pressure checks by their ophthalmologist. Ipratropium nasal sprays are very effective for autonomic rhinitis but compliance may be limited due to the frequency required.

Medications to be avoided in this population include antihistamines and decongestants. Antihistamines, particularly first-generation antihistamines, can exacerbate mucosal dryness and compound sedation from other medications. Antihistamines should be limited to second-generation antihistamines when indicated. Topical and systemic nasal decongestants do not provide long-term solutions for geriatric rhinitis, may exacerbate nasal dryness and irritation, and may also worsen underlying comorbid conditions such as hypertension and cardiac disease.

HIGHLIGHTS

- Nonallergic rhinitis is a common problem, which is likely underrecognized.
- There are no definitive tests for confirmation of nonallergic rhinitis (or its subcategories). Diagnosis is arrived upon with a thorough history, temporal associations to the patient's symptoms, and exclusion of other potential diagnoses.
- Though the terminology may be murky and categorization may be challenging, in the practical management of patients with chronic nonallergic rhinitis the approach to treatment is similar.
- Chronic rhinitis may be alleviated by many nonpharmacologic, nonsurgical therapies including patient education, environmental control, and nasal saline irrigation.
- Topical antihistamines demonstrate both antihistaminic and anti-inflammatory properties and are effective, first-line therapies for patients with idiopathic rhinitis.
- Topical nasal corticosteroids are particularly effective in nonallergic rhinitis patients with significant nasal eosinophilia.

Systemic Diseases that Affect the Nose and Sinuses

31

David A. Zopf *Mark A. Zacharek*

The role of the otolaryngologist in the diagnosis and treatment of the following systemic diseases discussed in this chapter is multifaceted. Certain disorders may manifest their initial presentation in the nasal/paranasal sinuses. In this instance, an opportunity is presented for an initial workup and diagnosis while obtaining appropriate consultation of additional medical specialists when necessary.

Many of the following diseases present a challenge to the head and neck surgeon. They are oftentimes chronic in nature, with suspicion of an underlying, more widespread issue arising after failure of response to several interventions. A thorough history and physical examination, followed by the appropriate laboratory assays, diagnostic imaging, and tissue biopsies are essential to guiding patients to treatment and relief.

Surgical interventions and procedures may be offered for symptomatic relief in certain pathologies, though treatment for systemic disease is more often medical. For example, a septal button may alleviate symptoms in a patient with septal perforation secondary to granulomatosis with polyangiitis (a newer nomenclature for Wegener granulomatosis [WG]), but the otolaryngologist's interventions provided in the clinic or operating room cannot replace steroid immunotherapy.

Furthermore, it is often possible to view several of the discussed systemic diseases as pathology on a continuum rather than distinct afflictions. As such, addressing individual conditions while keeping in mind their general pathophysiologic category will assist in understanding successful treatment and diagnosis.

Systemic diseases affecting the nasal and paranasal sinuses are presented in the following sections by pathophysiologic process: genetic/congenital, granulomatous, autoimmune, and hematologic (Table 31.1). However, these groupings are not mutually exclusive, and disease processes discussed may actually fit in more than one of these categories.

CONGENITAL/GENETIC

Cystic Fibrosis

Cystic fibrosis (CF), the most common autosomal recessive disorder in whites (1 case:2,500 live births) is a systemic disease affecting mucous viscosity secondary to a genetic mutation. Mutation in the CF transmembrane conductance regulator gene of chromosome 7 alters a transmembrane channel protein affecting chloride ion movement. An inflammatory reaction ensues leading to cellular breakdown and an accumulation of intracellular/intranuclear products, such as DNA (1). This affects the viscoelastic properties in the pancreas, reproductive organs, and respiratory tract, including the sinonasal cavities (2). In addition, increased bacterial colonization occurs, particularly with *Pseudomonas aeruginosa* and *Staphylococcus aureus* (3). Sinonasal disease is a proposed contributor of lung disease, a leading cause of death in CF (2).

Dysfunctional mucus clearance may lead to obstruction of the sinus ostia and mucosal edema leading to nasal obstruction, chronic sinusitis, and sinonasal polyposis. Nearly 100% of CF patients exhibit some aspect of sinus disease (4). The most common CT-imaging findings in CF include sinus opacification followed by the presence of pseudomucoceles. In one series of Brazilian patients, these findings were absent in only two of fifty patients. Hypoplasia or agenesis of the frontal sinuses has also been noted (3). Approximately 36% of carriers of recessive CF mutations reported chronic rhinosinusitis symptoms, versus 14% in the general population (5). In another series of homozygous recessive CF, 117/126 patients exhibited rhinosinusitis. Nasal polyps were discovered in 20% of this series (6).

Diagnosis is made with a positive sweat chloride test and/or genetic test with at least one of the following:

TABLE 31.1 SUMMARY OF SYSTEMIC DISEASES AFFECTING THE NOSE AND SINUSES

		Diagnostic	Therapeutic
Congenital/Genetic			
	CF	History, sweat chloride, genetic screen	Selective ESS
	Lymphoma	History, biopsy	XRT; XRT+CRT
Granulomatous			
	Sarcoidosis	History, biopsy, ACE levels	Corticosteroids, nasal irrigation, selective ESS
Autoimmune			
	Granulomatosis with Polyangiitis (Wegeners)	History, c-ANCA, biopsy	Corticosteroids, cyclophosphamide
	Relapsing Polychondritis	History	Corticosteroids, cyclophosphamide
	CSS	History, biopsy, ANCA	Corticosteroids, cyclophosphamide, nasal irrigation
	Sjogren syndrome	History, biopsy, SS-A,B	Corticosteroids, artificial moisture
Hematologic			
	HHT	History	[laser]coagulation, systemic therapies, hormonal therapy, septodermoplasty, Young procedure
	Thrombocytopenia	History, CBC, bleeding/clotting parameters	Transfusion, addressing underlying pathology

(a) typical chronic obstructive pulmonary disease, (b) documented exocrine pancreatic insufficiency, or (c) positive family history.

Treatment should be symptom directed based on severity. Mild symptoms may be managed with nasal irrigations (1). More severe symptoms can be addressed with mucolytics, nasal corticosteroids, and antibiotics (7). Surgical intervention in CF should be utilized with the intent to reduce sinonasal symptoms and improve quality of life, though not with curative expectations. Revision surgery is required in approximately one-third (2) to one-half (8) of CF cases and may be predicted by polyp severity (2). In a randomized double-blind prospective trial, dornase alpha (recombinant human deoxyribonuclease) has been shown to be effective in extending benefits of surgery when used as an adjuvant therapeutic (1).

Lymphoma

Lymphoma may present with nasal involvement that is clinically restricted to the sinonasal airway. The cell lineage of the lymphoma origin is variable. One report investigated the cellular origins of nasal lymphomas in a western patient population and found that 55% of tumors were comprised of natural killer (NK)/T cells, 29% B cells, and 16% T cells. However, these estimates differ in Chinese and Japanese populations where tumors derived from the NK/T-cell lineage are more common (9). An association with Epstein-Barr virus has been proposed for NK/T-cell lymphoma.

Midline destructive lesions have historically been described by several different variations in nomenclature, such as idiopathic midline granuloma, lethal midline granuloma, polymorphic reticulosis, and Stewart syndrome. Improvements in cellular and molecular diagnostics, including immunohistochemistry and flow cytometry, have revealed that many of these lesions are actually WG or lymphomatous (10). Furthermore, extensive investigation into subdivision of classifications of NK/T-cell lymphoma is an active area of current research. Subdivision into upper aerodigestive tract NK/T-cell lymphoma (nasal cavity, nasopharynx, oral cavity, oropharynx, hypopharynx disease) and nonupper aerodigestive tract NK/T-cell lymphoma has been proposed (11).

Clinical presentation of lymphoma involving the sinonasal compartments includes epistaxis, nasal obstruction, nasal swelling, and constitutional or B-type symptoms (malaise, weight loss, fever). More advanced disease may reveal a friable necrotic mass, potentially obstructing the nasal cavity/nasopharynx. Local extension, when present, has been reported to involve the maxillary sinus (42%), ethmoid sinuses (36%), nasopharynx (25%), and rarely skull base or cranial nerves (9).

Diagnosis may be particularly challenging in instances of mild or early stage disease. An initial routine workup with baseline serologic assays and clinical/endoscopic examination are followed by biopsy of suspicious nasal mucosal disease. Sufficient fresh samples should be obtained for immunophenotyping by flow cytometry. Histologic analysis may reveal lymphocytic infiltrates with angiocentric necrosis.

TABLE 31.2 ANN ARBOR CLASSIFICATION FOR LYMPHOMA

Ann Arbor Classification for Lymphoma	
Stage I	Involvement of a single lymph node region or single extralymphatic site
Stage II	Involvement of two or more lymph node regions on the same side of diaphragm, localized contiguous involvement of only one extralymphatic site and lymph node region
Stage III	Lymph node involvement on both sides of the diaphragm
Stage IV	Disseminated involvement of one or more extralymphatic organs with or without lymph node involvement

Table 31.2 details the Ann Arbor Lymphoma staging system. Alternate staging based on various classifications, such as anatomic subsites, or treatment responses have been proposed (11).

Treatment and follow-up should be directed by hematology/oncology specialists. No advantage for the addition of chemotherapy to radiation has been shown in early stage (I/II) NK/T- cell lymphoma (overall 5-year survival (OS) rates of 38%-RT versus 35%-CRT (12); 66%-RT versus 76%-CRT (13); 59.2%-RT versus 52.3%-CRT (14)). Lack of success with chemotherapy alone may be a result of P-glycoprotein expression that confers increased multidrug resistance in CD56+ NK cells (15). Studies of combination therapy reveal sequence impacts outcomes. In chemotherapy followed by 45 Gy of radiation, the complete response (CR) rate was 49.1%, compared to 100% in those who received radiation followed by chemotherapy (16). A review by Kohrt and Advani cite several studies lending support for combined chemoradiation in high-risk or advanced-stage disease (stage III/IV), where 5 year OS drops to 20%. Several aspects of the therapeutic strategy in nasal NK/T-cell lymphoma are topics of current investigations.

GRANULOMATOUS

Sarcoidosis

Sarcoidosis is a noncaseating granulomatous disease, oftentimes involving multiple systems (Fig. 31.1). A demographic predisposition for African American and Scandinavian individuals of age range in the twenties and thirties has been demonstrated (17).

Development is likely multifactorial, leading to an abnormal immune response, of which T cells and their proinflammatory cascades are thought to be at the center. Mycobacterial tuberculosis catalase-peroxidase protein was reported to be present in approximately 50% of sarcoidosis tissue samples (18). Activated tissue macrophages are the primary source for angiotensin-converting enzyme elevations (19). Genetics appear to contribute to predisposition of development of sarcoidosis. In one study involving 210 pairs of monozygotic and dizygotic twins and at least one proband, concordance rates of sarcoidosis were found to be significantly higher in monozygotic than in dizygotic twins. Compared with the general population, there was an 80-fold increased risk of developing sarcoidosis in cotwins of effected monozygotic brothers or sisters (20). Responsible genes, such as butyrophilin-like 2 gene, have been proposed (19). It is hypothesized that an environmental factor prompts an aberrant immunologic response, though no strong associations in the literature have led to a specific environmental offender.

The wide range of symptomatology makes recognition of sarcoidosis a challenge. Incidental discovery on chest x-ray (CXR) in asymptomatic patients accounts for a large proportion of presentations. In the symptomatic patient, one or more of the following systems may be involved: respiratory (cough, dyspnea, chest pain), integumentary (lupus pernio, erythema nodosum, papules, nodules, plaques), ocular (orbital pain, uveitis, visual changes), rheumatologic (arthralgia, myalgia), and constitutional (fevers, night sweats, fatigue) (21). Lupus pernio, the most characteristic skin lesion for sarcoidosis, occurs at a higher preponderance in sarcoidosis with sinonasal features (Fig. 31.2).

As pulmonary findings are a hallmark of sarcoidosis, a close collaboration with a pulmonologist is recommended. Chest radiographic findings are classified as follows: stage 0, normal CXR; stage 1, isolated intrathoracic adenopathy; stage 2, intrathoracic adenopathy and parenchymal disease; stage 3, parenchymal disease; and stage 4, pulmonary fibrosis (22).

Sinonasal manifestations occur in approximately 1% to 5% of cases, of which only 10% are present in absence of pulmonary disease (23–25), and include nasal congestion, nasal obstruction, rhinorrhea, nasal crusting, epistaxis, nasal mass, facial/nasal pain, and anosmia (23,26). On physical examination, purplish, friable nasal mucosa, mucosal

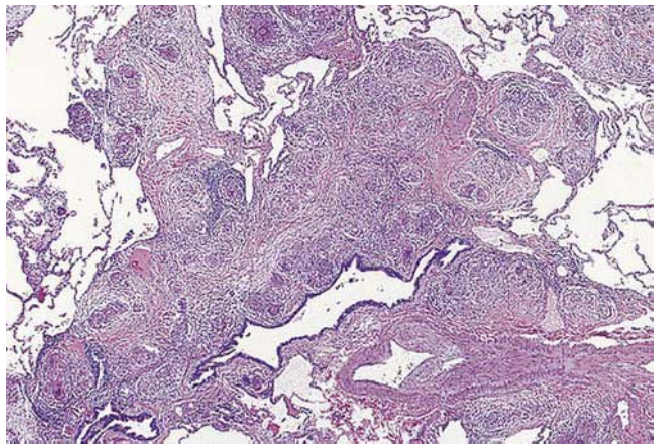

Figure 31.1 Sarcoidosis. Multiple noncaseating granulomas are present along the bronchovascular interstitium. Image from Rubin E, Farber JL. *Pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 1999.

Figure 31.2 Raised lesions of lupus pernio. (From Crapo JD, Glassroth J, Karlinsky JB, et al. *Baum's textbook of pulmonary diseases*, 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2004.)

hypertrophy, nasal polyps, and yellow submucosal nodules may be observed, most commonly involving the septum and inferior turbinates (Fig. 31.3). Thickening of sinus mucoperiosteum and radiologic paranasal opacification mark sinus involvement (24,27). Of 15 patients undergoing CT with sarcoidosis and sinus symptoms, the maxillary (14), ethmoid (9), frontal (6), and sphenoid (3) sinuses demonstrated complete or partial opacification (23).

When presented with sinonasal findings in suspected sarcoidosis, histological biopsy revealing noncaseating granulomas is the definitive mode of diagnosis. With the differential diagnosis including fungal and mycobacterial infections, the respective histopathology and tissue cultures are required to rule these out. However, patients who present with Lofgren syndrome (erythema nodosum, hilar adenopathy, and polyarthralgias) can be clinically diagnosed without the necessity of biopsy (19). ACE levels and serum calcium levels may be elevated. Though nonspecific, C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) levels are often elevated. Equally important are ruling out other potential disease processes and assessing the extent of pathology, for example, antineutrophil cytoplasm antibodies (ANCA) should be measured to rule out WG.

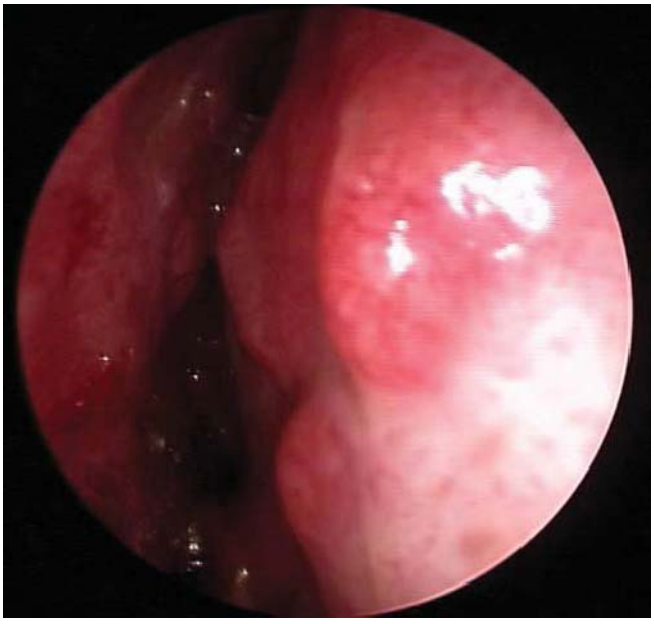

Figure 31.3 Endoscopic view of nasal sarcoidosis. The septal mucosa, as well as the lateral nasal wall reveals nodular, erythematous swellings.

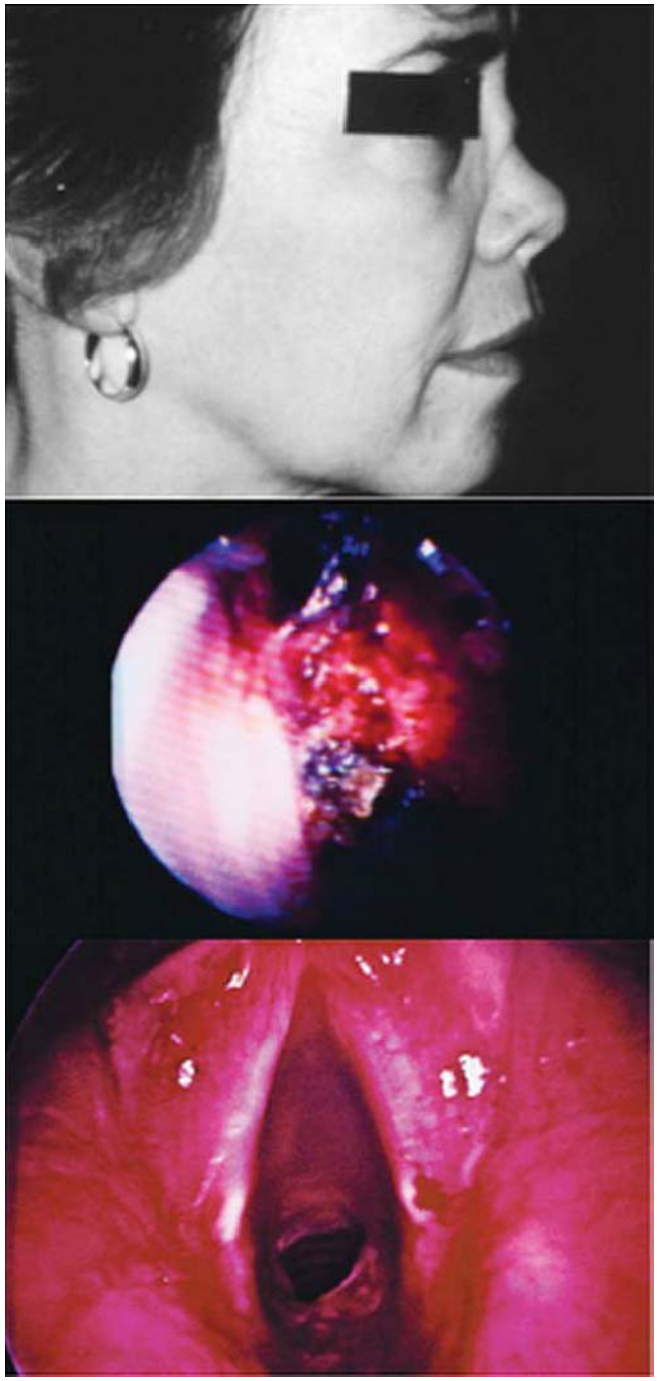

Figure 31.4 Saddle-nose deformity in WG, bloody crusts in WG, subglottic stenosis in WG. (From Koopman WJ, Moreland LW. *Arthritis and allied conditions a textbook of rheumatology*, 15th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005).

Treatment should be tailored to the severity and extent of disease involvement. Many patients diagnosed with sarcoidosis do not require treatment. In symptomatic patients, nasal corticosteroids for skin disease and non-steroidal anti-inflammatory drugs (NSAIDs) may be utilized for mild disease, where higher dose systemic corticosteroids and immunomodulators for more extensive disease may be initiated with close medical follow-up. Six to nine months of prednisone, initiated at a dose of 30 to 40 mg daily followed by a 5 mg/day taper to a 10 to 20 mg/day maintenance dose, is recommended (19). Methotrexate has been shown to be an effective therapeutic and allows for decreased doses of systemic steroid administration in a randomized double-blind trial (28). Additionally, hydroxychloroquine, azathioprine, pentoxifylline, statins, and tumor necrosis factor (TNF-α) TNF-alpha binding proteins/inhibitors, such as infliximab, etanercept, and adalimumab, have been described for the same intent (29). A multicenter randomized, double-blind, placebo controlled trial of infliximab has shown improvements in pulmonary function with pulmonary sarcoidosis, though the remaining biologics mentioned have otherwise not shown dramatic efficacy to date (19). Sinonasal involvement has been shown to be a poor prognostic indicator with a high frequency of recalcitrant disease involving multiple vital organs, thus oftentimes necessitating systemic therapy (23).

The goal for surgical intervention in sarcoidosis is not eradication of disease, but potential quality of life improvement. Kay and Har-El examined the role for endoscopic sinus surgery in sarcoidosis. Six of 86 sarcoidosis patients underwent endoscopic sinus surgery with indications including granulomatous or polypoid lesions causing severe nasal obstruction or blocking the osteomeatal complex leading to symptomatic chronic or acute recurrent sinusitis. CO_2 laser surgery has also been described for treating such granulomas (29). Patients should be informed of the uncertainty of duration and extent of symptom relief, with the risk of worsening sinonasal symptoms. Finally, prompt consultation of additional specialists should be elicited to assist in instances of multiorgan involvement.

AUTOIMMUNE

Granulomatosis with Polyangiitis (Wegener Granulomatosis)

The American College of Rheumatology has proposed a nomenclature free of eponyms, working towards etiology-based terminology (30). The term granulomatosis with polyangiitis, or GPA is now the preferred title for the disease entity WG. In the spirit of collaborative and cooperative efforts, we provide the reader with awareness of this anticipated shift, though we will utilize the previously used eponym for ease and accessibility, as this proposed change will take time and effort to gain widespread awareness.

WG is an idiopathic systemic small-medium vessel vasculitis characterized by necrotizing granulomas. Age of diagnosis is often 20 to 40 years old and there does not appear to be gender preponderance (31).

There is no definitive etiology established, though involvement of circulating ANCA in response to an environmental stimulus, such as an infectious agent or toxin in combination with a genetic predisposition is suspected (31). Genetic predisposition is supported by reports suggesting association with HLA DR4 and DR8. Moreover, there is an increased incidence of autoimmune diseases in first degree relatives of WG patients compared to a control population (32, 34). Serum levels of IgA and IgE are often found to be elevated, further supporting an autoimmune mechanism (32). A direct role of proteinase 3 (PR3) (and myeloperoxidase [MPO]) has been hypothesized through a delay in clearance of inflammation inducing neutrophils (33). *S. aureus* and silica have been implicated as possible etiologic triggers. Support for a role of staphylococcus involvement in pathogenesis include higher incidence of carrier status in WG and the success of antistaphylococcal antibiotics in treatment regimens (32).

WG is known to affect the upper respiratory tract, lungs, and kidneys. Limited forms of the disease are restricted to one or two of these systems. Constitutional symptoms including fever, weight loss, weakness, and arthralgias are common. Involvement of other systems including ophthalmologic, cardiac, and neurologic are also reported.

The nasal cavity/paranasal sinuses are the most frequently affected sites in the head and neck, with between 64% and 80% of patients exhibiting manifestations. Isolated nasal involvement is seen in approximately one-third of cases, with the septum and turbinates being the most commonly involved sites. Mucosal crusting, increased friability, and inflammation can be seen on rhinoscopy/endoscopy. Septal involvement can result in perforation or saddle-nose deformity, the latter of which is seen in 10% to 25% of WG patients (Fig. 31.4, top, middle). Chronic sinusitis occurs in approximately half of cases with nasal/paranasal involvement (32). Symptoms include obstruction, pain, malodorous sensation, rhinorrhea, epistaxis, and epiphora.

Clinical diagnosis of WG is based on the American College of Rheumatology Diagnostic Criteria of WG (Table 31.3). Serologic diagnosis of WG is made by assaying serum c-ANCAs. If assays for c-ANCA are positive, clinical testing for antibodies against PR3 and MPO should be sought since they have increased specificity (36). Additionally, tissue biopsies should be obtained, oftentimes sinonasal, which if positive show characteristic necrotizing granulomas and vasculitic inflammation. Of note, review of diagnostic data have shown c-ANCA to be negative in approximately 30% of biopsy positive WG and additionally false positives have been seen in amebiasis, leprosy, and infectious endocarditis. Important factors in a reliable biopsy include sampling sinonasal disease if present and obtaining a generous sample that includes adjacent healthy appearing mucosa. CT or plain films may demonstrate a multitude of findings from mucosal thickening to bony changes. The most common sinuses involved are the maxillary sinuses (32).

TABLE 31.3 THE AMERICAN COLLEGE OF RHEUMATOLOGY DIAGNOSTIC CRITERIA OF WG (TWO OF FOUR REQUIRED)

The American College of Rheumatology Diagnostic Criteria of WG
Oral ulcers and nasal discharge
Nodules, fixed infiltrate, or cavities on chest film
Nephritis urinary sediment (red cell cast or >5 red blood cells per high power field)
Granulomatous inflammation on biopsy

Respiratory symptoms, such as cough or hemoptysis, should prompt radiologic evaluation. Subglottic stenosis is a common finding and can be diagnosed on endoscopic examination (Fig. 31.4, bottom). Workup may also include urinalysis for monitoring renal involvement for possible progressive renal failure histologically seen with pauci-immune necrotizing crescentic glomerulonephritis (32).

Clinical presentation of WG can be very similar to other systemic diseases such as sarcoidosis and Churg-Strauss. Sarcoidosis generally does not manifest with the ulceration and more destructive lesions seen in WG. Ultimately, serologic and pathologic differences distinguish the two entities. WG is characterized by loose, caseating granulomas whereas sarcoidosis displays tight, noncaseating granulomas (32). Churg-Strauss is distinguished by relatively milder sinonasal findings and the presence of serum eosinophilia and asthma.

Immunosuppressive therapy is the general tenet to mollify symptomology of WG. Glucocorticoids and cyclophosphamide are the mainstays of initial treatment for symptomatic disease. Acute and chronic side effects—hyperglycemia, fluid retention, osteoporosis, infections, and joint and ophthalmologic disease—may prevent prolonged therapy with these agents. Methotrexate for maintenance therapy as well as a variety of newer immunomodulators such as rituximab, infliximab, etanercept, and leflunomide may be utilized (31,35). Trimethoprim-sulfamethoxazole is also employed as a component of a maintenance regimen to prevent remission.

Surgical treatment should be tempered with the risk for scarring and the potential for worsening of symptoms. It should be strongly recommended to only be performed when the systemic disease is in remission. The role of endoscopic surgery should be limited to refractory chronic sinusitis after failed maximal medical therapy. Close postoperative care and continued adjuvant medical management should be practiced to optimize the chances for symptom resolution (32). Septal perforation repair is an area of controversy and should be approached cautiously. Conservative management using a silicone button is one technique to address whistling. Surgery should only be considered in the setting of small perforations with adjacent healthy mucosa (32). Repair of saddle-nose deformity in WG should also be approached with caution and only considered when the patient is in remission (37).

Relapsing Polychondritis

Relapsing polychondritis (RPC) is an autoimmune disease resulting in inflammation of cartilaginous tissues. It is an extremely rare entity and thus epidemiologic data are sparse. The suspected mechanism of pathogenesis involves an autoimmune response to an innate cartilaginous component by either exposure, damage, alteration, or a mechanism of molecular mimicry involving an infectious agent. Approximately 30% of cases have a concurrent vasculitis, autoimmune disease, connective tissue disorder, or malignant disease (38).

Hyaline cartilage is the tissue that is chiefly involved in the pathogenesis of RPC, and clinical presentation is the result of an inflammatory response to these structures. The auricle is the most common site of inflammatory response, with most cases manifesting a lobule-sparing pattern of inflammation (Fig. 31.5). Inflammation in ophthalmic structures ([epi]scleritis, ulcerative keratitis, uveitis), distal airway (stridor, dyspnea, cough), joints (arthralgias), cardiac (aortic/mitral valve disease), and skin (aphthous ulcers, purpura, nodules) are commonly observed (38).

Nasal involvement manifests as crusting, epistaxis, rhinorrhea, chronic sinusitis, and nasal structural abnormalities secondary to nasal chondritis.

Clinical diagnosis is based on the presence of at least three of the McAdam criteria (Table 31.4) with histologic evidence of chondritis at two or more locations (39).

Histologic findings include an infiltration of lymphocytes (CD4 cells predominate over CD8), disrupted cartilage structure with invading granulation tissue, sequestered islands of cartilage, and degeneration of cartilage to cystic material and/or bony calcification (generally in later stages of the disease process) (38).

At the present time, there are no serologic markers that have demonstrated a high specificity for RPC in humans. Nonspecific markers of inflammation, such as ESR and CRP, may be assayed to support a systemic disorder.

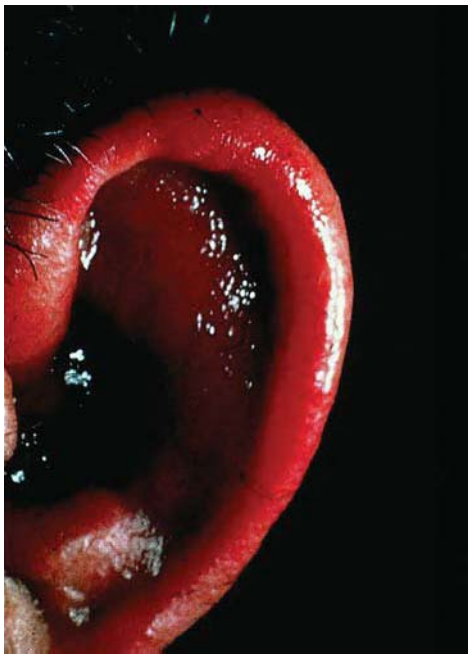

Figure 31.5 Auricular inflammation in relapsing polychondritis. (From Rubin R, Strayer DS. *Rubin's pathology: clinicopathologic foundations of medicine*, 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008.)

Antinuclear antibodies are positive in 20% to 60% of RPC (38). More specific antibodies to type II, type IX, and type XI collagen as well as matrillin-1, a cartilage matrix protein, have shown potential in animal data, but trials with humans are pending (38).

Systemic treatment depends on severity of clinical symptoms. Mild, local involvement may be managed with NSAIDs. More involved disease warrants systemic corticosteroid therapy. Furthermore, severe cases may call for immunosuppressives such as cyclophosphamide, azathioprine, cyclosporine, methotrexate, adalimumab, infliximab, etanercept, or anakinra. However, data supporting immunosuppressive therapies for RPC are largely based on case reports.

TABLE 31.4 McADAM CRITERIA FOR DIAGNOSIS OF RELAPSING POLYCHONDRITIS

McAdam Criteria for Diagnosis of Relapsing Polychondritis
Bilateral auricular chondritis
Nonerosive, seronegative inflammatory polyarthritis
Nasal chondritis
Ocular inflammation
Respiratory tract chondritis
Cochlear/vestibular dysfunction

Churg-Strauss Syndrome

Churg-Strauss syndrome (CSS) is a rare small to medium vessel necrotizing granulomatous vasculitis associated with bronchial asthma and eosinophilia. It is thought to be Th2-mediated with activation by eosinophils. Several rhinologic symptoms may appear early in the course of the disease, creating an opportunity for the otolaryngologist to make an early diagnosis. In fact, one series revealed approximately one-third of patients' reason for seeking care was worsening nasal symptoms (39). Furthermore, head and neck involvement was seen in approximately 75% of patients who participated in one retrospective case series, with allergic rhinitis (48%) and polyposis (53% to 76%) being the most common presenting symptoms (41,42). It is important for otolaryngologists to be familiar with these symptoms, since some estimates suggest that they diagnose up to 10% of all cases of CSS (40).

Clinical presentation oftentimes starts with a prodromal phase of asthma, allergic rhinitis, sinonasal polyposis, and/or rhinosinusitis. Initial presentation may also include crusting and epistaxis, making distinction from WG difficult. The next phases include eosinophilia and finally systemic vasculitis and its resultant manifestations (Fig. 31.6). Although involvement of many organ systems has been described, the sinonasal, respiratory, and peripheral nervous systems are predominantly affected by CSS (41).

The constellation of nasal polyps, asthma, constitutional symptoms, and additional systemic complaints should prompt evaluation with hematologic (CBC with differential blood count to examine the proportion of eosinophils) and metabolic serologies. It should be noted that eosinophilia may be masked if systemic steroid therapy is being utilized. Elevated ESR and CRP, though nonspecific, will further support a systemic inflammatory process. Immunoglobulin analysis may note

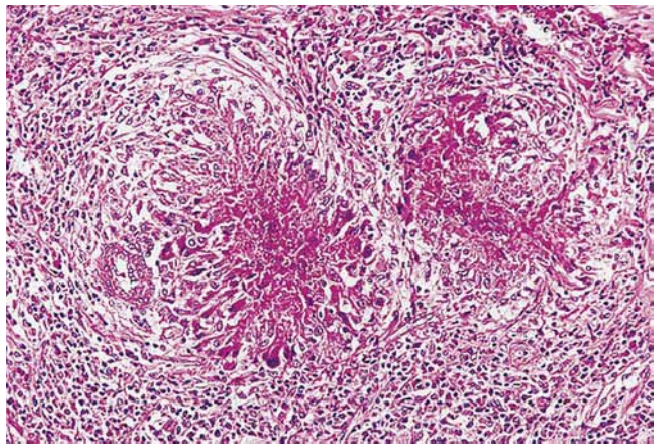

Figure 31.6 Churg-Strauss syndrome. A necrotic ("allergic") granuloma has a central eosinophilic area of necrosis surrounded by palisading macrophages and giant cells. Image from Rubin E, Farber JL. *Pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 1999.

TABLE 31.5 THE AMERICAN COLLEGE OF RHEUMATOLOGY CRITERIA FOR DIAGNOSIS OF CSS (AT LEAST FOUR REQUIRED FOR DIAGNOSIS)

The American College of Rheumatology Criteria for Diagnosis of CSS
History of asthma
Eosinophilia > 10%
Neuropathy
Nonfixed pulmonary infiltrates
Paranasal sinus abnormalities
Extravascular eosinophils on biopsy

hypergammaglobulinemia and elevation of IgE. Of note, ANCA has not been shown to be a reliable assay for CSS (40). The American College of Rheumatology requires four of six criteria detailed in Table 31.5 for diagnosis of CSS. Further biopsy findings include necrotizing vasculitis and extravascular necrotizing granulomas.

Treatment of CSS generally consists of treatment and subsequent maintenance therapy. Induction therapy involves treatment with oral or intravenous steroids in order to suppress the active disease process. Maintenance therapy follows for approximately 1 year with low-dose oral steroids and cyclophosphamide or methotrexate (41). In a retrospective analysis that utilized a Lund-Mackay grading scale, seventeen out of 29 patients had endoscopic evidence of polyposis with CSS. After initiation of medical treatment in this series, none of these patients required surgical intervention (42). We advise consultation with a rheumatologist for long-term follow-up and multidisciplinary coordination with otolaryngologists, medical pulmonologists, cardiologists, and/or nephrologists.

Sjogren Syndrome

Sjogren syndrome (SS) is a relatively common autoimmune entity marked by progressive inflammation of the salivary and lacrimal glands leading to xerostomia and keratoconjunctivitis sicca. Females are predominantly affected (9:1) and onset is commonly between 30 to 60 years of age. The classification of primary SS is used when exocrine dysfunction occurs in the absence of other autoimmune disorders, whereas secondary SS is seen with an associated autoimmune condition such as rheumatoid arthritis (43). Sicca syndrome describes the combination of xerostomia and keratoconjunctivitis sicca without salivary gland involvement.

Pathogenesis of SS has implicated viral infection and the resultant inflammatory response as an inciting event. Hepatitis C, human immunodeficiency virus, and human T lymphotropic virus type I have been proposed (44). HLA associations have been cited for SSA- and SSB-positive individuals (45). Extraglandular symptoms, similar to other rheumatologic conditions, likely result in a similar mechanism with autoantibodies, immune complexes, and lymphocytic infiltration (46). Several pharmacologic agents have been implicated in sicca syndrome, including antidepressants, anticholinergics, beta-blockers, diuretics, and antihistamines.

Retrospective analysis reveals approximately half of primary SS, secondary SS, and sicca syndrome will present with sinonasal symptoms, though physical exam findings are seen in only 20%. The most common complaints were obstruction and dryness, followed by epistaxis. Crusting, hyposmia, and recurrent sinusitis were rare. The most common physical examination finding was dry mucosa, with septal ulceration and crusting occurring less commonly (47).

Diagnosis is confirmed by parotid or labial mucosa (minor salivary gland) biopsy. At least four salivary gland lobules should be acquired for diagnosis. SSA/anti-Ro and SSB/anti-La autoantibodies are commonly used diagnostic serologies. SSB/anti-La is more specific and less sensitive, whereas SSA/anti-Ro has a higher sensitivity but may be positive in various other autoimmune conditions. Histopathologic findings include glandular lymphocytic infiltration and HLA-DR expression (48). Sialography may be used to exclude salivary duct obstruction or stricture. A multitude of additional serologic assays and diagnostics may be performed suggesting SS or a variant, though their presence or absence is not necessarily confirmatory (49). There are a number of salivary analysis assays currently under investigation, which may hold promise for improving the diagnosis of SS in the future (48) (Figs. 31.7 and 31.8).

Treatment of SS should be symptom targeted. For xerostomia and keratoconjunctivitis sicca, artificial lubricants and moisturizers, as well as pharmacologic and natural secretogogues may be utilized. For sinonasal symptoms, nasal saline sprays/irrigations and increasing environmental humidification are recommended. Immunomodulatory therapy may also hold promise. Rituximab was recently found to show improved salivary flow rate and lacrimal gland function in primary SS (50).

A 40-fold increased incidence of B-cell lymphoma are reported in SS, and as such, clinicians should have heightened surveillance in patients with positive predictive factors of palpable purpura and low serum C4 (51,48).

HEMATOLOGIC

Epistaxis in individuals with normal clotting and vascular components can cause alarming amounts of blood loss. When combined with a congenital or acquired bleeding or clotting disorder, this risk is amplified.

Hereditary hemorrhagic telangiectasia (HHT), or Osler-Weber-Rendu disease, is an autosomal dominant disorder affecting approximately 1:10,000 individuals. Characteristic vascular malformations are caused by mutations in the ENG gene and/or activin receptor-like kinase-1, which encode for factors (endoglin) involved in the transforming growth factor-β-vascular endothelial growth factor (VEGF) pathways. Dysregulation of angiogenic signals leads to abnormal endothelial–mural architecture and weakened vessels that are prone to bleeding (52). Presentation is often in middle age, occurring most commonly in the third and fourth decades. Diagnosis of HHT (Curacao criteria, Table 31.6) is based on signs and symptoms of epistaxis, telangiectasias, visceral vascular malformations, and family history (53,55). Telangiectasias are predominantly found in the anterior nasal septal mucosa (54), though also commonly seen in the circumoral/lip regions, helical rim of the ear, soft palate, and nail beds and finger tips (Fig. 31.9).

As the otolaryngologist, the opportunity for initial diagnosis of HHT arises due to the presentation of recurrent epistaxis. An essential component to patients' evaluations is addressing the possibility of multiorgan arteriovenous malformations (AVMs). Thirty percent of HHT patients have pulmonary AVMs, 30% have hepatic involvement, and 10% to 20% have central nervous system involvement. Cerebral AVM hemorrhage rates approximate those of non-HHT AVMs, 1.4% to 2.0% (56). A helical chest CT may be considered in evaluating for a pulmonary AVM. MRI and MR angiography should be considered in evaluating for cerebral lesions. Utilization of these modalities for screening in the nonsymptomatic HHT patient is currently under debate.

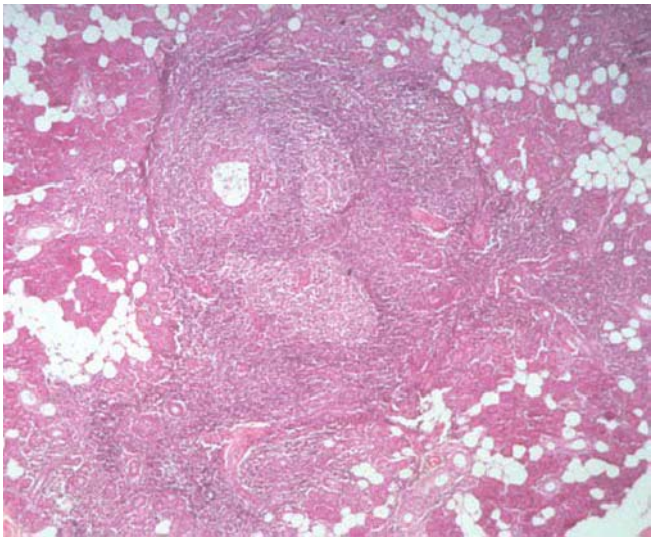

Figure 31.8 Sjogren syndrome involving a major salivary gland. An intense lymphoid infiltrate destroys the gland's acini but spares the ducts. Image from Rubin E, Farber JL. *Pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 1999.

Figure 31.9 Multiple small red spots on the lips strongly suggest HHT. From Langlais RP, Miller CS. *Color atlas of common oral diseases.* Philadelphia, PA: Lea & Febiger, 1992, with permission.

Conservative treatment begins with nasal ointment, irrigation, and humidification. Episodes of epistaxis can be treated with high-dose antifibrinolytic agents, such as tranexamic acid (57). Recalcitrant epistaxis can be further addressed with Nd:YAG (58), argon, and potassium titanyl phosphate (KTP) laser treatment. CO_2 lasers have also been used, though with less success (59). Attention to preventing injury to large areas of perichondrium, septal cartilage, and abutting nasal cavity mucosal surfaces can limit complications of septal perforation and synechiae. Due to severe potential complications, such as cerebrovascular events, embolization is preserved for severe and unresponsive epistaxis (60). Septodermoplasty involves replacing delicate nasal mucosa with stronger, keratinized split-thickness skin graft. A recent description of this technique in combination with bilateral inferior turbinectomies resulted in cessation or marked reduction of epistaxis in 90% of patients with HHT (61). Young's procedure, involving closure of the nasal vestibule, is mentioned as a last resort. Though likely to resolve epistaxis, side effects are severe and include loss of orthonasal olfactory input and creation of obligate mouth breathing (55). An algorithmic approach has been proposed for treatment of HHT epistaxis and is based on requirements of blood transfusion (59).

Advances in medical therapeutics for HHT show several promising avenues for modern treatment. Recent studies are showing potential for a role of thalidomide, which acts through an antiangiogenic-type mechanism. Enhanced mural wall coverage with endothelial cells was demonstrated in animal and human subjects. In a very small number of patients tested, thalidomide appeared to show promise with decreases in the number of nose bleeds incurred and number of blood transfusions required, and increased hemoglobin concentration, presumably due to decreased epistaxis (52). Bevacizumab, a monoclonal VEGF inhibitor has been shown to significantly improve epistaxis severity (62) when applied topically (intranasal), locally injected, or intravenously administered (55). Complications from bevacizumab injections include septal perforation, though this risk may be avoided if septal cartilage is avoided in injection with concurrent laser vessel coagulation (62). In a double-blind placebo controlled trial that enlisted 21 patients, antiestrogen therapy showed a significant decrease in frequency and severity of epistaxis (63). Whether these agents will have a significant role in the future treatment of HHT, will require additional investigation and remains to be answered.

Another important hematologic entity that may manifest in the sinonasal cavity is thrombocytopenia. Thrombocytopenia may occur secondary to impaired platelet production, excessive platelet destruction, sequestration in hypersplenism, or secondary to dilutional effect, such as in high volume transfusion. Impaired bone marrow production of platelets may occur due to infiltration in neoplastic processes, infection, or from toxic response to pharmacologics. Excessive platelet destruction can occur in aberrant immune responses, such as autoimmune thrombocytopenic purpura. Platelets may also be reduced in consumptive processes such as disseminated intravascular coagulation or thrombotic thrombocytopenic purpura. Regardless of the etiology of thrombocytopenia, the most common presenting symptom is epistaxis (64). Treatment should be aimed at addressing the underlying pathophysiologic issue.

Coagulation disorders may also manifest with severe, recurrent epistaxis. Acquired coagulopathies secondary to disseminated intravascular coagulation, liver disease, and vitamin K deficiency are more common than inherited coagulopathies. von Willebrand disease (vWD) is an autosomal dominant disorder. It is the most common hereditary bleeding disorder, affecting approximately 1% to 2% of the population (65). Epistaxis was the most common symptom and otolaryngologic surgery was found to be the surgical area with the highest proportion of postoperative bleeding in vWD (44%) (66). Preoperative evaluation and screening varies, though a recent cost-effective strategy analysis recommends not performing preoperative screening (67). In fact, the American Society of Pediatric Otolaryngology recommends preoperative coagulation testing only when indicated by history and physical examination. Obtaining a hematology consultation prior to pursuing surgical treatment with vWD is recommended. The medical goal is to correct the coagulation defect—low levels of FVIII coagulant activity and primary hemostasis. The surgical goal should be meticulous, atraumatic dissection minimizing intraoperative bleeding. Desmopressin acetate has been used with effectiveness that varies on the type of vWD mutation. Several protocols have been described. A recent prospective study examines a protocol used in pediatric adenoidectomy on patients with vWD. A preoperative desmopressin challenge (0.3 μg/kg in 50 mL of isotonic saline over 30 minutes) is performed. If activated partial thromboplastin time and factor VIII coagulant improved without evidence of side effects and with a negative history of seizures, desmopressin was used. Alternatively, factor VIII concentrate was used. Desmopressin was administered 1 hour preoperatively, then daily for 1 to 4 days. Tranexamic acid was administered daily at 10 mg/kg until postoperative day 7. In 41 patients with vWD, 5% had immediate postoperative hemorrhage and 0% had delayed hemorrhage (68). A recent cohort study showed treating with desmopressin alone resulted in comparable posttonsillectomy bleeding rates as in non-vWD (69). Aminocaproic acid (Amicar) (70) has been used as an alternative to tranexamic acid and is administered IV or orally at a dose of 50 to 70 mg/kg every 4 to 6 hours. Randomized prospective controls delineating an ideal, cost-effective regimen are needed.

Hemophilia A and B are X-linked factor VIII and IX deficiencies respectively. Presentation may be from intractable epistaxis or from upper airway bleeding. Of paramount importance is ensuring the patient has a protected airway followed by controlling the source of bleeding. Intravenous

concentrates of the deficient factor are used to treat severe bleeding episodes. Similarly to vWD, a hematology consult should be obtained prior to proceeding with surgical intervention.

OTHER

Reactive processes to trauma (such as giant cell reparative granuloma), infectious agents (*Mycobacterium, Actinomyces,* fungi) and foreign bodies (cocaine-induced granuloma) may lead to inflammatory and/or granulomatous lesions. These processes should be considered in the differential of many of the pathologies discussed above, but are out of the scope of this topic as they are reactions to local triggers.

Furthermore, additional systemic diseases manifest in the nasal and paranasal sinuses. In fact, the list can easily be extended well beyond the list of systemic diseases discussed in this chapter. We have attempted to highlight the more common diseases that the otolaryngologist will likely encounter. The ability to direct the diagnosis and care of these patients should equip the surgeon with the ability to improve these patients' lives.

HIGHLIGHTS

- Medical interventions are often the basis for treatment of systemic diseases, though surgical expertise is necessary in particular instances, such as when biopsy or other diagnostic is indicated.
- Early diagnosis and treatment results in improved therapeutic outcomes and prevents disease progression with associated complications.
- Systemic disease processes are often manifested in the sinonasal cavities. The highly vascular mucocutaneous area lends otolaryngologists the opportunity to observe some of the first pathologic changes and provide early diagnosis of these conditions.
- Understanding and addressing the underlying pathophysiology oftentimes allows optimal treatment of systemic conditions. For example, immunomodulation is the cornerstone of addressing autoimmune pathology.
- There is significant overlap in the presentation of many of the systemic diseases. This requires the astute clinician-surgeon to take into account the entirety of the patient's history, directed diagnostic workup, and disease responses when considering evaluation and management.
- The relative rarity of systemic conditions makes formulating strong randomized prospective based evidence a challenge; however, this must remain the goal in an attempt to achieve optimization of patient care.

Epistaxis

32

Benjamin S. Bleier *Rodney J. Schlosser*

EPIDEMIOLOGY

Incidence

Epistaxis is a common problem ranging from minor traces of blood or clot to isolated massive bleeds that may be life-threatening. Most patients have self-limiting episodes that do not require medical care and thus the true incidence is unknown. In spite of this, there is an estimated global lifetime incidence of 60% (1). From an otolaryngologic standpoint, epistaxis may account for up to 33% of emergency admissions with a median age of 70 years (2). The overall age of onset describes a bimodal distribution with an increased incidence in childhood followed by a peak incidence in the sixth decade. While younger individuals overwhelmingly present with minor bleeding derived from the anterior septum, older patients are far more likely to present with a severe acute bleed. Of note, epistaxis in children under 2 years old is rare and should raise the suspicion of an underlying illness or child abuse (3).

Some studies have also suggested a seasonal variation in the incidence of epistaxis with episodes being more common in the fall and winter. While this may reflect an overall decrease in the ambient humidity during the colder months these findings have not been universally accepted (4).

Etiology

When considering the management and prognosis of patients with epistaxis, it is useful to classify the bleeding site into anterior or posterior. There is no precise anatomic distinction between the two; however, anterior bleeds are more common (5) and tend to originate on the septum while posterior bleeds are generally higher volume and arise laterally from branches of the sphenopalatine artery (SPA). Bleeding may also be classified as primary (or idiopathic), which accounts for the majority of cases, or secondary, which results from known local or systemic factors. Spontaneous mucosal bleeding may occur in all age groups but is particularly problematic in children as this region is subject to mucosal desiccation, irritant exposure, and digital trauma. While the advent of the endoscopic era has greatly improved our ability to identify and manage the specific site of bleeding, many patients presenting to a general emergency department will continue to lack a definitive diagnosis and thereby remain in the idiopathic category.

Secondary epistaxis refers to bleeding resulting from a known cause (Table 32.1). Any disorder that disrupts the mucosal epithelium or impairs clotting and platelet function may result in nosebleeds. Management of secondary epistaxis requires addressing the underlying etiology and thus it is useful to subcategorize it into local or systemic causes.

There are many local causes of epistaxis including sinonasal tumors, granulomatous disease, and septal perforation; however, the majority are iatrogenic or posttraumatic. In adolescent males with unilateral epistaxis and nasal obstruction, the presence of a juvenile nasopharyngeal angiofibroma should be ruled out (6). Postoperative bleeding following endoscopic skull base surgery also deserves special consideration not only because of the potential for exposure of critical neurovascular structures but also for the fact that blind packing may potentiate a neurologic catastrophe. Isolated vascular lesions such as hemangiomas, pyogenic granulomas, and telangiectasias are another local source of epistaxis that can sometimes be difficult to identify but may result in recurrent large volume bleeding (Fig. 32.1).

In patients with epistaxis and multiple cutaneous, lip, oral, and intranasal telangiectasias, the diagnosis of hereditary hemorrhagic telangiectasia (HHT) must be considered (Table 32.2). This entity represents both a diagnostic and

TABLE 32.1 SECONDARY CAUSES OF EPISTAXIS

Local	Systemic
Trauma (blunt, digital, devices)	Drugs (Coumadin, NSAID, aspirin)
Surgery (sinus, endoscopic skull base)	Bleeding diatheses
Anatomic deformities (septal deviation, spurs)	Hematologic malignancy
Sinonasal tumors (benign, vascular, malignant)	Hypertension
Foreign bodies	Hepatobiliary disease
Inflammation, granulomatous disease	Alcoholism
Topical medications	Vascular/connective tissue disorders
Low humidity	Malnutrition

TABLE 32.2 CURAÇAO CRITERIA FOR THE CLINICAL DIAGNOSIS OF HHT

Criteria	Description
Epistaxis	Recurrent
Telangiectasia	Multiple at characteristic sites (lips, oral cavity, fingers, nose)
Visceral lesions	GI telangiectasia; pulmonary, cerebral, hepatic, spinal AVMs
Family history	A first degree relative with HHT according to these criteria
0–1 criteria	Unlikely
2 criteria	Possible or suspected
3 or more criteria	Definite

From Faughnan ME, Palda VA, Garcia-Tsao G, et al. International guidelines for the diagnosis and management of hereditary haemorrhagic telangiectasia. *J Med Genet* 2011;48(2):73–87.

therapeutic challenge as patients may have underlying life-threatening intracranial, gastrointestinal (GI), hepatic, and pulmonary arteriovenous malformations, (AVMs) which must be concomitantly evaluated. A recent international guidelines statement also recommended genetic testing of all patients to allow for identification of family members who have not yet met the diagnostic criteria for HHT (7). Due to the presence of multiple local sources of potential bleeding, HHT patients often require repeated and aggressive epistaxis interventions, which is covered later in the chapter.

Systemic causes of epistaxis typically relate to disorders or medications resulting in impaired clotting or platelet function including renal failure, NSAID, and salicylate use. For example, low-dose aspirin has been shown to increase the risk of epistaxis when compared with placebo (19.1% vs. 16.7% respectively) (8). Warfarin use may also

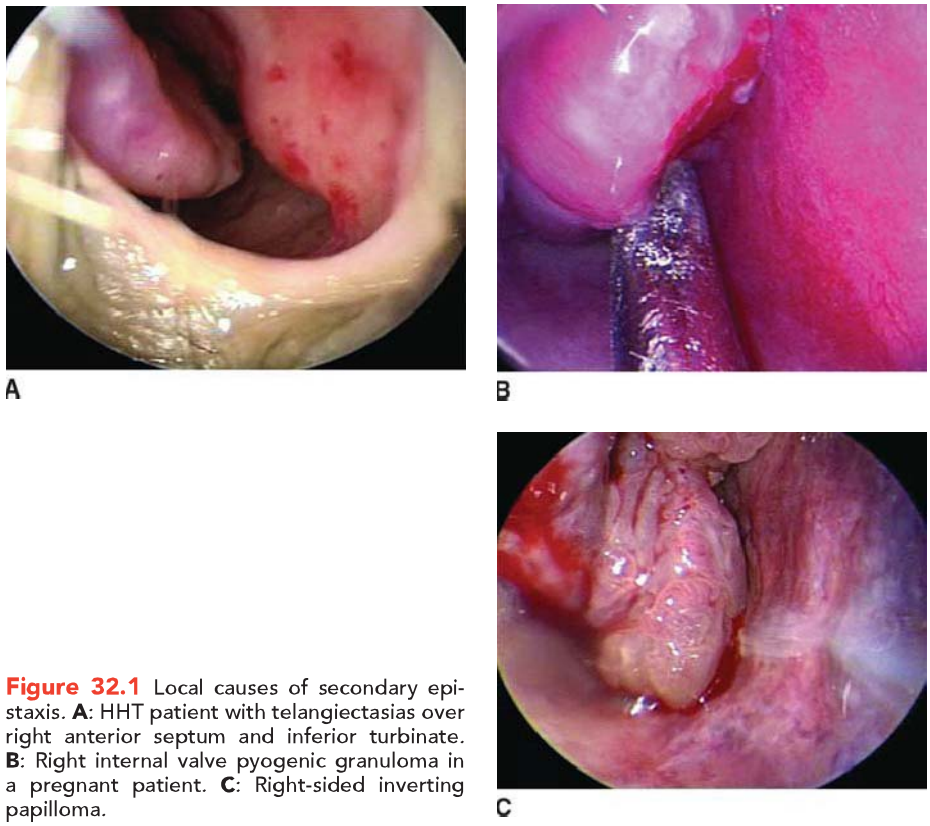

Figure 32.1 Local causes of secondary epistaxis. **A**: HHT patient with telangiectasias over right anterior septum and inferior turbinate. **B**: Right internal valve pyogenic granuloma in a pregnant patient. **C**: Right-sided inverting papilloma.

predispose to epistaxis, particularly when the INR is not tightly controlled. Epistaxis patients should also be questioned regarding the use of over-the-counter supplements including garlic, ginkgo, or ginseng, which can result in a mild systemic coagulopathy (9).

Inherited bleeding diatheses, the most common of which being hemophilia A followed by von Willebrand disease, and hematologic malignancies are less common causes of epistaxis although they should be considered in any broad differential diagnosis. Hepatobiliary disease may also result in coagulopathy related epistaxis secondary to a reduction in the production of vitamin K–dependent factors (prothrombin, factors VII, IX, and X, proteins C and S).

While hypertension exacerbates epistaxis, it has not been shown to be an independent causative factor (10). When hypertension is suspected in the setting of epistaxis, it should be investigated and managed appropriately.

VASCULAR ANATOMY OF THE NOSE

The nasal mucosa is supplied by a robust vascular arcade derived from both the internal and external carotid arterial systems. These arborizations travel within the mucoperiosteal/perichondrial layers except for small branches that traverse bony canals within the inferior and middle turbinates (Fig. 32.2).

The Internal Carotid Arterial System

The internal carotid artery supplies the nose via the ophthalmic artery, which traverses the superior orbital fissure to give off the anterior and posterior ethmoidal arteries. These arteries penetrate the anterior and posterior foramina within frontoethmoid suture line to travel in bony canals within the ethmoid roof finally entering the anterior cranial fossa through the lateral lamella of the cribriform plate. Intracranially, both arteries give rise to terminal branches that supply the anterior fossa dura and superior nasal cavity.

Occasionally, the bone over the paraclival and parasellar carotid may be thin or dehiscent within a well pneumatized sphenoid sinus. This anatomic relationship provides the opportunity for massive epistaxis derived from this segment of the internal carotid artery secondary to trauma or idiopathic aneurysmal/pseudoaneurysmal dilatation.

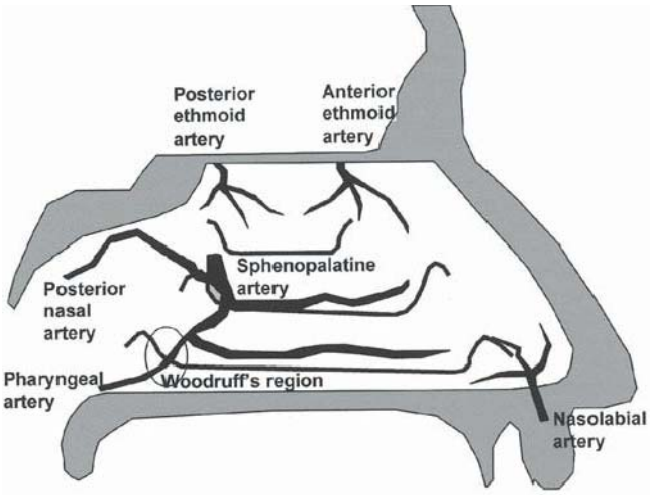

Figure 32.2 Vascular contributions to the nasal mucosa.

The External Carotid Arterial System

The external carotid system provides contributions to the nasal mucosa via the facial artery and internal maxillary artery (IMA). Anteriorly, the facial artery branches give rise to the superior labial artery, which projects a septal branch onto the anterior septum. Posteriorly, the IMA traverses the pterygopalatine fossa where it undergoes a complex series of branching patterns prior to entering into the posterolateral nasal cavity as the SPA via the sphenopalatine foramen. This branch carries the greatest volume of blood to the nose and is the source of most posteriorly based bleeds.

The crista ethmoidalis represents an important landmark for the position of the SPA and is located anteromedial to the sphenopalatine foramen in almost all cases (11). Although the number of SPA branches varies according to the reports, in one study 73 of 75 cadaveric specimens demonstrated 2 or more branches of the SPA medial to the crista ethmoidalis (12). Consequently, when performing an SPA ligation it is essential to explore the lateral wall of the nose, a maneuver that often requires resection of the crista ethmoidalis to enhance exposure. Once the SPA exits the sphenopalatine foramen, its more distal posterolateral contributions may continue to exhibit significant variability. Lee et al. noted that in 38% of cases, some portion of the artery may run anterior to the posterior maxillary wall. Furthermore in 50% of cases, a branch of the inferior turbinate artery extends anterosuperiorly to supply the posterior fontanel (13). These studies suggest that in a significant portion of patients, a large tributary of the SPA may be encountered within the posterior maxillary fontanels.

The posterior nasal branch of the SPA passes over the anterior sphenoid face approximately 1 cm above the choanal arch and travels anteriorly to anastomose in Kiesselbach plexus.

Venous Drainage

Generally speaking, the intranasal veins follow the course of the arteries within the nasal mucosa. However, there are mucosal emissary and pterygoid plexus branches that lead to the cavernous sinus. In 1949, Woodruff described a venous plexus located in the posterior section of the nasal cavity adjacent to the inferior turbinate. This

region comprises large, thin-walled veins enclosed by a thin mucosal layer, which is relatively devoid of other structures (14).

Vascular Anastomoses

The anterior nasal septum represents a highly consistent anastomotic loop (15) supplied by the septal branch of the SPA, the greater palatine artery via the incisive canal, the superior labial artery, and branches from the anterior ethmoidal artery superiorly. Within the literature, this area has been referred to as both Little's area after James Little, an American physician who described four patients with a bleeding ulcer at this site, and Kiesselbach's plexus after Wilhelm Kiesselbach, who subsequently described three patients with bleeding from distended vessels from this site.

CLINICAL MANAGEMENT

Initial Management of Acute Epistaxis

The vast majority of nose bleeds are self-limited with minimal blood loss. However, in rare situations bleeding can be significant and even fatal and thus each patient should be appropriately evaluated. A clear and logical plan of action should therefore be adopted. The American Heart Association Basic Life Support protocol guides prioritization of consideration in the management of emergent situations. As applied to epistaxis, the first consideration is always protection and management of the airway. Once this is deemed secure, attention may then be turned toward controlling the bleeding while simultaneously establishing vascular access for the provision of volume replacement and hemodynamic support.

The patient should be seated with the body tilted forward and mouth open. Assuming a recumbent position should be avoided in order to reduce venous pressures and prevent aspiration. The patient should be advised to compress the upper lateral cartilages for 10 to 15 minutes without releasing in an effort to tamponade the anterior septal vasculature. If available, topical decongestants such as oxymetazoline HCl may also be applied. For epistaxis that persists or is not controlled by this simple measure, direct visualization and more aggressive measures are mandated.

Assessment and treatment should take place in a room with monitoring, suction, adequate lighting, and preferably endoscopic equipment. Universal precautions should be strictly obeyed as the risk of blood exposure is high (16). Blood clot should be evacuated followed by topicalization using a vasoconstrictor and anesthetic agent. The nose may initially be examined with a nasal speculum and headlight. In the case of anterior bleeds, a site may be identified using this method, however the practitioner should not hesitate to proceed to rigid endoscopy for more posteriorly located sources.

Endoscopic-Assisted Nasal Cautery

After attaining adequate topicalization the nasal cavities can be carefully examined with the aid of a rigid endoscope and gentle suction. When possible, the entirety of the nasal cavity including the inferior and middle meatuses, sphenoethmoidal recess, and nasopharynx should be visualized to exclude the possibility of multiple bleeding sites or the presence of a mass or lesion. The specific site of bleeding can often be clearly identified and subsequently controlled. The specific hemostatic technique used is highly dependent on the availability of equipment and the experience of the practitioner. These may include chemical cautery, mono or bipolar diathermy, or local application of absorbable hemostatic matrices. Monopolar cautery near the orbital apex, pterygopalatine fossa, or within the sphenoid proper should be used with great caution as neuropraxia can occur from propagation of current through the adjacent neurovascular structures. In the setting of HHT, laser-assisted cauterization is especially useful. This may be achieved with an argon or potassium titanyl phosphate (KTP) laser by first applying the laser energy to the periphery of the lesion prior to focusing on the lesion itself.

Silver nitrate application is a common method of chemical cautery, particularly for anterior bleeds. The stick should be applied precisely to the bleeding point and held for only a few seconds. The white coagulum that forms is thought to be due to protein denaturation. It is generally taught that cautery must not be applied bilaterally to the anterior nasal septum simultaneously to avoid the potential risk of septal perforation. While this is largely anecdotal and highly unlikely, the resultant perforation can be quite difficult to manage and thus bilateral cauterization is not recommended.

Absorbable Nasal Packing

If identification of a bleeding site is deemed ineffective or not possible, the practitioner should next proceed to nasal packing. Packing refers to the placement of any material within the nose in an effort to control or limit the egress of blood. While a wide variety of products exist, globally they may be divided into absorbable and nonabsorbable materials.

The development of biodegradable topical hemostatic agents has enabled a shift away from the exclusive use of nonabsorbable packing. These materials include oxidized cellulose, microfibrillar collagen, porcine or bovine gelatin, and human thrombin solutions. While these materials provide less mechanical tamponade, they are able to penetrate the interstices of the sinonasal labyrinth in order to achieve direct contact with the area of bleeding (Fig. 32.3A). In one Baxter-sponsored randomized nonblinded trial comparing the gelatin-based agent FloSeal (Baxter Biosurgery) to nonabsorbable nasal packing,

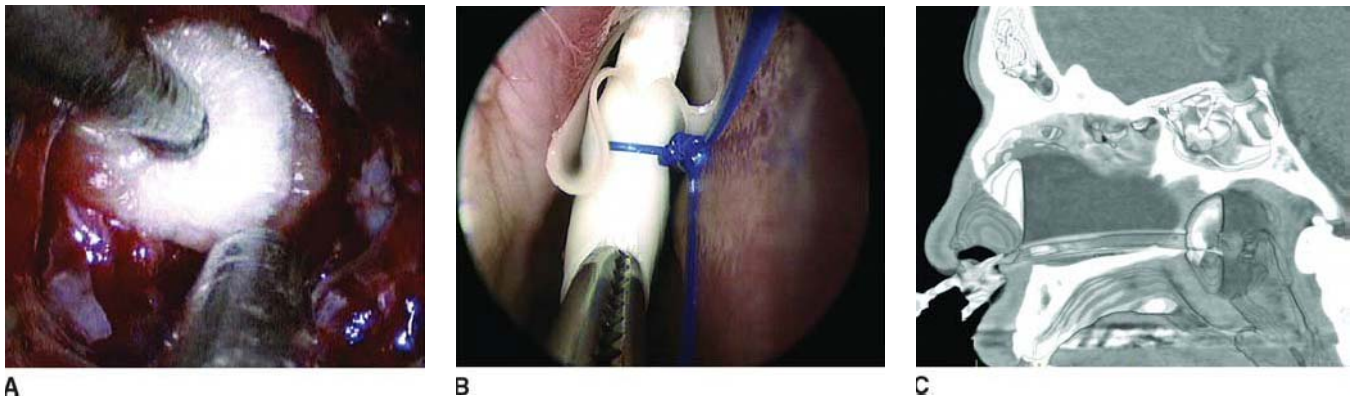

Figure 32.3 Application of absorbable and nonabsorbable packing materials. **A**: Placement of a hemostatic gelatin solution over site of bleeding during tumor removal. **B**: Insertion of a PVA sponge into the right nasal cavity. The sponge is wrapped in the finger of a nonlatex glove to prevent mucosal adhesions. **C**: Sagittal CT demonstrating proper positioning of an inflated balloon catheter within the nasopharynx.

FloSeal was found to significantly reduce the rate of rebleeding at 1 week (17). While patient satisfaction and comfort were also improved with the absorbable agent, it should be noted that these agents tend to be more expensive than traditional packing.

While multiple materials have been shown to promote hemostasis, most act in a similar manner to provide a stable platform for fibrin and platelet aggregation. An alternative mechanism for hemostasis has been exploited by a new class of aminopolysaccharide known as chitosan. Chitosan is a mucoadherent biocompatible polymer that has known tissue-adhesive and drug-eluting properties (18). Chitosan is also strongly cationic and is able to attract red blood cells at the site of a vascular injury thereby promoting hemostasis independent of the innate clotting cascade. A chitosan/dextran gel was studied by Valentine et al. (19) and found to be both hemostatic and capable of inhibiting adhesion formation following sinus surgery.

Nonabsorbable Nasal Packing

If absorbable packing is unavailable or ineffective, larger nonabsorbable packs may be considered. Traditionally this was achieved by using layered ribbon gauze; however, modern expandable polyvinyl acetate (PVA) polymer sponges have largely replaced this practice (Fig. 32.3B). No statistically significant difference has been demonstrated between the use of ribbon gauze and a PVA sponge, but the latter is much easier to insert and more comfortable for the patient (20). Nasal packing containing lipid materials such as petroleum should be used with caution as they have been shown to be associated with myospherulosis, which may lead to increased adhesion rates and poorer outcomes (21).

In massive posterior bleeds, sponge packs may fail to adequately control the epistaxis. In these cases, expandable devices may be required where balloons are inflated in the nasopharynx and nasal cavity in order to tamponade the entire nasal cavity (Fig. 32.3C). If nasal balloons are unavailable, a 14 Fr Foley catheter inflated with 15 mL of saline may also be used to tamponade the nasopharynx and provide a foundation against which anterior packing may be placed.

As with any acute intervention, nasal packing does carry several theoretical risks. Packing, particularly if placed bilaterally, may compress the septal mucosa resulting in ulceration and potential subsequent perforation. Bilateral posterior packs can also theoretically induce the nasopulmonary reflex leading to hypercarbia, hypoxia, and decreased lung volume (22,23), and thus hospital admission with telemetry monitoring is recommended. Toxic shock syndrome (TSS) is a rare possibility if packs are left *in situ* for several days. TSS results from a staphylococcal exotoxin and typically presents within the first 24 hours although it has been reported up to 5 weeks following sinus surgery. Of note, TSS is not associated with any particular type of packing and it can neither be predicted nor prevented by prophylactic antibiotics (24). Given that most packs are removed after 1 to 7 days, the need for antibiotics is controversial although they are still commonly used.

Management of Comorbid Systemic Factors

Once bleeding has been controlled, the systemic effects of blood loss should be considered. If the patient is hypovolemic fluids and plasma expanders may be administered. Blood transfusion should be considered following a significant loss of blood volume with associated hemodynamic derangement. In patients who are otherwise healthy, the risks associated with transfusion should be weighed against the patient's overall hemodynamic status and availability of alternative methods of fluid resuscitation.

Management of hypertension, thrombocytopenia, and coagulopathies will also aid in epistaxis management and

prevention of recurrence. Appropriate reversal of iatrogenic platelet or clotting factor dysfunction is beyond the scope of this chapter however specialist consultation with attention toward the risks of reversal in the setting of the underlying disorder is generally recommended.

SURGICAL MANAGEMENT

Surgical management of epistaxis is typically reserved for those patients whose bleeding is refractory to more conservative therapies, have chronic or recurrent episodes, or have had a single life-threatening bleed. The choice of procedure depends on a variety of preoperative factors including, most importantly, the suspected site of bleeding. The goal of these procedures is to isolate and ligate the offending arterial input while preventing disruption of adjacent structures and preserving normal sinonasal function.

Sphenopalatine Artery Ligation

The SPA can be exposed endoscopically by raising a posterolateral mucosal flap over the orbital process of the palatine bone. As the flap is elevated, the crista ethmoidalis and accessory posterolateral neurovascular bundles will be encountered (25). The SPA can then be identified and dissected from the surrounding tissue using a ball tipped probe. The artery may be occluded using clips, bipolar cautery, or some combination thereof. If bipolar cautery is to be used, it should precede clip application as tissue desiccation may shrink the tissue away from a previously applied clip (Fig. 32.4A). Dissection should be continued posteriorly toward the choanal arch to rule out the possibility of an additional posterior nasal branch that may enter the nose through a separate foramen posterior to the SPA. Alternatively, the artery may be traced laterally into the pterygopalatine fossa in order to ligate it prior to its terminal bifurcation. The mucosal flap may then be replaced that hastens remucosalization and often can avoid the need for nasal packing.

Ethmoidal Artery Ligation

The ethmoidal vessels may be accessed within the orbit using a limited medial canthal (Lynch) incision. This incision is often broken into a seagull shape to prevent linear contracture postoperatively. The anterior ethmoidal artery is identified running from the periorbita into its foramen at the frontoethmoidal suture (Fig. 32.4B). This suture line is typically located immediately superior to the medial canthus and care should be taken not to disrupt the canthal tendons during the periorbital dissection. The posterior ethmoidal artery may be found approximately 12 mm posterior to the anterior ethmoidal artery. Once exposed, the arteries can be clipped or divided following diathermy or suture ligature. Some authors have also described endoscopic identification and cauterization of the anterior ethmoid artery either within the ethmoid roof or intraorbitally following removal of the lamina papyracea (26).

Other Sources of Intranasal Bleeding

Experience with surgical management of epistaxis has also formed the basis of the principles of vascular control in sinonasal and skull base tumor resection. Previously described endoscopic landmarks may be used to identify the vascular supply of lesions in the setting of highly distorted anatomy providing the opportunity for directed arterial ligation using bipolar cautery, endoscopic vascular

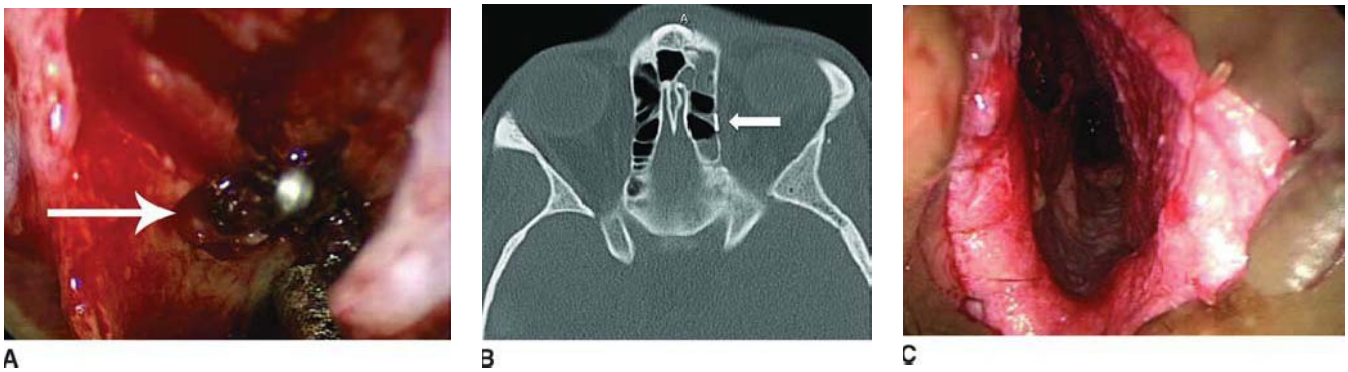

Figure 32.4 Examples of surgical management of epistaxis. **A**: Clip placed over the SPA after bipolar diathermy (*white arrow* indicates origin of vessel at sphenopalatine foramen following resection of the crista ethmoidalis). **B**: Axial CT image demonstrating proper placement of a clip over the intraorbital origin of the anterior ethmoid artery (*white arrow*). **C**: Endoscopic view of the right internal valve following septodermoplasty in an HHT patient with replacement of the mucosa using an allograft.

clips, or more recently ultrasound energy (27). High volume venous plexus bleeding may also be encountered during these procedures derived from the cavernous, basilar, or pterygoid plexuses depending on the site of surgery. Absorbable hemostatic agents have also been used successfully in the management of these areas as they are capable of permeating through the venous channels providing localized tamponade as well as scaffolding for clot formation.

Rarely, bleeding from the proximal internal carotid system may occur secondary to aneurysm/pseudoaneurysm, trauma, or iatrogenic injury. Endoluminal occlusion or stenting is typically required in these instances for definitive vascular control. However, the exposed endosphenoidal portion of the carotid must be also dealt with to prevent further complications related to exposure of the vessel to the sinonasal milieu. In these situations a wide sphenoidotomy may be performed with rotation of a pedicled nasoseptal flap to provide reliable and robust coverage of the dehiscent region.

Septodermoplasty

In the setting of HHT refractory to multiple prior attempts at monopolar, argon, or KTP laser cauterization, the affected mucosa may require wide resection via septodermoplasty. In this procedure, the nasal mucosa is excised in a supramucoperichondrial plane and replaced by an allograft or split thickness skin graft taken from another site such as the thigh. The graft is then sutured or fixed by mattress sutures (Fig. 32.4C). The operation can be performed bilaterally in a staged fashion. While good control is often achieved in the short term, eventually bleeding will often recur as new lesions develop in different sites of the nose (28).

ENDOVASCULAR EMBOLIZATION

In patients who are poor surgical candidates, selective endovascular embolization of the internal maxillary arborizations may be attempted via catheterization of the femoral artery. Embolization has been described using microcoils, polyvinyl alcohol particles, dextran microspheres, absorbable gelatin sponge, or detachable balloons and has reported success rates of 60% to 90% (29). However, the proximal location of the arterial occlusion relative to surgical ligation allows for the formation of collateral arterial inputs, which may result in recurrent epistaxis. Reported complications include facial pain, trismus, amaurosis, and ophthalmoplegia. This method also carries a significant risk of embolic stroke and ultimately, even death. The combination of increased risk, poorer long-term control rates, and inability to address the internal carotid system suggests that embolization should be utilized only after surgical arterial ligation has been attempted or ruled out as a possibility.

HIGHLIGHTS

- Epistaxis most commonly originates from the anterior septum and is self -limited in nature. It has a bimodal age distribution with posterior and more severe bleeding being more common in the sixth decade.
- Secondary causes of local epistaxis may frequently be identified on rigid endoscopy. The presence of a sinonasal tumor should be ruled out in patients presenting with unilateral epistaxis and concomitant nasal obstruction.
- Many over-the-counter and herbal therapies may result in systemic coagulopathies or platelet dysfunction. A complete patient history should always include a review of nonprescription medications.
- In patients with HHT, work up for the presence of AVMs and genetic testing of family members is currently recommended. These patients will often require multiple surgical interventions including repeated laser assisted cauterization and potential septodermoplasty.
- When treating a patient with acute epistaxis, adherence to universal precautions and management of the airway are paramount. The choice of intervention should escalate from conservative to more aggressive as the individual situation demands.
- Surgical management of epistaxis should be considered if more conservative measures have failed or in the setting of a single life-threatening bleed. The goal of surgery is to occlude the offending artery while preserving normal sinonasal function.
- Endovascular embolization may be less effective than surgery, carries increased associated risks, and is typically unavailable for bleeding derived from internal carotid artery arborizations. While this intervention is appropriate in many instances, it should always be weighed against the practicality and efficacy of endoscopic arterial ligation.

Acute Rhinosinusitis

33

Elizabeth K. Hoddeson *Sarah K. Wise*

ABSTRACT

This chapter provides an in-depth discussion of acute rhinosinusitis, beginning with definitions of rhinosinusitis and its epidemiology and economic impact. The pathophysiology of acute viral rhinosinusitis and acute bacterial rhinosinusitis are reviewed. Next, a discussion of appropriate components of patient history and physical examination, as well as indications for radiologic imaging in the setting of acute rhinosinusitis, is undertaken. Finally, acute rhinosinusitis treatment modalities and complications are highlighted.

Sinusitis is defined as inflammation of the paranasal sinuses, and *rhinitis* as inflammation within the nasal cavity. In 1996, the Task Force on Rhinosinusitis, sponsored by the American Academy of Otolaryngology-Head and Neck Surgery, the American Rhinologic Society, and the American Academy of Otolaryngologic Allergy recommended the replacement of the term sinusitis with *rhinosinusitis*. This recommendation was based on rhinitis commonly preceding sinusitis, as well as the fact that sinusitis without rhinitis is extremely rare (1).

There are multiple potential contributors to the development of rhinosinusitis, including both host and environmental factors (Table 33.1). Examples of host characteristics that may contribute to rhinosinusitis include congenital conditions, such as cystic fibrosis or immotile cilia syndrome, allergic states or altered immune function, anatomic abnormalities, systemic diseases, and neural mechanisms. Some external factors that can result in rhinosinusitis are infectious agents, trauma, exposure to noxious chemicals or medications, and surgical changes.

In a given patient with rhinosinusitis, many host and environmental factors may be present simultaneously. For example, a patient with cystic fibrosis who has altered anatomy from prior surgery may present with an acute bacterial infection of the sinonasal cavities. Therefore, defining rhinosinusitis based on etiology could become very complicated. For this reason, the Task Force on Rhinosinusitis elected to classify this disorder based on temporal factors (1) (Table 33.2). *Acute rhinosinusitis* is defined by the presence of the condition for up to 4 weeks (1). *Chronic rhinosinusitis* can be diagnosed after the condition has been present for at least 3 months (1). The term *subacute rhinosinusitis* is used when the duration is between 4 and 12 weeks (2). When there are four or more episodes of acute bacterial rhinosinusitis (ABRS) in 1 year with resolution of symptoms in between episodes, the diagnosis is *recurrent acute rhinosinusitis* (2).

The Task Force on Rhinosinusitis examined the definition, diagnosis, management, and outcome analysis of rhinosinusitis in order to facilitate patient care and research (1,3). These efforts have been furthered by additional panels in 2004 (sponsored by the American Academy of Otolaryngology-Head and Neck Surgery, the American Rhinologic Society, the American Academy of Otolaryngologic Allergy, the American Academy of Allergy, Asthma, and Immunology, and the College of Allergy, Asthma, and Immunology) and in 2007 (sponsored by the Academy of Otolaryngology-Head and Neck Surgery Foundation) (2–4). The goal of this chapter is to utilize these resources in addition to current literature to review acute rhinosinusitis, including its epidemiology, pathophysiology, clinical presentation, the role of imaging, current treatment recommendations, and complications.

EPIDEMIOLOGY

Rhinosinusitis is a significant health care problem, believed to be increasing in both incidence and prevalence (1). According to the 2009 Summary Health Statistics for U.S. Adults

TABLE 33.1 PREDISPOSING FACTORS AND CONTRIBUTORS TO THE DEVELOPMENT OF RHINOSINUSITIS

Host Factors
- Congenital conditions
  - Examples: Cystic fibrosis; Immotile cilia syndrome
- Allergic or immune conditions
  - Examples: Environmental allergy; Human immunodeficiency virus; Immune suppressive agents (i.e., chemotherapy); Bone marrow transplant
- Paranasal sinus anatomic abnormalities
  - Examples: Middle turbinate concha bullosa; Obstructing frontal recess cells; Severe nasal septal deviation
- Systemic inflammatory conditions
  - Examples: Wegener granulomatosus; Sarcoidosis
- Presence of neoplasm

Environmental Factors
- Infectious agents
  - Examples: Viruses; Bacterial pathogens
- Trauma
  - Examples: Resultant mucosal edema and inflammation; Altered bony anatomy
- Exposure to noxious chemicals
- Iatrogenic
  - Examples: Medications; Surgery

National Health Interview Survey, over 29.3 million adults in the United States had been diagnosed with rhinosinusitis by a physician (5). This comprises approximately 12.6% of the United States population. It has been previously reported that the prevalence of rhinosinusitis is almost twice as common in women (20.9%) as in men (11.6%) (5,6). Other demographic factors, such as geography and race, may play a role as well. The frequency of rhinosinusitis is generally lower in the Western United States (12.1%), as compared to Southern regions (19.5%) (5). Non-Hispanic white persons (17.5%) and non-Hispanic black persons (15.7%) have approximately twice the prevalence of rhinosinusitis as Hispanics (8.6%) (5,6). While prior survey data have not demonstrated that poverty status is relevant to the frequency of rhinosinusitis, regional variation in the frequency of rhinosinusitis may potentially be attributable to differences in air quality, including presence of pollutants and allergens (5,6).

TABLE 33.2 TEMPORAL CLASSIFICATION OF RHINOSINUSITIS

Term	Duration of Symptoms
Acute rhinosinusitis	Up to 4 wk
Subacute rhinosinusitis	4–12 wk
Chronic rhinosinusitis	Longer than 12 wk
Recurrent acute rhinosinusitis	>4 acute episodes in 1 y with resolution between episodes

Economic Burden of Acute Rhinosinusitis

The economic impact of rhinosinusitis is staggering. Although references on this topic are few, thorough investigations were published in 1999 and in 2004, based on the 1996 and 1998 National Health Interview Surveys, respectively (6,7). The direct annual health care cost was estimated at $5.8 billion in 1996, of which about 30% was incurred to treat pediatric patients 12 years of age or younger (5,7). Nearly 90% of the expenditures were associated with ambulatory or emergency department visits (5,7). In 1996, there were 16.7 million outpatient physician, hospital office, and emergency department encounters attributed to the primary treatment of sinusitis (7). The majority of outpatient office-based physician care for sinusitis was delivered by primary care physicians (64.9% by family medicine and internal medicine doctors, and 15.4% by pediatricians) (7). Overall, outpatient visits with sinusitis as the primary diagnosis accounted for 36% of total medical expenditures in 1996, and medications to treat this condition added another 17% (7). In 1992, Americans spent $200 million on prescription medications and more than $2 billion on over-the-counter medications to treat sinusitis (8). The Integrated Health Interview Series for 1997 to 2006 shows that 55.8% of patients with sinusitis spend more than $500 annually on health care, higher than the amount spent by those suffering with chronic diseases such as chronic bronchitis, hay fever, ulcer disease, and asthma (9).

The indirect costs of rhinosinusitis are, as one would expect, not insignificant and are also increasing. The number of total restricted activity days due to rhinosinusitis rose from approximately 50 million per year in the period between 1986 to 1988 to 61.2 million per year between 1997 and 2006 (5,9,10). According to the 2007 estimates of workday productivity, this translates into $18.3 billion in lost opportunity cost (9). Based on the 2006 survey data, patients with sinusitis miss an average of 5.67 workdays due to illness annually, as opposed to 3.74 missed workdays for those without sinusitis (9). More difficult to quantitate, but certainly relevant within the realm of indirect costs, are the detrimental effects of rhinosinusitis on quality of life and the impairment of daily functioning due to the significant physical symptoms present when someone is suffering from rhinosinusitis (4).

PATHOPHYSIOLOGY AND MICROBIOLOGY

In order to fully understand the pathophysiology of rhinosinusitis, one must consider the concepts of *inflammation*

and *infection*. Inflammation is a cascade of processes and signals via which mediators, such as leukocytes, are enabled to eliminate foreign agents and repair damaged tissues (4,11). Acute inflammation is characterized by exudation of fluid and plasma proteins from blood vessels with emigration of leukocytes, predominantly neutrophils, as these cells gather to combat the offending entity (4,11). It can be identified within minutes to hours of an insult or trigger. Chronic inflammation develops as the condition persists over weeks to months. The hallmarks of chronic inflammation are the presence of lymphocytes, macrophages, eosinophils, and basophils, along with increased vascularity, fibrosis, and tissue necrosis (4,11). Subacute inflammation is described as the interval period when overlapping patterns of inflammation are observed (4). Infection is traditionally diagnosed when microorganisms present in a host, directly interacting with the host tissue and replicating. This results in expression of disease in the host organism (4). Bacterial infection is characterized by the presence of one or more bacteria per high density field, which correlates to at least 1,000 colony forming units per milliliter (4).

Histopathologically, acute rhinosinusitis is predominantly an exudative process (1,12). Examination of tissue specimens reveals a mixed inflammatory cell infiltrate in which neutrophils predominate. Hemorrhage, ulceration, and the presence of bacteria or fungi may also be seen (1,4,12).

Acute Viral Rhinosinusitis

The majority of acute rhinosinusitis is infectious in etiology (4) (Table 33.3). The leading pathogen is viral. A sinus puncture study in patients with acute community-acquired rhinosinusitis demonstrated the most common identifiable viral organisms in descending prevalence to be rhinovirus 15%, influenza virus 5%, parainfluenza virus 3%, and adenovirus 2% (4,13). The pathogenesis of infection by the most common of these, the rhinovirus, was very well delineated in the end of the twentieth century by Gwaltney's group at the University of Virginia. The rhinovirus enters the body through the nose, either by direct inoculation or by large airborne particles (4,14). Viral particles travel in the mucus stream to the adenoid region where they attach to a specialized receptor (rhinovirus receptor intercellular adhesion molecule 1) on lymphoepithelial cells overlying lymphoid follicles (4,15–17). An inflammatory reaction is thus incited, and common acute viral rhinosinusitis (AVRS) symptoms, including sore throat, nasal obstruction, and rhinorrhea develop within hours of exposure (4,18).

Although historically viruses were thought to cause predominantly rhinitis, involvement of the paranasal sinuses in the clinical setting of AVRS is well documented radiologically in both adults and children (19,20). These studies were performed predominantly in the late 1980s and early 1990s at a time when people were comparing the relatively new modalities of computed tomography (CT) and magnetic resonance imaging (MRI) against the standard imaging modality for rhinosinusitis, plain film radiography. Abnormalities, including air–fluid levels, aerosolized secretions, and thickened mucosa are seen most often in the maxillary sinuses 87%, but also in the ethmoid sinuses 65%, the frontal sinuses 32%, and the sphenoid sinuses in 39% (4,21). These findings are associated with exocytosis of large amounts of mucin by goblet cells in the paranasal sinus epithelium after they have been stimulated

TABLE 33.3 RELATIVE FREQUENCY OF INFECTIOUS ORGANISMS IN ACUTE RHINOSINUSITIS

Cause	Organism	Frequency
Virus	Proportion of total acute rhinosinusitis (ARS) cases	39%–87%[a]
	Proportion of viral pathogen recovered on sinus puncture:	
	Rhinovirus	
	Influenza virus	15%
	Parainfluenza virus	5%
	Adenovirus	3%
		2%
Bacteria	Proportion of total ARS cases	0.05%–2%
	Proportion of each bacterial species in acute bacterial	
	rhinosinusitis (ABRS):	20%–43%
	S. pneumoniae	22%–35%
	H. influenzae	2%–10%
	M. catarrhalis	2%–6%
	Anaerobes	<5%
	S. aureus and *Streptococcus pyogenes*	

[a]Percentages given are culture-proven viral infections. A proportion of acute rhinosinusitis is culture-negative, which is presumably due to difficulties in technicalities of viral culture. In the rhinosinusitis literature, culture-negative disease is presumably viral in origin.

by inflammatory mediators in the setting of acute viral infection (4).

Acute Bacterial Rhinosinusitis

ABRS classically occurs when a patient with AVRS develops a superimposed or secondary bacterial infection (2). Only about 0.5% to 2.0% of AVRS are complicated by a bacterial infection (2,13). Yet, there are still about 20 million cases of ABRS annually in the United States (2,22). AVRS can promote development of ABRS by several mechanisms. The inflamed, edematous mucosa can obstruct sinus ostia and impair mucus drainage (2,23,24). Mucociliary function and clearance is also directly affected by inflammation; this deficit is magnified in a setting of increased mucus production (24). Infection by bacterial pathogens that colonize the nose and nasopharynx is promoted by mucus stasis and enabled as the bacteria are deposited into the paranasal sinuses by nose-blowing (2,13,25).

This concept of the transition from AVRS to ABRS is critical as we discuss patient presentation and accurate evaluation of progression of symptoms for diagnostic purposes. An episode of AVRS can be complicated by a bacterial infection at any point, but early in the presentation the clinical distinction between the two is essentially impossible. The more specific diagnostic criteria pertaining to the timeline of the infection will be discussed later in this chapter, and are directly related to recommended management of acute rhinosinusitis.

Microbiology of Acute Bacterial Rhinosinusitis

Knowledge regarding the microbiology of acute community-acquired bacterial rhinosinusitis in adults has been predominantly delineated from cultures of maxillary sinus mucus, as these are the most accessible of the paranasal sinuses (4). The majority of ABRS infections are due to a single bacterial isolate, but about one-fourth of cases have polymicrobial infection, more commonly seen in pediatric cases (4,26). The most common bacterial species isolated from the maxillary sinuses of patients with uncomplicated ABRS are *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis* (2,27) (Table 33.3). The relative frequency of bacterial isolates in ABRS has proven to be a reproducible relationship; *S. pneumoniae* is identified in 20% to 43% of cases, *H. influenzae* in 22% to 35%, and *M. catarrhalis* in 2% to 10% (2,26–31). The *H. influenzae* identified are predominantly the nontypeable organisms (4). In the last several decades of the twentieth century there was a very large increase in the prevalence of β-lactamase-producing *H. influenzae* to greater than 50%; however, in the 21st century this appears to have stabilized at about 40% of the isolates (4,13,32,33). Macrolide-resistant *S. pneumonia* is an increasing concern, and has been associated with increased risk of treatment failure (34–36). Anaerobic bacteria account for only 2% to 6% of ABRS, some of which arise from primary dental pathology (4). *Staphylococcus aureus* and *S. pyogenes* play an interesting role in ABRS. Overall, they account for less than 5% of cases, although *S. aureus* is often overestimated based on culture from nasal swabs, as opposed to endoscopically-directed sinus cultures or direct sinus aspirates (4). Of note, *S. aureus* and *S. pyogenes* have a higher propensity to cause complications of acute rhinosinusitis, such as intracranial or orbital extension of the disease (4).

Special Scenarios—Microbiology of Nosocomial Acute Bacterial Rhinosinusitis

Nosocomial rhinosinusitis has a much higher prevalence of gram-negative organisms than community-acquired ABRS. Examples of organisms found in nosocomial infections include *Pseudomonas aeruginosa, Klebsiella pneumoniae, Enterobacter* species, *Proteus mirabilis, Serratia marcescens,* and gram-positive cocci, such as streptococci and staphylococci (4). For many years we have known that patients at high risk for nosocomial rhinosinusitis are those who require extended periods of intensive care with prolonged endotracheal intubation or nasogastric tubing (4,37). Nasotracheal intubation has a higher risk for nosocomial sinusitis than orotracheal intubation (4,38). Nosocomial sinusitis develops in 25% of patients requiring nasotracheal intubation for longer than 5 days (4,39).

Special Scenarios—Acute Fulminant Invasive Fungal Sinusitis

Acute fulminant invasive fungal sinusitis is an aggressive disease characterized by the rapid spread of fungi from the sinonasal mucosa into the orbit, soft tissues, and brain parenchyma via direct and vascular invasion (40). Affected patients typically have a clinical condition associated with impaired neutrophil function, such as hematologic malignancies, aplastic anemia, diabetes, acquired immunodeficiency syndrome, organ transplant, or iatrogenic immunosuppression due to chemotherapy (40). The most common etiologic organisms are *Aspergillus* and *Mucormycosis* species. In this special patient population with decreased ability to mount an immune response to infectious organisms, the signs and symptoms of disease may be subtle. The most common physical finding on sinonasal endoscopy is an alteration in the mucosa of the nose and sinuses that suggest angioinvasion by the fungal organisms, with ultimate hypoperfusion of tissues. White discoloration may suggest tissue ischemia, whereas black discoloration is a late finding of tissue necrosis (40). Decreased mucosal bleeding and sensation of anesthetic regions of the face or oral cavity may be signs of this invasive process (40). The most common locations of mucosal abnormalities are middle or inferior turbinate, nasal septum, and palate (41). The gold standard for diagnosis of this disease is permanent section with Gomori methamine

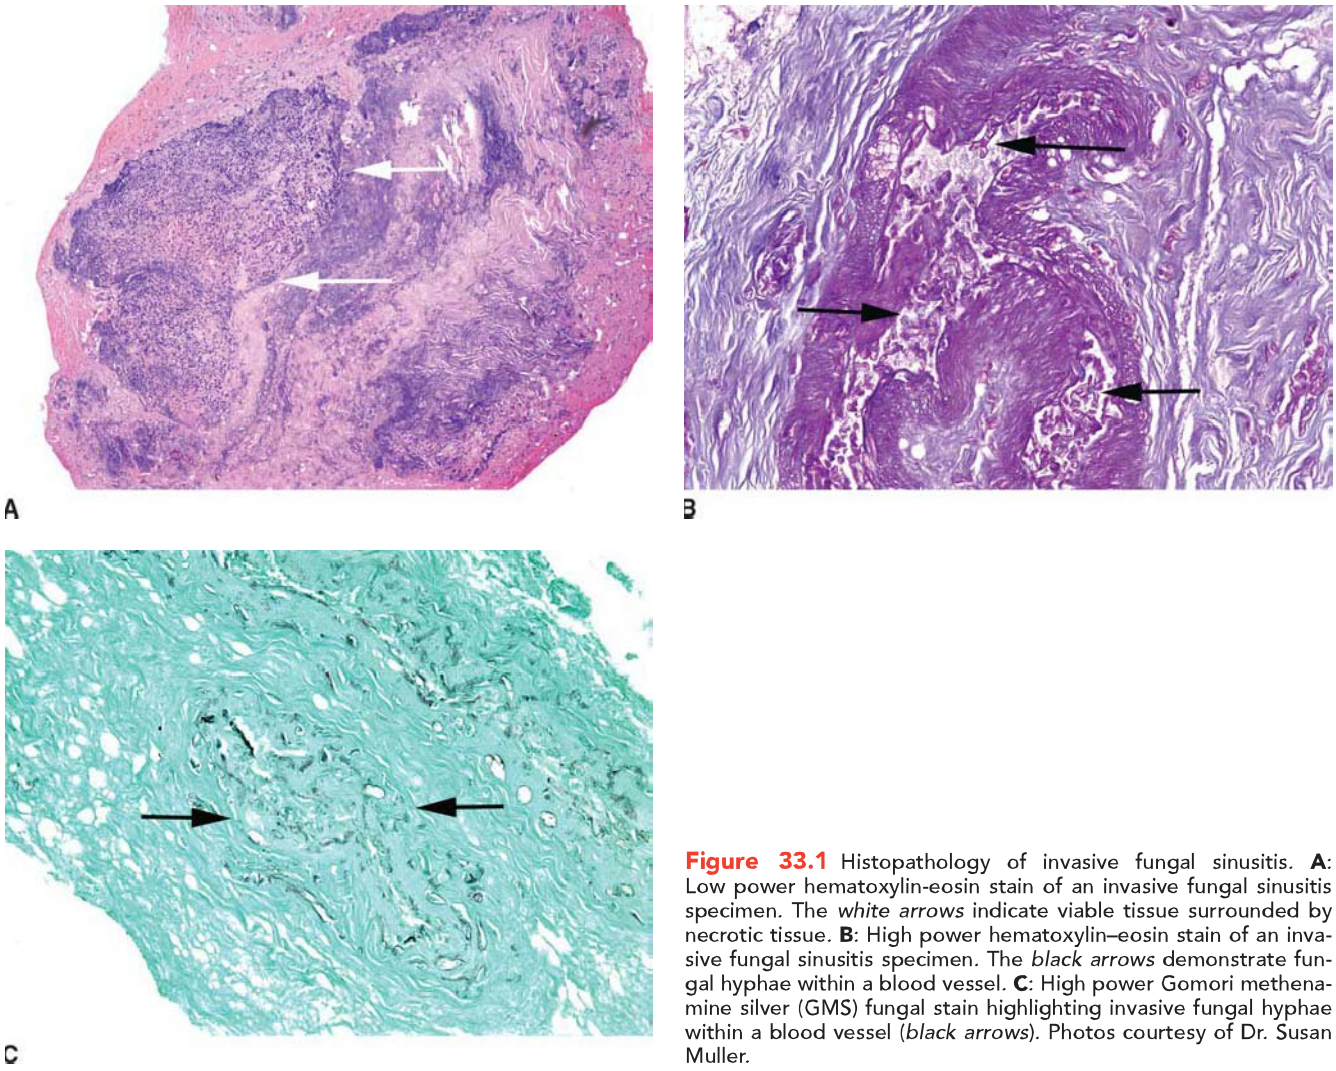

Figure 33.1 Histopathology of invasive fungal sinusitis. **A**: Low power hematoxylin-eosin stain of an invasive fungal sinusitis specimen. The *white arrows* indicate viable tissue surrounded by necrotic tissue. **B**: High power hematoxylin–eosin stain of an invasive fungal sinusitis specimen. The *black arrows* demonstrate fungal hyphae within a blood vessel. **C**: High power Gomori methenamine silver (GMS) fungal stain highlighting invasive fungal hyphae within a blood vessel (*black arrows*). silver stain showing "hyphal forms within the submucosa with or without angiocentric invasion and tissue necrosis with minimal host inflammatory infiltrate" (40) (Fig. 33.1A–C). Because prompt diagnosis is imperative with this condition, frozen section with histopathologic evaluation of any suspicious lesions is necessary to facilitate surgical resection and initiation of antifungal therapy without delay. The potassium hydroxide–calcofluor white method is an alternative rapid diagnostic technique in which potassium hydroxide is used to dissolve human material, and the calcofluor white is used as an optic brightener that binds to the cell wall of the hyphae and fluoresces when viewed with a fluorescent microscope (40).

CLINICAL PRESENTATION AND EVALUATION

Symptoms associated with rhinosinusitis are well recognized. The common symptoms include nasal obstruction, nasal discharge, nasal purulence, postnasal drip, facial pressure and pain, alteration in the sense of smell, cough, fever, halitosis, fatigue, dental pain, sore throat, aural fullness, otalgia, and headache.

Patient History

When a patient presents with a constellation of symptoms consistent with acute rhinosinusitis, the care provider should document all relevant symptoms. Clarification of the severity of symptoms and their time course is critical in establishing an accurate diagnosis and forming an appropriate treatment plan. Assessment of the patient's pain within this evaluation is strongly encouraged. Pain is one of the three cardinal symptoms described as the diagnostic criteria for ABRS, and pain is a major reason why patients seek medical care (4,42).

The early consensus report outlined by the Task Force on Rhinosinusitis in 1996 outlined a stratification of major and minor symptoms in order to facilitate appropriate diagnosis of ABRS and help emphasize its distinction from AVRS (1). Subsequent reports have replaced this model with a new concept, highlighting three cardinal

TABLE 33.4 THREE CARDINAL SYMPTOMS TO DIAGNOSE ABRS

1. Purulent nasal discharge
2. Nasal obstruction
3. Facial pain, pressure, or fullness

symptoms: purulent nasal discharge, nasal obstruction, and/or facial pain, pressure, or fullness (2,42) (Table 33.4). The logic behind this new slant in symptom interpretation for the diagnosis of ABRS is based upon the high sensitivity and relatively high specificity of these indicators for ABRS, especially when they are present for 10 days or longer (2,42–44). Presence of purulent nasal drainage, whether reported by the patient or seen on physical exam in the posterior pharynx or intranasally near the sinus ostia, correlates to the presence of bacteria on antral aspiration (2,45,46). Findings of purulence also correlate with radiographic evidence of ABRS (2,47). Nasal obstruction is associated with objective measures, such as rhinomanometry or nasal peak flow rate (2,48). Facial pain and dental pain are also predictive of ABRS according to culture results and to radiographic findings, but the location does not correlate with the specific sinuses involved (2,44,45,49).

After a thorough history of symptomatology is obtained, a physician can often distinguish ABRS from AVRS or from acute rhinosinusitis due to noninfectious etiologies (2). According to the 2007 guidelines, "ABRS is diagnosed when the three cardinal symptoms are present for 10 days or longer beyond the onset of upper respiratory symptoms, or when the symptoms or signs of acute rhinosinusitis worsen within 10 days after a period of initial improvement (double-worsening)" (2). In the first 3 to 4 days of illness, AVRS cannot be distinguished from an early transition to ABRS (2). Purulent discharge does not indicate the presence of bacteria within the mucus, but rather it demonstrates the presence of neutrophils, which is characteristic of acute inflammation regardless of the etiology. Clear rhinorrhea may be indicative of AVRS, allergic rhinosinusitis, or other causes of nonallergic rhinosinusitis, such as vasomotor rhinitis. At 10 days or more, inflammation and edema from AVRS may still be present; however, the condition should be improving. If the symptoms are progressing at the 10 day timeframe, a diagnosis of ABRS is suggested (2,42).

Fever is not included as a cardinal sign of ABRS because it only has a sensitivity and specificity of about 50% for this diagnosis (2,42–44). Patients with AVRS may have fever during the initial several days of illness, which does not necessarily implicate an evolving secondary bacterial infection. However, if a patient presents with the three cardinal symptoms, which seem to be particularly severe or with a high fever within the first 3 to 4 days of onset of illness, a diagnosis of ABRS may be considered early (2,4,42). Additionally, if there are symptoms suggesting progression beyond uncomplicated ABRS, despite the duration of symptoms, treatment should be initiated early.

In addition to the thorough disease-specific history outlined above, a care provider for a patient presenting with symptoms of acute rhinosinusitis should perform a thorough medical and social history. Presence of significant comorbid conditions, such as diabetes mellitus, immunocompromised status, pulmonary disease, or congenital conditions are important to recognize when delineating a treatment plan. A history of atopy or perennial allergic rhinitis is also relevant in treatment planning. Prior nasal or facial trauma, facial surgery, or sinonasal surgery may affect a patient's experience of symptoms and disease course. A thorough review of a patient's medications and medication allergies should be obtained prior to applying any decongestant or local anesthetic to facilitate examination in the clinic, and certainly prior to prescribing medications. Understanding the patient's social history, including tobacco exposure and conditions of their home and work environments is important for comprehensive patient counseling. These factors may also suggest underlying conditions that are capable of predisposing a patient to symptoms of rhinosinusitis and to the development of ABRS.

Physical Examination

Although a diagnosis of AVRS or ABRS can be accurately made with a patient history, a thorough physical exam is imperative. Vital signs should be recorded. Examination of the head and neck should begin with facial examination. Swelling, erythema, or edema localized over the involved cheek or periorbital edema may suggest complicated ABRS with extension into the soft tissues. Palpation and percussion over the face and maxillary dentition may assist in localizing pain. Examination of the eyes includes assessment of the appearance of the conjunctiva, visual status testing, extraocular muscle function evaluation, inspection for the presence of proptosis, and funduscopic or Tonopen exams if clinically indicated. Otoscopic exam may reveal serous otitis media or acute otitis media. Anterior rhinoscopy is the basic tool of the physical exam that most specifically relates to detecting pathology in the sinonasal passages (4). Typically, the nose is evaluated before and after topical decongestion. Prior to application of decongestant, such as oxymetazoline or neosynephrine, the anterior nasal passages and inferior turbinates are inspected. After the nose has been decongested, one is usually able to visualize the middle turbinate and inspect for pus in the region of the middle meatus as well as hyperemia, edema, or crusting. Enlarged turbinates, presence of nasal polyps or masses, and nasal septal deviations may limit the extent of this examination. Visualization of purulent postnasal drainage upon oropharyngeal examination is rather sensitive and specific for ABRS (1). Vocal analysis may reveal

TABLE 33.5 INDICATIONS FOR SINONASAL ENDOSCOPY IN ACUTE RHINOSINUSITIS

Failure to improve on empiric therapy
Unilateral disease
Severe symptoms
Suspicion of complications of ABRS
Recent sinonasal surgery
Immunocompromised status

a hyponasal quality, consistent with reduced resonance due to decreased aeration of the paranasal sinuses (2). Auscultation of the chest is especially important in any patients with history of pulmonary dysfunction given the potential of lower airway inflammation coincidentally with upper airway infection. A full neurologic evaluation including cranial nerve examination is indicated if there is any concern for complicated ABRS with intracranial extension.

Endoscopic Evaluation

Endoscopically-directed middle meatus cultures are well correlated with cultures obtained by direct maxillary sinus aspiration (2,50). Cultures of secretions from the nose or nasopharynx, however, are poorly representative of maxillary sinus cultures (2,50). Blind swabs of the nasal cavity are not recommended since they are likely to be contaminated by normal colonizing bacteria (51). Directed cultures are not necessary for the diagnosis or treatment of uncomplicated ABRS (2). Often the initial evaluation of a patient with ABRS is by a primary care provider not trained in sinonasal endoscopic techniques, which should not deleteriously affect delivery of appropriate care. The most important role of endoscopy is the assessment and treatment of patients with refractory or chronic symptoms and in patients who have impending or existing complications of rhinosinusitis (4). The indications for the consultation of an otolaryngologist for endoscopy are symptomatic patients who fail to improve on empiric therapy, patients with unilateral disease, patients with severe or disabling symptoms, patients in whom complications are suspected, patients who have had recent sinonasal surgery, or immunocompromised individuals (4) (Table 33.5). Sinonasal endoscopy can be performed with either a flexible or a rigid scope. Flexible fiberoptic endoscopy is more comfortable for the patient and facilitates access toward the sinuses in a nonoperated patient. Rigid sinonasal endoscopy provides superior image quality, allows one to obtain cultures and tissue samples if indicated, and provides the ability to control epistaxis if encountered. Cultures can be obtained with a sterile swab or utilizing suction into a sterile trap device.

IMAGING

Imaging modalities available to evaluate the nose and the paranasal sinuses are plain film radiography, CT, and MRI (Table 33.6). Ultrasound has been used for evaluation of maxillary sinus disease, but its sensitivity is poor (9,52). Ultrasound has limited capacity to accurately image the paranasal sinuses given that they are surrounded by bone and contain air. It is very important to understand the strengths and weaknesses of each of these imaging techniques in order to incorporate them into practice in a cost-effective and algorithm-based manner. Information gained from a test should provide relevant data that can be used to impact clinical decision making.

TABLE 33.6 IMAGING MODALITIES IN ACUTE RHINOSINUSITIS

Modality	Strengths	Weaknesses	Indications in the Setting of ARS
Ultrasound	Low cost No radiation exposure	Low sensitivity	Not recommended
X-ray	Low cost Low radiation dose Portable exam	Low sensitivity Low specificity	No longer used routinely
CT	Excellent bony anatomy High sensitivity (>90%)	Higher cost Higher radiation dose Poor soft tissue differentiation Cannot distinguish AVRS from ABRS Findings do not correlate well with localizing symptoms	Suspicion for a complication of ABRS Suspicion for alternative diagnosis, such as neoplasm Presence of comorbidities that may predispose to complications of ABRS
MRI	Excellent soft tissue differentiation Excellent intracranial diagnostic capacity	Higher cost Longer scan time Poor delineation of bony anatomy Cannot distinguish AVRS from ABRS	Suspicion of neoplasm Suspicion of intracranial involvement

Note: No imaging modality is recommended in the routine diagnosis of uncomplicated ABRS.

X-ray

Sinus plain film radiography series consist of three views: a lateral, Caldwell or posterior–anterior view (central ray angle 15 degrees), and Waters or occipitomental view (orbitomeatal line angled 37 degrees to horizontal plane) (2). Radiographs must be obtained with the patient in an upright position, as the primary feature that is used to diagnose ABRS by plain film is the presence of air–fluid levels. Other imaging findings consistent with a diagnosis of ABRS on plain film radiography are sinus opacification and mucosal thickening (2). Relative advantages of plain films of the sinuses are low cost, low radiation dosage (1.4 cGy per film), and possibility of a portable exam in an intensive care setting (53). A prospective study using antral puncture results as the gold standard for diagnosis of ABRS showed that complete opacification, air–fluid levels, or both on plain film radiography of the maxillary sinuses have a diagnostic sensitivity of 73% and specificity of 80% (2,53–55). A similar study evaluating plain radiography and using CT as the gold standard for diagnosis of acute maxillary sinusitis reported the sensitivity of radiography as 67% and specificity as 87% (53,55). The positive and negative predictive values were reported as 82.5% and 76.9%, respectively (53,55). The sensitivity of plain film radiography to diagnose ethmoid, frontal, and sphenoid sinusitis was worse at 0% to 58.9%, 1.9% to 54.0%, and 0% to 38%, respectively (53,55). A negative plain film does not rule out the presence of sinusitis. By now most agree that plain radiographs have limited value for acute rhinosinusitis (1,56).

Computed Tomography

CT is considered the gold standard for radiographic evaluation of the paranasal sinuses (1,2). Standard sinus CT without contrast with 3-mm coronal cuts provides appropriate information regarding bony anatomy, permitting understanding of the complex structure of the paranasal sinuses (53). Findings on CT that correlate with ABRS are "opacification of the sinus cavities, air–fluid levels, and moderate to severe mucosal thickening" (2). The most accepted objective staging system used to evaluate the paranasal sinuses on CT is the Lund-Mackay classification system, which quantitates sinus disease by number of sinuses with any degree of opacification in addition to evaluation for any anatomic variants (57). Some of the limitations of CT are increased cost and increased dose of radiation (5 to 6 cGy), which may reach values up to 10 times the dose of a radiograph (2). Multidetector CT is a technology that facilitates reduced total radiation in imaging of the sinuses because the patient is scanned in a single plane and the remaining triplanar images are reconstructed from the original data set (2). Additionally, although findings on CT may be consistent with a diagnosis of ABRS, they cannot accurately distinguish between AVRS and ABRS (2,21). Further, there is a lack of correlation between localizing symptoms and findings on CT (2,49,58).

Using the presence of an air–fluid level or total opacification of a sinus as diagnostic criteria, sinus CT has a 90% positive predictive value for diagnosis of ABRS when compared with culture of aspirated sinus secretions (9,59). Still, the use of CT in diagnosis of uncomplicated ABRS is not cost-effective and universally not recommended (49,60–62). The role of CT in acute sinusitis outlined in the literature is very specific and consistent. CT should only be performed when a complication of acute rhinosinusitis or an alternative diagnosis is suspected (1,2,42). The complications of acute rhinosinusitis include orbital, intracranial, or soft tissue involvement. Alternative diagnoses of facial pain may include neoplasm (2,42). CT may also be utilized when the patient has comorbidities or a clinical condition that predisposes him to complications, such as diabetes, immunocompromised state, or a past history of facial trauma or surgery (2). Iodine-contrast enhancement may help to identify extra-sinus extension of disease in clinical situations when this is suspected (2).

Magnetic Resonance Imaging

Gadolinium-enhanced MRI does not display bony anatomy as well as CT, but it provides excellent soft tissue differentiation (53). Bacterial and viral inflammation remains indistinguishable from one another on MRI, but they are easily differentiated from fungal concretions or neoplasm (4). MRI is the best modality for delineating extension of disease beyond the paranasal sinuses into the orbits or intracranial compartment (4). Drawbacks of MRI include longer acquisition time and higher cost (53). CT remains the diagnostic modality of choice when sinusitis with complications is suspected, but MRI is the gold standard for the diagnosis of intracranial complications (63).

TREATMENT

Antibiotics are the most frequently recommended medications for the treatment of acute rhinosinusitis, accounting for 21% of antibiotics prescribed for adults and 9% of antibiotics prescribed for children (64–66). One study showed that physicians ordered, supplied, administered, or continued at least 1 antibiotic in 82.74% of visits for acute rhinosinusitis (65). Antibiotics are prescribed far in excess of the predicted incidence of ABRS (65). Appropriate antimicrobial use for ABRS requires knowledge of the natural history of untreated illness and the incremental benefit of antimicrobials on clinical outcomes in different scenarios (64) (Table 33.7).

Medical Management of Acute Viral Rhinosinusitis

The management of AVRS should be focused on symptom control, as this is a self-limited condition and there is no evidence that use of medications will help to decrease the potential for conversion into ABRS (2,3). Analgesic and antipyretic medications will help with pain and fever, two major symptoms prompting a patient to seek medical care

TABLE 33.7 MEDICAL TREATMENT MODALITIES FOR ACUTE RHINOSINUSITIS

Class	Generic Example	Clinical Benefit	Recommended Use
Analgesic/antipyretic	Acetaminophen	Decreases pain and fever	Recommended for AVRS and ABRS
Saline irrigations		Thins mucus, enhances mucociliary clearance, decreases inflammation	Recommended for AVRS and ABRS; may consider hypertonic irrigations
Topical decongestant	Oxymetazoline	Reduces mucosal edema and nasal airway obstruction	Consider in AVRS and ABRS for 3 d duration only
Systemic decongestant	Pseudoephedrine	Limited reduction of mucosal edema	Not as effective as topical decongestant
Topical corticosteroid	Fluticasone propionate	Improved symptom control in ABRS	Consider in ABRS with allergic component
Systemic corticosteroid	Prednisone	Not supported in literature	No evidence supporting use in AVRS or ABRS
Nonsedating antihistamine	Loratadine	Dries secretions	Consider in AVRS or ABRS with allergic component
Mucolytic	Guaifenesin	Thins tenacious secretions and phlegm	Improves symptom control in AVRS, limited literature support in ABRS
Antibiotic—*penicillins*	Amoxicillin ± clavulanate	Bactericidal, inhibit peptidoglycan cross-linking in cell wall synthesis	First-line for severe ABRS or mild ABRS that fails to improve with observation
Antibiotic—*cephalosporins*	Cefpodoxime proxetil, cefuroxime axetil, cefdinir	Bactericidal, inhibit peptidoglycan cross-linking in cell wall synthesis	Second most efficacious class for ABRS
Antibiotic—*sulfonamides and trimethoprim*	Trimethoprim-sulfamethoxazole	Bacteriostatic, inhibit folate synthesis, thereby preventing DNA replication and transcription	Alternative for first-line for severe ABRS or mild ABRS that fails to improve with conservative management in patients with penicillin allergy
Antibiotic—*tetracyclines*	Doxycycline	Bactericidal, inhibits protein synthesis	Good efficacy for ABRS
Antibiotic—*erythromycin, lincosamides, and macrolides*	Azithromycin, clarithromycin, erythromycin	Bactericidal, inhibits protein synthesis	Least efficacious for ABRS; consider as alternative for patients with penicillin allergy

in this clinical scenario (2). Nasal irrigations with hypertonic saline solution have been shown to improve symptoms and reduce the use of pain medications in AVRS (3,67). They thin mucus and help with mucociliary clearance (42). Decongestant options include systemic and topical administration, although topical nasal decongestants offer increased symptom relief given increased potency (2). Although theoretically they may help to restore patency of sinus ostia, this has not been demonstrated (2). Prescribers must inform their patients of the potential for development of *rhinitis medicamentosa* with use prolonged beyond 3 days (2,42). Systemic steroid therapy has not been shown to be effective for AVRS, and carries a risk of behavioral changes, increased appetite, and weight gain, even with short courses (2). Topical nasal steroids have minimal systemic absorption and consequently carry a very low risk for systemic side-effects (2). Yet, there is only weak evidence supporting their use in AVRS (2). If an allergic component is identified in the clinical presentation, their use may be more beneficial (2). Antihistamines are another class of medications that may be beneficial if allergy is suspected to play a role in the disease process. Although the drying effect of antihistamines may be desirable in certain clinical scenarios, there are no studies demonstrating their capacity to decrease duration of illness or to decrease the potential of conversion to ABRS (2). Antihistamines, particularly first-generation, carry risks of drowsiness and behavioral effects. These side effects are seen less frequently with second-generation antihistamines (2,42). Mucolytics are used to thin mucus in an attempt to facilitate mucociliary clearance, and their use is shown to decrease symptom scores compared to placebo (42,65).

Medical Management for Acute Bacterial Rhinosinusitis

For patients presenting with uncomplicated ABRS who have mild illness with mild pain and fever less than 38.3°C (101°F) and in whom there is assurance for follow-up, physicians can limit management to symptomatic relief and defer antibiotic treatment for up to 7 days after diagnosis (2). The 2007 guidelines emphasize that, "this observation

option is only appropriate if a system is in place that permits reevaluation if the illness persists or worsens" (2). Antibiotics are initiated if the patient's condition fails to improve by 7 days or worsens at any point during the observation period (2). Although illness severity largely determines whether a patient is suitable for observation, the clinician must take into account the overall clinical picture, including the patient's age and comorbidities when determining a treatment plan (2).

In cases of uncomplicated mild ABRS, antibiotics can safely be deferred as randomized controlled trials (RCTs) show that there is a high percentage of spontaneous improvement when patients receive placebo with only a moderate incremental benefit from the addition of antibiotics (2). In an era of growing concern about the overuse of antibiotics and resultant problems, including drug resistance and increasingly virulent bacteria, adherence to these guidelines is encouraged (65). A meta-analysis of 13 RCTs in 2007 shows complete spontaneous clinical cure in 8% of patients at 3 to 5 days after diagnosis of ABRS (95% CI, 5% to 14%), in 35% at 7 to 12 days (95% CI, 24% to 48%), and 45% by 14 to 15 days (95% CI, 23% to 70%) (64). Rates of spontaneous clinical improvement were 30% at days 3 to 5 (95% CI, 0% to 99%) and 73% at days 7 to 12 (95% CI, 56% to 85%), which remained stable at days 14 to 15 (64). Antimicrobial therapy had no effect on clinical cure at 3 to 5 days after diagnosis of ABRS, increased absolute cure rates by 15% at days 7 to 12 (95% CI, 4% to 25%) with a number needed to treat of seven patients, and had no statistical benefit at days 14 to 15 (64). The effects of antibiotics on clinical improvement rates were very similar to its effects on cure rates (64). This data correlates well with prior systematic reviews, which showed spontaneous improvement in 62% to 69% of patients after 7 to 14 days after diagnosis of ABRS, spontaneous cure in 19% to 39%, and an absolute increase of 13% to 19% in favorable outcomes when antibiotics are used (2,64,68–70). Of course, antibiotics are also associated with side effects and adverse events, which must be taken into account when prescribing them. The number needed to harm is nine patients, with the most common side effects being gastrointestinal, but also including skin rash, vaginal discharge, headache, dizziness, and fatigue (64). One analysis estimates that antibiotics result in 15 days (best case) to 89 days (worst case) of diarrhea, nausea and vomiting, or both per 100 patients treated with antibiotics for ABRS versus only 8.5 days for those treated with placebo (2,71).

Symptomatic relief for ABRS is essentially the same as for AVRS. Although one may consider adjunctive treatments for ABRS including analgesics, antipyretics, nasal saline irrigations, decongestants, corticosteroids, antihistamines, and mucolytics, none of these therapies has been specifically approved by the Food and Drug Administration for use in acute rhinosinusitis. Buffered hypertonic saline (3% to 5%) irrigations have shown a modest benefit for ABRS with decreased symptoms and decreased medication use (2,3). Compared with isotonic saline, the use of hypertonic saline in sinonasal irrigations may have superior anti-inflammatory effects and better ability to thin mucus, thereby enhancing mucociliary clearance, although this issue remains controversial (2,3,72–75). While keeping in mind the risk of *rhinitis medicamentosa*, use of topical decongestants is recommended in the management of ABRS, given improvement in outcomes and reduction of congestion on sinonasal mucosa on MRI seen in studies (2,76,77). Further, the superior potency of topical decongestant over systemic is depicted by the decreased congestion appreciated on MRI after topical administration as compared to systemic administration (77). Trials support the use of topical corticosteroids for ABRS with improved symptom control in patients, but there is no evidence for the use of systemic glucocorticoids for this illness (2,78–80). The use of antihistamines in nonatopic patients with ABRS is not supported (2,65). In fact, there is concern that the cholinergic effects may actually worsen congestion and prolong the infectious process (2,65). Use of second-generation antihistamines should be limited to patients whose symptoms suggest an allergic component to their disease process (2,65). Although, in theory, the use of mucolytics would seem beneficial in airway infections characterized by phlegm and mucus, the literature does not provide evidence supporting their use in ABRS (2).

Patients who present with ABRS and moderate to severe pain or temperature greater than 38.3°C (101°F) are considered to have severe illness and should be treated initially with oral antibiotics. Ideally, the antibiotic should be efficacious, cost-effective, and result in minimal side effects (2). Amoxicillin is the first-line antibiotic recommended for most patients (2,3,42,64,65). Amoxicillin is safe, inexpensive, efficacious, and has a narrow microbiologic spectrum (2,42) Meta-analysis confirms that treatment with amoxicillin decreases the duration of symptoms (2,42,64). Comparison of treatment durations of 5 and 10 days does not show a difference in resolution of symptoms, but does show that longer durations of treatment are associated with an increase in adverse events (2,42,64). The recommended alternatives for patients with penicillin allergy are trimethoprim-sulfamethoxazole or a macrolide antibiotic (2,42,64,65). It is important to remember when prescribing antibiotics that a regimen with simple once daily dosing for a short duration will have the highest compliance rate (2). Counseling a patient about the natural history of acute rhinosinusitis, the importance of completing a prescribed antibiotic regimen, and additional adjunctive measures for symptom control, including hydration and analgesia, is an important part of treatment planning with your patient (2).

Certain clinical scenarios warrant particular attention in antibiotic selection. If a patient has been treated with antibiotics in the recent past (4 to 6 weeks), they are at increased likelihood for infection with a resistant bacterium, and a fluoroquinolone or high-dose amoxicillin-clavulanate (4 g/250 mg/d) should be used, according to the 2004 Sinus and Allergy Health Partnership (SAHP)

Antimicrobial Treatment Guidelines (2,42,81). In the SAHP Guidelines, amoxicillin-clavulanate had the highest calculated clinical efficacy in both the groups that had and those that had not recently received antibiotics (65). Patients with young children in daycare are at risk for penicillin-resistant *S. pneumoniae* infection, and high-dose amoxicillin should be considered in this group (42,65). The SAHP Guidelines show that, in decreasing order of efficacy, other antibiotics that can be used for treatment of ABRS are cefpodoxime proxetil, cefuroxime axetil, cefdinir, trimethoprim-sulfamethoxazole, doxycycline, and azithromycin, clarithromycin, or erythromycin (65,81). This is an important list, especially given that a study in 2002 showed the second most frequently prescribed class of antibiotics for ABRS behind penicillins (including amoxicillin and amoxicillin-clavulanate) was the group including erythromycins, lincosamides, and macrolides (65). An antibiotic from this group was prescribed in 24.32% of visits for ABRS, ahead of cephalosporins, sulfonamides and trimethoprim, and tetracyclines, which all have demonstrated increased efficacy for this illness (65).

Management for Patients Who Have Failed Primary Treatment of ABRS

The most recent treatment guidelines from 2007 recommend using 7 days as a cut-off point after initial diagnosis to assess for treatment failure (2). Treatment failure entails *worsening*, defined as progression of presenting signs or symptoms or onset of new symptoms or signs, and *failure to improve*, defined as lack of reduction in presenting signs or symptoms of ABRS (2). Failure to improve, therefore, would not be diagnosed in a patient undergoing treatment for ABRS who has persistent, but slowly resolving symptoms of ABRS. Seven days is chosen as the cut point based on studies showing that between 7 and 12 days after diagnosis 73% of patients randomized to placebo and 85% of patients receiving antibiotics have clinical improvement (2,64). At 3 to 5 days after diagnosis, only 30% of patients receiving placebo and 41% of patients taking antibiotics have clinical improvement, thus a cut point at 5 days would include many false positives (2,64). If a patient fails treatment at the 7-day mark, they should be reevaluated for complications of ABRS, drug-resistant bacteria, or nonbacterial cause (2). If the patient was initially managed with observation, the clinician should begin treatment with amoxicillin or an appropriate alternative in patients with penicillin allergy (trimethoprim-sulfamethoxazole or macrolide antibiotic) (2). Patients who have been taking an antibiotic, such as amoxicillin, and who have treatment failure are more likely to be infected with reduced susceptibility bacteria (2). Organisms that should be suspected, particularly in a patient with previous antibiotic therapy, are beta-lactamase producing *H. influenzae* or *M. catarrhalis* and *S. pneumoniae* with reduced susceptibility to beta-lactams, macrolides, tetracyclines, and trimethoprim-sulfamethoxazole (2). Optimal antibiotic therapy recommended by the 2007 Guidelines for ABRS treatment failures are high-dose amoxicillin-clavulanate (4 g/d) or a respiratory fluoroquinolone (levofloxacin, moxifloxacin, gemifloxacin) (2). Cephalosporins and macrolides are predicted to offer inadequate coverage (2).

Management of Acute Fulminant Invasive Fungal Sinusitis—Medical and Surgical

The management of acute fulminant invasive fungal sinusitis necessitates combined medical and surgical modalities with a multidisciplinary approach. Systemic antifungal therapy with amphotericin or voriconazole is necessary, but alone not sufficient to treat this condition (40). Early aggressive endoscopic sinonasal debridement of all involved tissue is necessary for any patient with biopsy-proven disease or in anyone in whom there is high clinical suspicion. The goals of debridement include reduction of the fungal load, slowing progression of disease, and obtaining a specimen for culture and sensitivity studies (40). Many patients affected by this disease will inherently have thrombocytopenia or coagulopathy as part of their underlying condition. This must be addressed with platelet and factor transfusion pre- and intraoperatively in order to minimize hemorrhage (40). Adjunctive measures to tackle this disease involve strategies to correct the underlying immune deficit, such as correction of diabetic ketoacidosis, transfusion of white blood cells, or administration of granulocyte colony-stimulating factor (40). The mortality rate for this condition approaches 100% if there is symptomatic intracranial involvement, but overall is about 20% (41,82). Mortality is also strongly related to the underlying condition, with diabetics having significantly higher mortality (40%) than patients with hematologic malignancy (11%) (82). This disparity is likely due to a greater incidence of *Mucormycosis* over *Aspergillus* in diabetic patients, with the reverse true in patients with hematologic malignancy, and a delay in diagnosis in diabetic patients resulting in more advanced disease at the time of diagnosis (82).

COMPLICATIONS

Acute rhinosinusitis has three possible clinical courses: resolution, development of sequelae, or development of chronic rhinosinusitis. Adverse sequelae of acute rhinosinusitis can be broadly classified as extracranial, which includes local complications, extension into the soft tissues, or extension into the orbit, and intracranial involvement. Despite widespread use of antibiotics and reactionary concerns about their overuse in ABRS, a small but significant percentage of patients still develop adverse sequelae of acute rhinosinusitis, and specifically of ABRS.

Several factors have been identified as risk factors for development of complications from ABRS. The majority

of patients admitted for complications secondary to ABRS present in the winter months, from January through March (83). This seasonal incidence is likely secondary to an increased incidence of viral infections in the fall and winter (83). In the pediatric population, the highest risk age group for hospital admission due to complications of ABRS is 3 to 6 years of age (83). However, among pediatric patients admitted with orbital complications of ABRS, those most at risk for intracranial extension are age 7 years or older (40). In adults, intracranial extension is more commonly seen in patients with a history of chronic rhinosinusitis (40,84,85). However, in the pediatric population, intracranial involvement almost exclusively occurs in the setting of ABRS (40,86–89). Overall, the highest risk group for intracranial complications are males during adolescence and young adulthood (10 to 29 years old) (40,86,90,91). It has been suggested that this age group is disproportionately affected because this is the age at which the valveless diploic system is at its most vascular, therefore providing a good conduit for propagation of bacterial infection (40,86,92). Additionally, it is thought that the maturing posterior table of the frontal sinus is a poor barrier to spread of organisms (86). Infants are at particular risk for the development of meningitis because, as opposed to the efficient barrier to infection provided by the mature arachnoid mater, bacteria are freely transmitted across the immature arachnoid layer (40,93). Additional information regarding Complications of Rhinosinusitis may be found in Chapter 38.

Extracranial Complications

A relatively benign sequela of acute rhinosinusitis is anosmia. Acute rhinosinusitis accounts for 18% to 36% of anosmia (94). While transient hyposmia is common in acute rhinosinusitis, permanent anosmia may also occur, though rarely (51). Women are disproportionately affected, comprising 67% of patients presenting with viral-induced olfactory loss in one study (51). Two recent studies show promising results with improvement in olfaction in over 80% of patients with sensorineural deficits in olfaction, including those related to acute rhinosinusitis, treated with systemic steroids (94,95).

Pott puffy tumor (PPT), first described by Sir Percivall Pott in 1775, is a subperiosteal abscess of the frontal bone associated with frontal osteomyelitis (40,96). The pathophysiology occurs as bacterial infection, most commonly *S. aureus*, nonenterococcal *streptococcus*, and oral anaerobes, often polymicrobial, spreading from the frontal sinuses into the frontal bone causing inflammation and suppuration of the valveless diploic veins, which propagates to the Haverian system of the inner and outer tables of the skull, resulting in localized demineralization and necrosis (40). This ultimately results in perforation of the frontal sinus anterior table, facilitating the subperiosteal pus collection and formation of granulation tissue that characterizes PPT (40). This entity is managed with a combined surgical and medical approach.

Orbital extension of acute rhinosinusitis is the most common complication in both pediatric and adult populations (40,83). In the preantibiotic era, 17% of patients with orbital infection died of meningitis and 20% became blind in the affected eye (83,97). By 1991, the incidence of blindness had fallen to 10.5%, and in a pediatric study from 2009 reviewing 157 orbital complications of ABRS, the incidence of subsequent blindness was 0.6% (83,98). The Chandler classification for orbital complications of rhinosinusitis was introduced in 1970 (97). The strength of this system is its organization as a progression of patterns that describes the pathogenesis of orbital extension of ABRS from preseptal cellulitis (I) to postseptal cellulitis (II), and ultimate progression to subperiosteal abscess (III) and finally orbital abscess (IV) (97). Preseptal or periorbital cellulitis (class I) is the most common of the orbital complications in all age groups (70%) (40). The drawback of this classification scheme is its omission of the most advanced stages of orbital inflammation, including orbital apex syndrome, retrobulbar phlegmon, retrobulbar abscess, and cavernous sinus thrombosis which may also develop as a result of complications of acute rhinosinusitis (83).

Management of secondary orbital involvement is determined according to the Chandler stage of disease. All patients need antibiotics. For patients with preseptal cellulitis over 3 years of age in whom there is assurance of follow-up, treatment may be with broad-spectrum oral antibiotics, head elevation, warm compresses, topical decongestant, and saline irrigations (40,83). For more advanced disease, empiric IV antibiotic management may begin with high-dose beta-lactamase antibiotics, with cognizance of possible resistance, or a third-generation cephalosporin (83). Most preseptal and postseptal cellulitis (grade I and II) can be successfully managed medically (83). Indications for surgical intervention include: in stage I or II disease if the patient's condition fails to improve significantly within 24 to 48 hours of appropriate antibiotic administration so that cultures may be obtained to direct antibiosis, immediately if visual acuity worsens, if the patient develops increasing proptosis and/or ophthalmoplegia, and if an abscess is demonstrated on CT (83). Subperiosteal abscesses must be evaluated individually, and the treatment plan should be tailored to the specific clinical situation. The recommended criteria for medical management of medial subperiosteal abscesses are normal vision, pupil, and retina, no ophthalmoplegia, intraocular pressure of less than 20 mm Hg, proptosis of 5 mm or less, and abscess width of 4 mm or less (40,99). These patients will need attentive monitoring, and if they have any deterioration or fail to improve clinically within 48 to 72 hours, they will likely require repeat imaging and surgical intervention (40,83,99,100). Surgical intervention for secondary orbital involvement includes endoscopic sinus surgery to drain the affected sinuses and obtain cultures.

The extent of surgery is dictated by the degree of sinus involvement (83). The approach to an abscess, if present, depends on its location within the orbit. Many subperiosteal abscesses, particularly in young children, are along the medial orbital wall due to extension from the ethmoid sinuses and can be drained at the time of endoscopic ethmoidectomy (83,101). The main limitation with an endoscopic approach in the acute setting is potential for increased bleeding, which could compromise visualization (40). If this is a concern, a traditional Lynch incision can be considered to approach the medial orbital abscess and to perform external ethmoidectomy (40). An abscess that is lateral, superior, or inferior within the orbit will likely require external orbitotomy for drainage (83). Although often involved in surgical intervention for lesser degrees of orbital infection, ophthalmologists are integral while addressing an intraconal abscess (40).

Intracranial Complications

Intracranial complications affect between 0.5% and 24% of patients admitted to the hospital with rhinosinusitis (86,102,103). The intracranial complications include meningitis, extradural abscess, subdural empyema, intracerebral abscess, and cavernous and superior sagittal sinus thrombosis (86) (Fig. 33.2A and B). Their relative frequencies have been disputed in the literature (86). Infection of the paranasal sinuses can spread to the intracranial compartment directly via osteomyelitis of the skull, by retrograde thrombophlebitis and septic emboli, or through a posttraumatic, congenital, or postsurgical defect that connects the sinuses with intracranial contents (86). The proportion of brain abscesses secondary to either an otologic or sinogenic origin has been estimated at nearly two-thirds, and although historically this predominantly comprised otologic etiology, literature suggests that sinogenic cause has become nearly as common (86,102,104–106). Despite advances in imaging techniques facilitating early detection as well as pharmaceutical and surgical developments, the morbidity and mortality of intracranial complications have remained stable since the 1980s at 5% to 21% and up to 40%, respectively (86,103–106). Morbidities include long-term neurologic deficits, cognitive impairment, cranial nerve palsy, aphasia, epilepsy, hydrocephalus, and visual and hearing loss (40).

SPECIAL CONSIDERATIONS IN THE PEDIATRIC POPULATION

Pediatric patients are particularly susceptible to all infections given their evolving and maturing immune system. They frequently experience six to eight episodes of upper respiratory infection annually, as compared to the average one to three for adults (30). Given an average conversion of AVRS into ABRS of 0.5% to 2%, they are statistically projected to have more ABRS than adults. A large retrospective review of 339 pediatric patients admitted to the hospital for treatment failure of ABRS identified the peak age-group

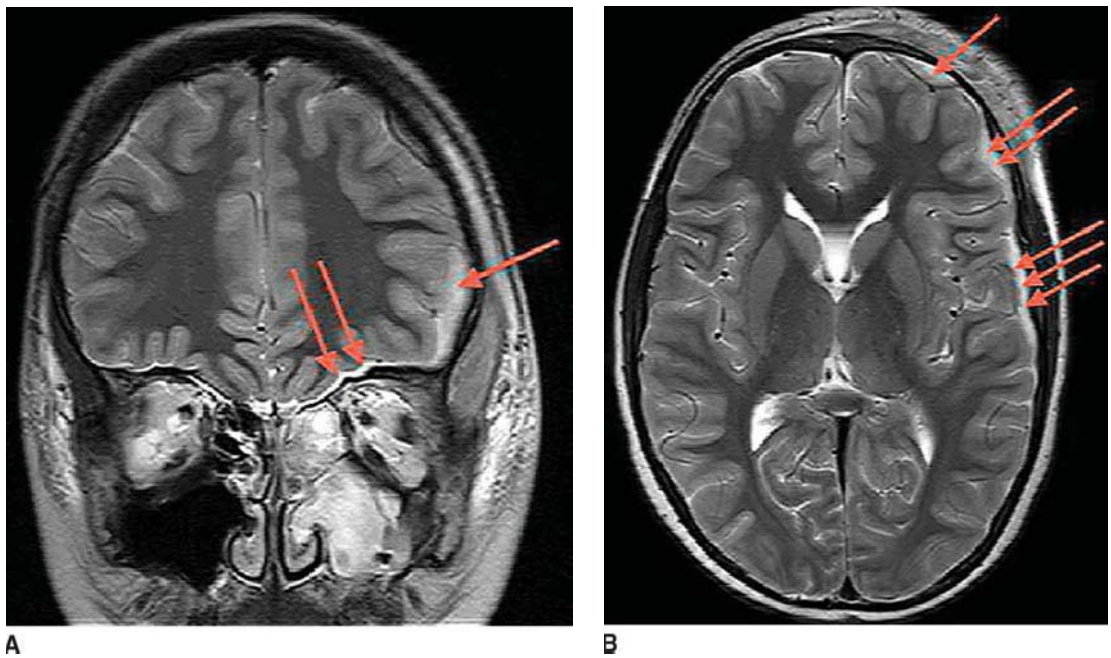

Figure 33.2 Intracranial abscess as a complication of acute rhinosinusitis. Coronal **(A)** and axial **(B)** T2-weighted MRI images of a child with epidural and subdural intracranial abscesses as a result of acute sinusitis. In the coronal image, opacification of the left maxillary and ethmoid sinus cavities can be appreciated. There is an intracranial fluid collection and meningeal enhancement along the floor and lateral aspect of the left temporal fossa (*arrows*). The axial image demonstrates epidural and subdural fluid collections along the left frontal and temporal aspects of the intracranial region (*arrows*).

for treatment failure between 3 and 6 years of age (83). This is potentially explained with a correlation to the age of first attendance at daycare, preschool, and kindergarten, with concomitant first exposure to pathogens that cause acute rhinosinusitis (83).

The patterns of complications from ABRS in the pediatric population are explained by sinus development and maturation during childhood. The maxillary sinus and ethmoid labyrinth are present at birth. Because orbital complications of sinusitis are frequently associated with ethmoid sinusitis, young children are particularly susceptible to orbital extension of disease (83). The sphenoid sinuses are frequently pneumatized by age 5, but the frontal sinuses don't appear until age 7 or 8. Over the next 5 or so years, the frontal sinuses pneumatize and mature, and accordingly intracranial complications, particularly related to the frontal sinuses, are seen most often in the preteen and adolescent years of life (83).

CONCLUSION

Although otolaryngologists are not frequently the ones providing care for uncomplicated AVRS and ABRS, it is important to be familiar with this disease process. Acute rhinosinusitis is common and has an associated tremendous economic impact. Adherence to guidelines in the treatment planning and follow-up evaluation of patients with acute rhinosinusitis will hopefully help to minimize the economic and quality of life burden associated with this disease, in addition to avoiding future patterns of multidrug resistant, increasingly virulent bacteria. Familiarity with the diagnosis and management of the life-threatening complications of ABRS is necessary as the otolaryngologist will certainly be involved in the care of the patient at that point.

HIGHLIGHTS

- Rhinosinusitis is a common illness with a large economic burden in the United States.
- The most common infectious cause of acute rhinosinusitis is viral illness. Less than 5% of viral illnesses transition into an ABRS. When ABRS does occur, the most common bacterial pathogens are *S. pneumoniae*, *M. catarrhalis*, and *H. influenzae*.
- The three cardinal symptoms of ABRS are purulent nasal discharge, nasal obstruction, and/or facial pain, pressure, or fullness. ABRS is diagnosed when the three cardinal symptoms are present for 10 days or longer beyond the onset of upper respiratory symptoms or when there is a double-worsening of symptoms within 10 days of illness onset.
- Sinonasal endoscopy is indicated in ABRS for symptomatic patients who fail to improve on empiric therapy, who have unilateral disease, who have severe or disabling symptoms, in whom complications are suspected, or who are immunocompromised and consequently at risk for complications.
- CT of the sinuses is recommended when a complication of ABRS is suspected or an alternative diagnosis is considered. It may also be used when patients have comorbidities that predispose to complications. MRI is the gold standard imaging modality for diagnosis of intracranial extension of sinusitis.
- The recommended management for acute viral rhinosinusitis is analgesia and antipyretics, saline irrigations, and topical decongestants for 3 days or less. Topical corticosteroids can be used in addition to mucolytics or second-generation antihistamines if clinically indicated.
- The first-line antibiotic for ABRS is amoxicillin. For patients with penicillin allergy, first-line alternatives are trimethoprim–sulfamethoxazole or macrolides. Patients who have had antibiotics within 4 to 6 weeks prior or who have young children in daycare may be at increased risk for infection with resistant bacteria, and should receive high-dose amoxicillin, high-dose amoxicillin-clavulanate, or fluoroquinolone.
- The possible clinical outcomes for ABRS are resolution, development of complications, or development of chronic rhinosinusitis. The risk factors for development of sequelae of ABRS are male gender, age 10 to 29 years old, and illness during the winter months.
- The most common complication of ABRS in all age groups is orbital extension of disease, which includes the spectrum of illness from preseptal cellulitis through orbital abscess. There is a risk of blindness with extension of infection into the eye.
- Intracranial complications include meningitis, extradural abscess, subdural abscess, intraparenchymal abscess, and cavernous and superior sagittal sinus thrombosis. These have a high risk for associated morbidity and mortality and require aggressive multidisciplinary approach to management.

Chronic Rhinosinusitis with Nasal Polyposis

34

Matthew W. Ryan

Nasal polyps (NPs) are among the oldest recorded ear nose and throat disorders, with historical references that date back to the ancient Egyptians of approximately 2000 BC. NP disease was later the subject of work by Hippocrates who gave these nasal masses their name "polypus." Today we recognize NPs to be benign nasal growths that usually arise as a result of paranasal sinus inflammation, that is, chronic rhinosinusitis (CRS). For this reason, NP disease is considered a subtype of CRS and is labeled chronic rhinosinusitis with nasal polyposis (CRSNP) (1). A variety of other terms have been applied to inflammatory sinonasal conditions with bilateral or diffuse polypoid inflammation: chronic hyperplastic sinusitis, nasal polyposis, or simply NP disease. However, NPs may also arise as isolated lesions in otherwise healthy paranasal sinuses; these solitary polyps are pathophysiologically distinct, and are not considered under the umbrella of CRSNP. Despite the fact that NP disease has been a matter of scientific interest for thousands of years, we do not yet have a widely accepted classification system for NP disorders, the diverse pathophysiologic mechanisms for NP formation are unsettled, and the ideal treatment approach continues to evolve. This chapter reviews the pathophysiology, diagnosis, and classification of NP disease. Treatment for NP disease is covered in Chapters 39 and 40.

The pathophysiology of CRSNPs may differ significantly from other forms of chronic rhinosinusitis without polyps. Thus chronic rhinosinusitis is generally subclassified as "polypoid" or : "nonpolypoid" (based upon the presence of polyps). Nevertheless, the clinical and pathologic presentation of these two entities often overlaps, resulting in a significant spectrum of inflammatory disease in the paranasal sinuses that defies distinct classification (2). Histopathologically, most NPs are noted to have pronounced eosinophilic inflammation. For this reason, allergic mechanisms were assumed to play a causative role in polyp formation. In contrast, chronic rhinosinusitis without nasal polyposis is more commonly found to have a neutrophilic inflammatory infiltrate, and bacterial infection was assumed to play a causative role. We now know that neither of these explanations is consistent or accurate. For example, CRSNP may arise as a result of disease processes that lead to chronic infection (e.g., ciliary dyskinesia, cystic fibrosis [CF]) and the inflammatory infiltrate may be either neutrophilic or eosinophilic. There are some cases in which nasal polyposis evolves out of an underlying CRS without polyps. While the distinction of polypoid and nonpolypoid CRS may be useful clinically, many studies consider them together. So our current classification system should be regarded as tentative, awaiting further clarification of the pathophysiology and appropriate subclassification of chronic rhinosinusitis (Table 34.1).

EPIDEMIOLOGY OF NASAL POLYP DISEASE

The epidemiology of NP disease is difficult to characterize because the diagnosis incorporates multiple syndromes and possible etiologies for NP formation. Questionnaire and survey studies are likely to be inaccurate, and nasal endoscopy is usually required for definitive diagnosis. Despite these limitations, data from a few well-designed studies reveal the prevalence of NP disease to be 1% to 4% (3). Autopsy studies report a higher prevalence but it is not clear that these polyps are clinically significant. NP disease appears to be more common in males and the incidence peaks in the fourth to sixth decades of life (3).

Ethnic and geographic differences may impact the incidence of the various forms of NP disease. Allergic fungal rhinosinusitis (AFRS), which may represent 5% to 10% of CRSNP cases taken to surgery, appears to be more common in warm or humid climates, and is predominantly a disease of teens and young adults. Noneosinophilic NP disease appears to be more common in Asian populations (4).

TABLE 34.1 CLASSIFICATION AND FEATURES OF VARIOUS FORMS OF NP DISEASE

Choanal polyp	Isolated, extends from site of origin (antrum, sphenoid, ethmoid, septum) to the posterior choana
CF	Children, neutrophilic infiltrate, sinus hypoplasia, or mucoceles
AFRS	mucocele formation with eosinophilic mucin, asymmetric sinus involvement, bone erosion, teens, and young adults
Eosinophilic mucin rhinosinusitis	eosinophilic mucin, symmetric sinus involvement, asthma, middle age, and older adults
AERD	asthma, history of asthma exacerbation after NSAID ingestion, symmetric sinus involvement
Churg-Strauss syndrome	asthma, peripheral eosinophilia >10%, vasculitis

TABLE 34.2 DIFFERENTIAL DIAGNOSIS OF NP DISEASE

Angiofibroma
Inverted papilloma
Encephalocele
Nasal glioma
Malignant tumor

Whether there is a difference in incidence of NP disease in Asian versus European peoples is unclear.

Age is an important factor in the incidence of various forms of NP disease. Nasal polyposis in childhood is very rare with an estimated incidence of 0.1% to 0.2%. For this reason, the discovery of an NP in a child should prompt an evaluation to secure an accurate diagnosis and rule out causative conditions such as CF. Antrochoanal polyps account for approximately 5% of polyp cases and present more commonly in young adults (3). AFRS, an important subtype of CRSNP (discussed further in Chapter 37), is also predominantly a disease of teenagers and young adults. Patients with other (non-AFRS) eosinophilic mucin rhinosinusitis tend to be middle aged (average age 48) (5).

Genetic predisposition quite plausibly accounts for at least some cases of NP disease, given the heritability of other eosinophilic inflammatory diseases such as allergic rhinitis and asthma. A genetic basis is also clearly established for diseases that are known to cause NPs, such as CF and Kartagener syndrome. While this topic has not been extensively investigated, one study found that 25% of NP patients had a first degree relative with NP disease (6). However, the majority of NP disease is not clearly heritable via Mendelian genetics.

CLINICAL PRESENTATION

NPs cause symptoms that are typical of other forms of chronic rhinosinusitis. Most patients will have months or years of progressively worsening sinonasal symptoms before they are diagnosed. In some cases, patients without a history of significant sinonasal symptomatology will present with continuous symptoms that can be traced back to an initial inciting event—usually a severe upper respiratory infection or flulike illness. Nasal obstruction, hyposmia, and rhinorrhea are common symptomatic complaints, but nasal congestion, facial pressure or headache, and postnasal drainage are also common. Symptoms alone are unreliable for the diagnosis of polypoid CRS, but smell dysfunction seems to be one feature that is more commonly encountered in CRSNP. This smell dysfunction may be a result of obstruction of airflow into the olfactory cleft or direct inflammation of the mucosa of the olfactory cleft.

The definitive diagnosis of NP disease requires histopathologic examination. A wide variety of tumors and other lesions can mimic NP disease (Table 34.2). These polyp mimics tend to be solitary and unilateral. A suspected polyp that is isolated or unilateral should be further evaluated with computed tomography (CT) imaging followed by biopsy. In most cases of CRSNP the polyps are present bilaterally, owing to their inflammatory etiology, and a clinical diagnosis can be made with information from the history and examination.

Large NPs may be visible on anterior rhinoscopy. Polyps appear as smooth rounded masses with a pale to yellow coloration, usually occurring in clusters (Fig. 34.1) The polyps may be almost translucent. However, there is a great variability in NP appearance with some having an erythematous or irregular mucosal covering. It must be noted that depending upon the degree and type of inflammation,

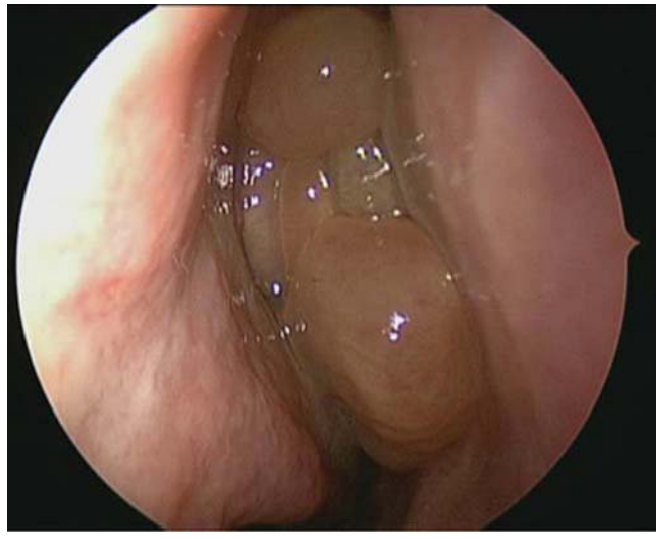

Figure 34.1 Endoscopic appearance of NPs in right nasal cavity, obscuring the middle turbinate.

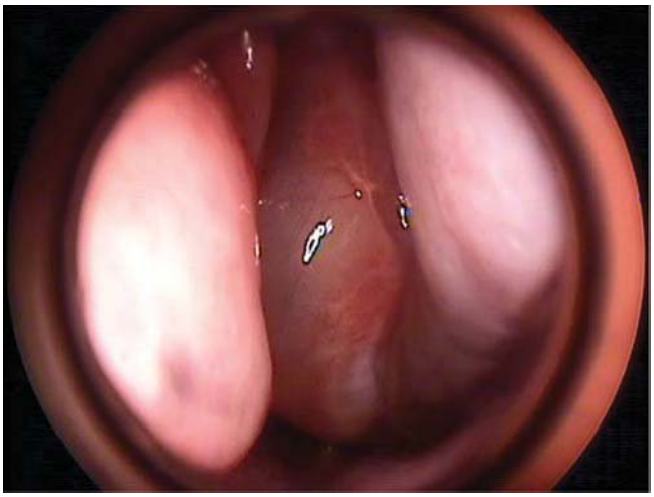

Figure 34.2 Endoscopic view of a smooth, rounded, pale, polypoid mass filling the left nasal cavity and extending almost to the nasal floor. Imaging revealed this mass to be a meningoencephalocele.

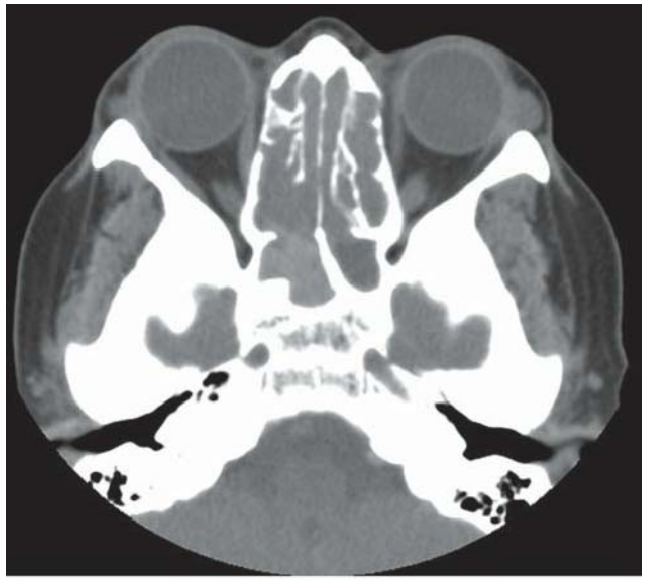
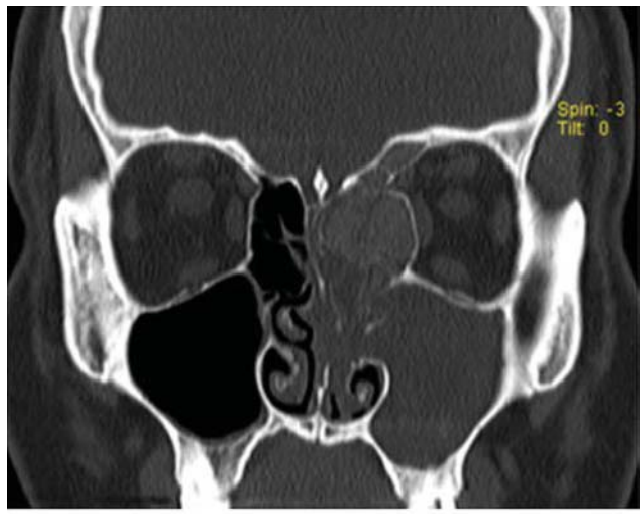
Figure 34.3 Endoscopic view of dense golden eosinophilic mucin in the right middle meatus with generalized nasal edema.

certain NPs may be indistinguishable from tumors. Likewise, some neoplastic lesions or encephaloceles may have an appearance very similar to an NP (Fig. 34.2). Thus in cases of suspected NP disease, imaging, biopsy, or close follow-up are indicated. Clinically significant NPs may not be visible on anterior rhinoscopy, however.



In most cases, NPs are only revealed with thorough nasal endoscopy. The development of office endoscopy has greatly improved our ability to diagnose and monitor the activity of NP disease. With the magnification and illumination of endoscopy it is possible to identify smaller polyps. Polyps usually arise from the lateral nasal wall in the middle meatus or sphenoethmoidal recess. Those polyps that originate lateral to the middle turbinate usually take their origin from the frontal, anterior ethmoid, or maxillary sinuses. Polyps medial to the middle turbinate are usually arising from the posterior ethmoid or sphenoid sinuses. In rare cases, polyps may originate on the nasal septum or from the olfactory cleft. In general, however, a nasal mass that appears to arise or take its origin from the nasal mucosa is less likely to be a benign polyp. NP disease may also be seen in conjunction with abnormal mucus secretions or purulent exudates. Eosinophilic mucin, which is a feature of eosinophilic mucin rhinosinusitis and AFRS, may sometimes be seen on endoscopy, especially in operated patients with an exacerbation of their inflammatory disease. Grossly, eosinophilic mucin is dense, gelatinous to clay-like with color that ranges from yellow to fluorescent green to brown (Fig. 34.3). The finding of eosinophilic mucin may point to one of these diagnoses but is not otherwise diagnostically useful.

As a clinical tool, nasal endoscopy is extremely helpful to monitor the disease burden in patients with CRSNP. Subjective symptoms are a notoriously poor predictor of polyp size or inflammatory disease burden. The treatment approach for CRSNP is discussed in Chapters 39 and 40. In general, while a patient with CRSNP is undergoing medical treatment or being followed up after sinus surgery, regular endoscopic examinations are warranted to evaluate the degree of sinus inflammation and polyp burden. Symptoms alone may not provide adequate warning of significant polyp recurrence until nasal airway obstruction or hyposmia recur. Accurate assessment of disease activity is best performed with surveillance endoscopic evaluations. Medical therapy can then be adjusted based upon the degree of sinonasal inflammation as well as the patient's symptom burden.



Imaging studies are an important component of the diagnostic workup of suspected NP disease. For sinonasal imaging, noncontrast CT is the study of choice. Imaging serves a variety of purposes in this setting. Nonpolyp lesions such as meningoencephalocele or nasal glioma can be distinguished from polyps based upon their location and associated skull base defects. Some tumors such as inverted papilloma and juvenile angiofibroma have characteristic imaging features. In CRSNP, CT enables a delineation of the involved sinuses, can reveal the presence of eosinophilic mucin, and can identify mucoceles, lamina disruption, or skull base erosion that may alter the treatment approach (Fig. 34.4). This imaging provides important anatomic information if surgery is performed. CRSNP causes a significant quality of life (QOL) burden, but is not usually a threat to life or bodily function. Imaging can identify those cases in which a conservative treatment approach is reasonable as well as cases in which more immediate surgical intervention is advisable (e.g., mucocele formation, intraorbital or intracranial expansion of disease). Magnetic resonance (MR) imaging is not usually necessary for the evaluation of NP disease. While MR can delineate polyp from retained secretions, establish a diagnosis of meningoencephalocele, and determine the extent of sinonasal neoplasms, the bony detail of the paranasal

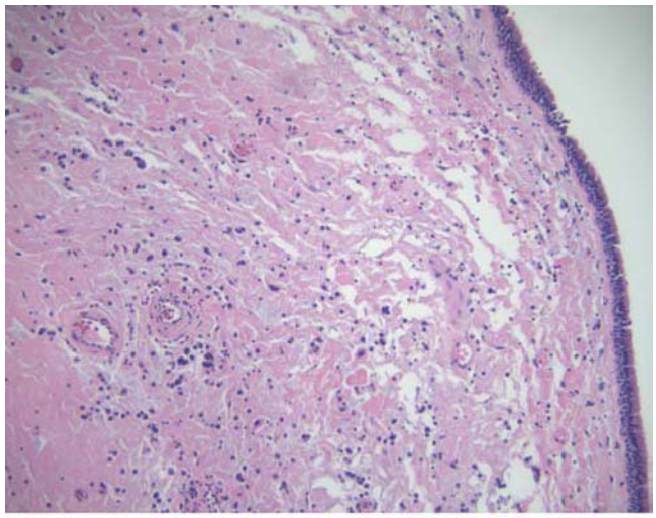
sinuses is lacking. Therefore MR imaging is reserved for special circumstances.

SEVERITY CLASSIFICATION IN NASAL POLYP DISEASE

The severity of NP disease can be measured along several different axes. Like many other chronic medical conditions, the symptom burden of CRSNP is only loosely correlated with objective measures of disease severity. From a patient's standpoint the symptom burden and QOL impairment are paramount. However, the treating physician must also use information from objective measures to formulate an appropriate treatment approach.

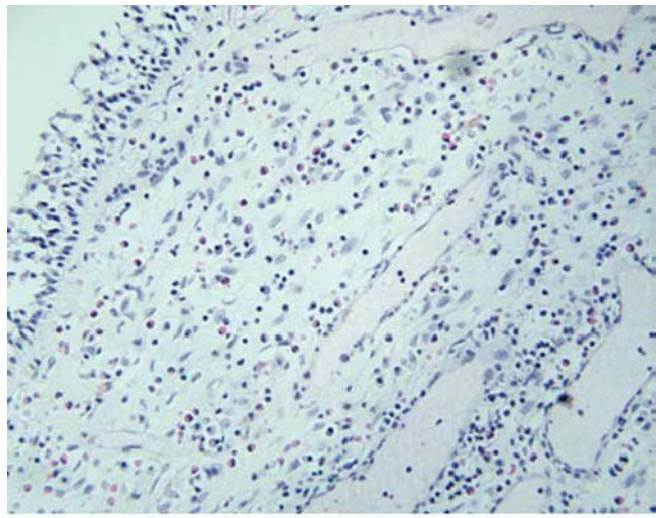
Symptomatic burden in CRSNP can be assessed with a variety of tools including nonvalidated symptom scales and validated disease-specific QOL instruments such as the sinonasal outcome test and rhinosinusitis outcome measure (7). These tools may be used during follow-up visits to assess patient symptom burden over time, and this information should be integrated with objective information to make appropriate adjustments in treatment.

Nasal endoscopy is the most useful objective tool for assessing the burden of inflammatory polyps in the nose and paranasal sinuses. Reliable estimation of polyp size is facilitated by the use of a grading system. One such method described by Lildholdt et al. (8) estimates the bulk of NPs in relation to fixed anatomical landmarks within the nose. A 0–3 grading system is used where 0, no polyps; 1, small polyps not reaching the upper edge of the inferior turbinate; 2, medium sized polyps reaching between the upper and lower edges of the inferior turbinate; and 3, large polyps reaching below the lower edge of the inferior turbinate. However, other similar grading systems have been devised with different scales (e.g., 1–4); therefore, it is important to describe the grading system used when reporting findings (8,9).



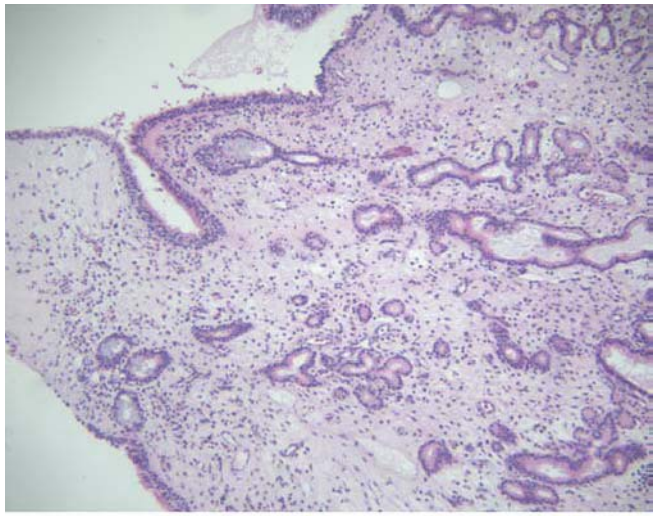
NATURAL HISTORY OF NASAL POLYP DISEASE

The clinical course of CRSNP is highly variable with some patients bothered only by nasal obstruction and others with a pattern of recurrent acute exacerbations that may represent episodes of obstructive bacterial sinusitis. In general, however, many patients with CRSNP will have functionally obstructed sinuses without associated bacterial sinusitis episodes. The natural history of most forms of NP disease is uncertain. Some NP diseases like antrochoanal polyp may be "cured" with a single surgery. Other individuals who develop NP disease in youth appear to "grow out of" their problem over a number of years. Yet others may develop the disease in middle age or later and appear to have an inexorable chronic disease that requires multiple surgeries and repeated courses of systemic steroids. Most CRSNP requires a disease management approach that incorporates current and future burdens of disease. The goals of treatment are to minimize the symptomatic burden over time, prevent rare complications, and minimize the impact of treatment—usually this means minimizing the number of surgeries required over time and minimizing the use of systemic steroid bursts.



CRS with NP has a highly variable prognosis and we lack the tools to determine who will best respond to available therapies. For these reasons the etiopathogenesis of NP disease has generated considerable interest.

HISTOPATHOLOGY



The grape-like masses of NPs are composed of respiratory epithelium with a variable degree of basement membrane thickening, encasing an underlying stroma that differs markedly from normal sinus submucosa. The histologic appearance of NPs is not specific for an underlying etiology of disease. The underlying stroma of NPs has historically been divided into three subtypes: (a) edematous, eosinophilic, (b) fibroinflammatory, and (c) glandular (Fig. 34.5). Of these, the edematous, eosinophilic polyps are the most common, representing up to 85% of polyp specimens. These consist of scattered fibroblasts with tissue edema and a variable infiltrate of mononuclear cells and other granulocytes such as

A

B

C

Figure 34.5 Histopathology of NPs. H&E stained photomicrographs, **(A)** fibroinflammatory polyp (40×), **(B)** edematous, eosinophilic polyp (100×), and **(C)** glandular polyp (40×).

neutrophils and mast cells. The overlying epithelium may have a variety of changes including ulceration, squamous metaplasia, epithelial hyperplasia, or goblet cell hyperplasia. This eosinophilic, edematous histopathology may be seen with a wide variety of conditions that are associated with NP disease including aspirin exacerbated respiratory disease (AERD), AFRS, Churg-Strauss syndrome, and CF. However, polyps in CF are more likely to have significant neutrophilia and therefore labeled "neutrophilic polyps." The fibroinflammatory polyp makes up 10% of NPs and is characterized by submucosal fibrosis with variable mixed inflammatory infiltrate. It is possible that fibroinflammatory polyps are "old" polyps that have undergone secondary fibrotic change. Glandular polyps are the rarest and share some histopathologic overlap with seromucinous hamartoma and respiratory epithelial hamartoma (10). Further examination of the histopathology of NPs with correlation to underlying pathophysiologic states and the clinical course of disease may one day provide the opportunity to more appropriately classify NP diseases and improve our prognostic capability. However, currently there do not appear to be histologic predictors of response to treatment or prognosis.

ETIOLOGY

A variety of theories have been offered over the millennia to explain the development of NPs including an imbalance of humors, obstruction of glandular ducts, lymphatic or vascular blockage, glandular neoplasia, and epithelial rupture with lamina propria prolapse. While it is now recognized that inflammation is an important feature of NP disease we still do not understand why only some patients with CRS develop NPs. Similarly, the anatomic events that lead to polyp formation are unclear. Polyps represent a common phenotypic endpoint that results from a variety of proinflammatory internal derangements of immunity or external triggers for inflammation (Table 34.3).

The inflammation in eosinophilic NPs (which makes up the majority of polyp types in Western populations) has been well characterized from a cellular and molecular standpoint. Inflammation in most CRSNP includes an infiltrate of chronic inflammatory cells with a predominance of eosinophils, lymphocytes, and increased expression of proeosinophilic cytokines (e.g., interleukin-5 [IL-5], granulocyte-macrophage colony stimulating factor) and chemokines (e.g., eotaxin, RANTES, MCP 3 and 4). Studies of NP inflammation have focused on mediators that regulate the recruitment, activation, and survival of eosinophils, and the effect of eosinophil products on polyp formation and growth.

Recent attention has also been directed toward the role of T cells as directors of NP inflammation. T cells are the predominant lymphocyte in NPs (11,12). The role of T lymphocytes in NP disease may depend on many factors including the phenotype (e.g., eosinophilic mucin rhinosinusitis), histology of the polyp (eosinophilic vs. neutrophilic), associated conditions such as allergy, asthma, and aspirin sensitivity, as well as genetic, racial, and ethnic differences (13–16).

Interest in T cells as important cellular actors in the inflammation in CRSNP has been fueled by the theory that superantigen stimulation of T cells drives the inflammation in NP disease. Bachert et al. (17) were the first to show that staphylococcal enterotoxins were potential contributors to the pathophysiology of CRSNP. The sinonasal cavities of CRSNP patients are frequently colonized by *Staphylococcus aureus*, which can secrete protein enterotoxin superantigens (18). Superantigens bind to the T-cell receptor/MHC class II receptor complex in a nonspecific manner and trigger cellular activation in up to 30% of the available lymphocyte pool. Mucus from CRSNP patients has been found to contain toxin producing *S. aureus* (18), and NP T cells show evidence of clonal expansion in response to stimulation by local staphylococcal enterotoxins (19–21). Additionally, staphylococcoal enterotoxins stimulate proinflammatory cytokine secretion by NP tissue *ex vivo*, with a reduction in immunomodulatory cytokines (IL-10, TGF-β1) (22). Regulatory T cells (Treg) are thought to suppress TH2 type inflammation, and defective or deficient Treg function may be partially responsible for the inflammation in eosinophilic airway diseases like CRSNP (23).

A variety of other mechanisms of disease are also being explored as potential causative factors in CRSNP. Chronic infection with biofilm forming bacteria, derangements of innate immunity, and dysfunctional IgE homeostasis are all potential mechanisms that may cause inflammation leading to NP formation. While our current understanding of the etiology of CRSNP is incomplete, clinicopathologic correlation is improving our differentiation of the several phenotypes of NP disease (24).

TABLE 34.3 CONDITIONS ASSOCIATED WITH NP DISEASE

Asthma
AERD
CF
Churg-Strauss syndrome
Ciliary dyskinesia
Allergy

NASAL POLYPS AND ALLERGY

For many years, allergy was presumed to be a causative factor in NP disease. This linkage is plausible given the eosinophilic inflammation in NPs, and the known role of allergy as a mechanism for the production of eosinophilic inflammation. Ample evidence links "allergic-type" inflammation, (i.e., the presence of eosinophils, IgE, and IL-4, IL-5, and IL-13) with CRSNP. A number of studies support this connection. For example, Newman et al. (25) showed

a correlation between severity of sinusitis on CT scan and asthma, allergy, and peripheral eosinophilia. However, detailed investigation has failed to consistently show that individuals with allergic rhinitis alone have an increased prevalence of NP disease (1). Approximately half of CRSNP patients have allergic sensitization (which is similar to the prevalence in the general population). Cross-sectional studies have not shown that skin test positivity correlates with severity of disease or responsiveness to treatment in CRS (26–28). Finally, there are no randomized controlled trials of immunotherapy for the treatment of NP disease.

The conflicting reports raise the possibility that atopic disease may only be important in a subset of patients with NP disease, or that systemic specific IgE does not relate to the local inflammatory milieu within the polyp. For many years it has been recognized that tissue IgE levels are elevated in NPs irrespective of allergy test results (2). Local IgE production within NP tissue may be involved in the pathophyisology of some polyp disease, even in the face of negative skin testing. For example, elevated, specific, and total IgE levels have been correlated with tissue eosinophilia in NP disease (17). Local nasal allergy without positive skin prick testing or serum specific IgE directed against allergens, what is now called "entopy," may explain in part the lower prevalence of "allergy" reported in some studies of NP disease (29). At present, allergy should be addressed as a comorbid condition with CRSNP and treated appropriately.

NASAL POLYPS AND ASTHMA

CRSNP and asthma are significantly linked. From an epidemiologic standpoint these two conditions frequently coexist. Approximately 7% of asthma patients have NPs, and it is estimated that 50% of NP patients have asthma. This relationship appears to be independent from allergic sensitivity (30). In addition to the long recognized clinical association of asthma and NP disease, histopathologic and molecular findings in asthma and NPs are similar. The similarity of these two conditions reinforces the concept of the "unified airway." That is, asthma and chronic rhinosinusitis may be separate clinical manifestations of a single systemic inflammatory disease. This linkage is further supported by the observation that treating upper airway inflammatory disease results in reduced burden of disease in the lower airway (30). Multiple uncontrolled cohort studies have shown that surgical treatment of chronic rhinosinusitis improves asthma. The relationship between CRS and asthma is further explored in Chapter 36.

FUNGI AND NASAL POLYP DISEASE

Fungi may be one extrinsic trigger for sinonasal inflammatory disease. The nasal cavities are commonly exposed to inhaled fungal spores, and it has been hypothesized that fungi serve as an extrinsic trigger for most eosinophilic chronic sinusitis, including NP disease.

In 1999 Ponikau et al. (31) proposed that the inflammation in chronic sinusitis may be a nonallergic immunologic response to fungi within nasal secretions. This theory, known as the "fungal hypothesis," generated significant interest because it offered an explanation for the extrinsic trigger of persistent inflammation in chronic sinusitis patients. This theory is supported by an *in vitro* study that demonstrated that peripheral blood mononuclear cells from chronic sinusitis patients exposed to Alternaria antigen secreted greater amounts of IL-5 than control subjects, suggesting that chronic sinusitis patients develop an inflammatory response to fungi that is not seen in normal subjects (32). The important corollary of the fungal hypothesis is that antifungal treatment administered either topically or systemically might be an effective treatment approach for chronic rhinosinusitis.

The inoculation of fungal spores into the nose is a daily event and multiple studies have shown that fungi can be cultured from most normal and "diseased" noses (31,33). Thus the presence of viable fungi within nasal secretions does not imply causation of disease. A more direct way to establish causation is to examine the clinical benefits of eradication of fungi. Indeed, initial uncontrolled cohort studies suggested that amphotericin B nasal irrigation improved symptoms and endoscopic findings in chronic sinusitis patients (34). However randomized controlled trials have failed to identify a benefit of antifungal treatment. A randomized trial showed that a 6-week course of oral terbinafine at 2.5 times the usual daily dosage did not improve symptoms or radiologic findings in chronic sinusitis patients (35). Multiple randomized trials of topically administered amphotericin B utilizing sprays and irrigations with different dosing schedules and treatment durations have also shown that this approach is not an effective treatment for chronic sinusitis (36–38).

While the fungal hypothesis has not be disproven, a study attempting to replicate the universal IL-5 response to Alternaria in PBMCs from patients with chronic sinusitis revealed a more heterogeneous response than that found by Shin et al. Specifically, this IL-5 response varied based upon disease state, allergic status, and geographic location of the patient (39). It remains to be determined whether antifungal treatment might be effective in certain subpopulations with chronic sinusitis. But current evidence suggests that identification and eradication of resident fungi within the sinonasal cavities may not be an effective approach for most forms of eosinophilic chronic sinusitis, and the role of fungi in triggering chronic sinus inflammation is unclear.

ASPIRIN EXACERBATED RESPIRATORY DISEASE

AERD, also known as aspirin-triad disease, or Samter triad, is an adult-onset disorder of rhinosinusitis, nasal polyposis, and asthma. Urticaria, angioedema, and anaphylaxis

are additional clinical manifestations in some individuals. Affected individuals can usually recount one or more episodes of an "asthma attack" after the ingestion of aspirin or other NSAID. A wide variety of other symptoms may be induced within an hour of NSAID ingestion including rhinorrhea and nasal congestion, conjunctivitis, urticaria, laryngospasm, and abdominal symptoms. The mechanism by which NSAIDs trigger these reactions is COX-1 inhibition. Selective COX-2 inhibitors are usually well tolerated in AERD (40). NSAID ingestion does not cause the condition; the reaction to aspirin is merely the means by which condition becomes manifest, and aspirin challenge in a controlled environment is the most definitive method of diagnosis. The prevalence of AERD depends upon the population under study. It is estimated that 1% to 4% of the population may have AERD. Among asthmatics who undergo aspirin challenge the prevalence rises to 10% to 20%, and in asthmatics with chronic rhinosinusitis/nasal polyposis 30% to 40%. Among asthmatics who report a prior NSAID reaction, challenge studies will be positive in 66% to 97% (40). AERD usually presents initially with symptoms of chronic rhinitis followed by the development of asthma and eventually nasal polyposis, but this sequence is by no means universal as some subjects have preexisting allergic rhinitis or asthma. About 20% of all patients with CRSNP have aspirin sensitivity (41). The condition appears to be more common in women with an onset in the 30s to 40s. The condition does not appear to be familial, with only 1% reporting a family history of the disease (40).

The pathogenetic mechanisms of aspirin sensitivity are incompletely understood but include an abnormal metabolism of arachidonic acid in the cyclooxygenase and lipoxygenase pathways. This results in an overproduction of proinflammatory cysteinyl leukotrienes and prostaglandin D_2 and reduction in the production of anti-inflammatory prostaglandin E_2. These aberrations lead to eosinophilic upper and lower airway inflammation (42). These alterations have been demonstrated in NPs. For example, leukotriene-forming enzyme genes are upregulated in NP tissue with a resulting increase in cysteinyl leukotriene concentrations (43).

While AERD has a spectrum of severity, these patients are generally felt to have a particularly severe form of disease that is difficult to manage (44). Aspirin-sensitive patients are more likely to require multiple endoscopic surgeries to manage their disease (45). Management consists of leukotriene modifiers (montelukast, zafirlukast, and zileuton), topical or systemic corticosteroids, endoscopic sinus surgery, and aspirin desensitization

CYSTIC FIBROSIS

CF is an autosomal recessive disease caused by mutations of the CFTR gene on chromosome 7q31. The molecular defect leads to defective chloride channels and increased mucus viscosity in the respiratory tract, and hyperviscosity of mucus leads to severe dysfunction of mucociliary clearance in the sinonasal cavities with secondary infection, inflammation, sinus blockage, and polyp formation. Infectious sinusitis, usually due to *Pseudomonas* and *S. aureus*, leads to accumulation of DNA from neutrophils recruited to the infected tissue further increasing the viscosity of secretions. Up to 5% of the Caucasian population carries the gene, and one in 20,000 infants are affected. Nasal polyposis is rare in children but may be present in 5% to 86% of CF children (gysin). Essentially all patients with CF have sinus inflammation whether they are symptomatic or not. Interestingly, the sinonasal consequences of the CF mutation may not be confined to homozygotes with two abnormal genes. In a case-control study, 7% of CRS patients had a CF mutation, while non-CRS controls had a 2% rate of mutation of one allele (46). In another study (47), 53% of CF carriers self-reported CRS. These findings suggest that in some patients, heterozygosity for a CF gene may be a contributing factor in the development of CRS.

The goals of medical and surgical management of CRSNP in CF patients are altered by the disease process. The sinonasal mucosa usually fails to normalize after appropriate medical and surgical treatment (48,49). Surgery in CF CRS is indicated for medically refractory polyposis with nasal obstruction, pulmonary exacerbations associated with sinusitis, to improve sinus health in anticipation of transplant, and for mucoceles. The pattern of rhinosinusitis also leads to frequent anatomic changes such as medial displacement of the lateral nasal wall, demineralization of the uncinate, frontal and sphenoid hypoplasia, and mucocele formation. Chronic sinusitis in CF is notorious for recurrence and refractoriness to treatment.

Surgical series have documented high rates of polyp recurrence and return to baseline symptoms within the first few years after surgery (50,51).

However no studies are available that compare CF to non-CF patients with CRSNP, with regard to symptom severity or polyp recurrence.

CONCLUSION

Rather than being a single disease, CRSNP is a clinical phenotype that results from a variety of pathologic conditions that cause sinonasal inflammation. The inflammation that leads to NP formation is heterogeneous though eosinophilic inflammation predominates. AERD, ciliary dyskinesia, and CF are clearly causative factors in NP formation, but most polyp disease remains idiopathic. A variety of external triggers or intrinsic derangements of immunity are likely involved in these cases. NPs are usually diagnosed on clinical grounds, but should be carefully differentiated from other sinonasal mass lesions with imaging or biopsy in select circumstances.

HIGHLIGHTS

- NPs are a common manifestation of a variety of pathologies including infection, mucociliary dysfunction, deregulated eosinophilic inflammation, atopy, and altered eicosanoid metabolism
- NPs should be clinically distinguished from other sinonasal masses through imaging, biopsy, or close follow-up
- While NP disease is commonly associated with atopy, the role of specific allergy as a causative or disease modifying factor is controversial
- Children with NPs should be evaluated for CF
- The histopathology of NPs is not predictive of treatment outcome or prognosis
- Eosinophilic mucin rhinosinusitis is a subtype of NP disease characterized by the accumulation of dense eosinophil-rich mucin in the paranasal sinuses. This condition may be confused with allergic fungal sinusitis.

35 Nonpolypoid Rhinosinusitis: Pathogenesis, Diagnosis, Staging, and Treatment

Zara M. Patel *Peter H. Hwang*

Rhinosinusitis is one of the most common diseases diagnosed in the United States. Approximately 20 million cases of acute bacterial rhinosinusitis (ABRS) are diagnosed annually (1). In addition, more than 30 million people suffer from chronic rhinosinusitis (CRS). This corresponds to an annual prevalence of 13% to 16%, which has been increasing (2). CRS, therefore, is one the most common chronic conditions reported in the United States, more prevalent than asthma, heart disease, diabetes, or headache.

The costs associated with rhinosinusitis are substantial and are also increasing. Direct health care expenditures associated with acute rhinosinusitis are estimated at $3.5 billion annually, while those of CRS total $4.3 billion (1,3). These figures do not take into account indirect costs such as lost or restricted workdays or decreased productivity. For the individual CRS patient, this represents an approximate annual cost of $1,539 (4).

CRS can significantly worsen patients' quality of life. When compared to the general population, CRS patients report more pain, less vitality, and decreased social functioning. Outcomes studies have shown that patients with CRS have worse scores in several quality of life domains compared to patients with chronic obstructive pulmonary disease, diabetes, and congestive heart failure (5).

Our understanding of the pathophysiology of CRS has improved dramatically over the last decade, although these findings have inevitably led to even more questions about CRS etiologies. Progress in basic science coupled with technologic improvements in endoscopy, imaging, and surgical technique have progressively enhanced our ability to diagnose and treat rhinosinusitis.

PATHOPHYSIOLOGY

Acute Rhinosinusitis

The etiology of acute rhinosinusitis is thought to be more straightforward than that of CRS. In acute rhinosinusitis, the role of viral and bacterial pathogens has been well established (1,2). Acute viral rhinosinusitis is by far more common than acute bacterial rhinosinusitis (ABRS). Adults, on an average, have two to three acute viral upper respiratory tract infections annually, many of which involve the paranasal sinuses. Specific incidence rates are not known, but it is estimated that 39% to 87% of acute viral upper respiratory tract infections result in acute viral rhinosinusitis. Rhinovirus is responsible for approximately half of the cases, with other viruses such as coronavirus, influenza, parainfluenza, respiratory syncytial virus, adenovirus, and enterovirus accounting for the rest. Of all viral upper respiratory tract infections, approximately 0.5% to 2% will become complicated by a secondary ABRS (6).

During the acute viral infection, multiple inflammatory mediators are upregulated. Acute inflammation of the sinus mucosa, manifested by mucosal hypersecretion and edema, may cause obstruction of the sinus outflow tracts. The resulting mucus stasis may provide a rich environment for bacterial proliferation. Viruses may also damage or disrupt the nasal epithelium and impair mucociliary clearance, further predisposing the patient to a secondary bacterial infection. While acute viral infection is a primary etiology of ABRS, host factors such as odontogenic infection, atopy, systemic immunodeficiency, dysfunctional innate immunity, or anatomic obstruction may be secondary predisposing factors.

The most common pathogens associated with ABRS are *Streptococcus pneumoniae* (33%), *Haemophilus influenzae*

(32%), *Staphylococcus aureus* (10%), and *Moraxella catarrhalis* (9%) (7). Since the introduction of the 7-valent pneumococcal vaccine for children, there has been a trend toward decreasing prevalence of *S. pneumoniae* isolates and increasing prevalence of *H. influenzae* isolates derived from adults with acute maxillary sinusitis (8).

Chronic Rhinosinusitis

The pathophysiology of CRS has revealed itself to be much more complex than previously assumed, and the paradigm of treating rhinosinusitis simply as a prolonged infection is long past. The contribution of inflammation to CRS pathogenesis is increasingly appreciated, with multiple varied pathways potentially leading to a common endpoint of mucosal inflammation.

The categorization of CRS subtypes has evolved to reflect an improved understanding of varied pathophysiologies in CRS. Indeed, CRS subtypes may demonstrate differential clinical responses to treatment, likely due to differing pathophysiologies. The first branching point of classification is polypoid versus nonpolypoid rhinosinusitis; as another chapter in this book covers the polypoid type, we do not concentrate on it here. Further subcategories include eosinophilic versus noneosinophilic, and finally allergic fungal versus nonallergic fungal (Fig. 35.1). As another chapter in this text covers fungal rhinosinusitis, we only discuss fungus as it may relate to other forms of CRS (9).

Our understanding of underlying mechanisms of CRS has evolved beyond the local milieu of the nose and paranasal sinuses towards a greater appreciation of systemic pathophysiology. For example, the emerging concept of unified airway disease emphasizes the mutual influence and interplay between the upper and lower respiratory tracts, with shared inflammatory mediators such as T-cell cytokines IL-4, IL-5, and IL-13 and similar leukocytic profiles, especially eosinophils (10).

Paranasal sinus inflammation can be incited by the interaction of multiple etiologies, including microbial factors, environmental factors, and host factors such as abnormalities in structure, genetics, physiology, and innate immunity (Fig. 35.2).

Microbial Factors

Although antimicrobial agents are ubiquitously used to treat CRS, the actual role that infectious organisms play in CRS has been a controversial topic over the last decade. Bacteria have been cultured from the sinuses of patients with CRS but also from those of healthy normals. With the identification of bacterial superantigens and bacterial biofilms associated with CRS, it appears that bacteria may have a much more complex role in the etiology of CRS beyond the classic pathway of infection as is seen in ABRS.

Superantigens are exotoxins produced by a wide array of infectious microorganisms that have the ability to activate a much larger subpopulation of the T-lymphocyte pool (5% to 30% as opposed to less than 0.01% activated by traditional antigens). The activation of the T cell is able to occur without antigen–peptide receptor specificity due to cross-linking of both the outside portion of the major histocompatability class II complex on antigen presenting cells as well as the T-cell receptor in its variable beta portion.

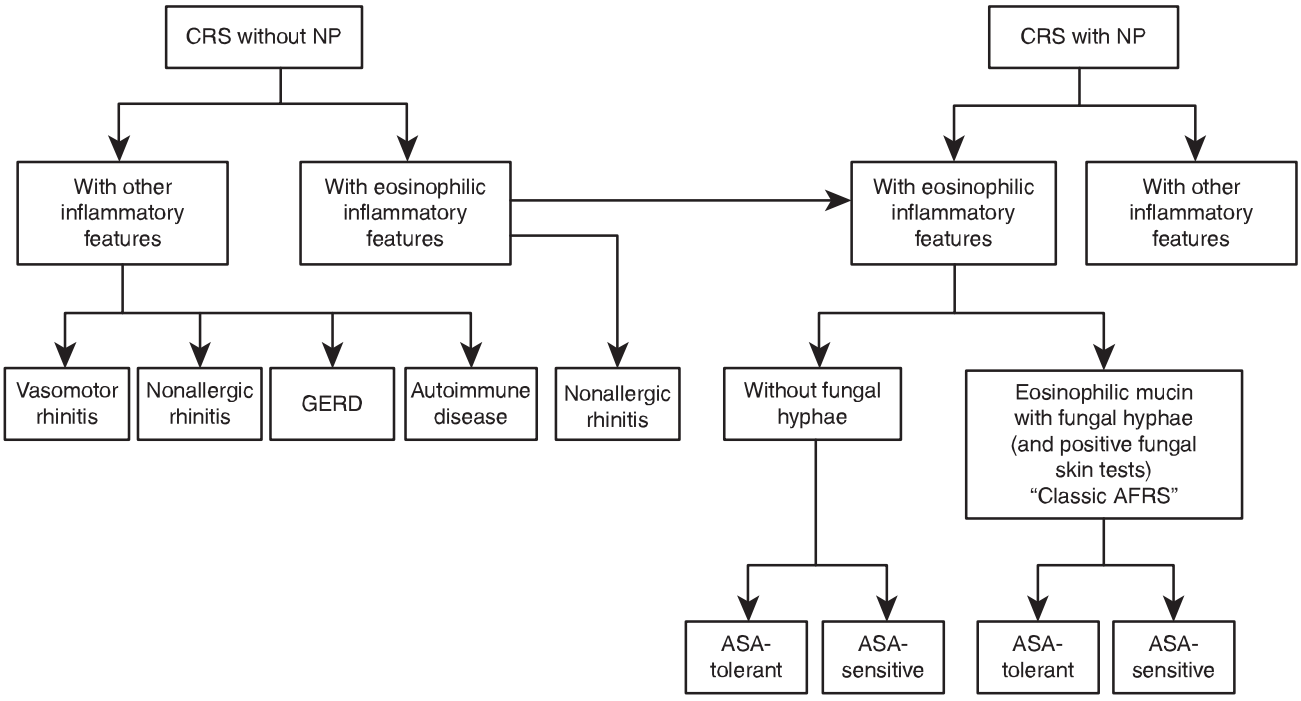

Figure 35.1 Classification for CRS.

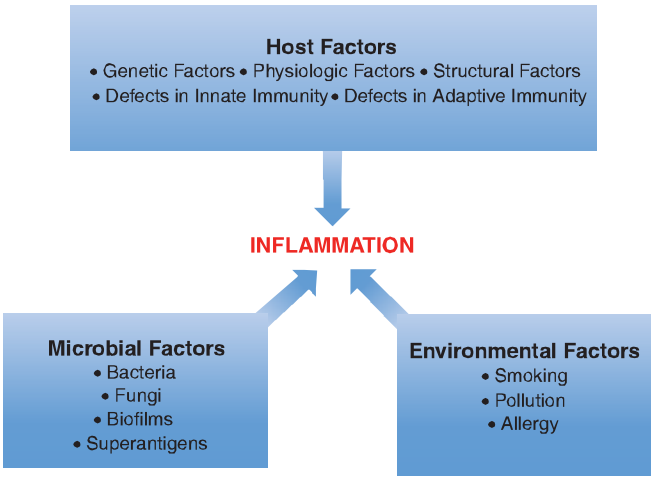

Figure 35.2 Underlying factors contributing to the pathophysiology of CRS.

Without requiring antigen specificity, T-cell–mediated inflammation may be propagated and magnified by the presence of bacterial exotoxins. Superantigens are not only linked to a dramatic upregulation in T-cell response, but have also been associated with increased eosinophils, increase in IL-5 and upregulation of PGE_2 (11).

Staphylococcus aureus is well recognized for its production of superantigens, synthesizing more than a dozen exotoxins associated with superantigen effects. Investigators have shown that patients with an elevated specific IgE to staphylococcal enterotoxins A and B had a higher incidence of asthma (12). Other investigators have expanded on these findings by identifying antibodies to other bacterial superantigens in CRS patients and by demonstrating altered steroid sensitivity in the presence of these superantigens (13,14).

Odontogenic infections are important to note as a potential etiology of CRS due to potential differences in microbial flora. The most common isolates in these cases are anaerobic streptococci, gram-negative bacilli, and enterobacteriaceae (15).

A biofilm is an organized community of bacteria adherent to an inert or living surface, embedded in a self-produced extracellular polymeric matrix. Biofilms appear to be the preferred form of bacterial existence, with only approximately 1% of bacteria existing in the free-floating planktonic form (16). The Center for Disease Control (CDC) estimates that around 65% of all human infections are caused or persist due to biofilms. Within the field of otolaryngology, biofilms have been implicated in varied diseases, including otitis media, chronic tonsillitis, adenoiditis, and device infections (such as in cochlear implants, tympanostomy tubes, and tracheostomy tubes) (17).

The extracellular matrix which constitutes biofilms is thought to protect against multiple defense systems such as antibodies, immune-system phagocytosis, and complement binding, making it up to 1,000 times more resistant to treatment when compared with the planktonic form (18). In addition, biofilms facilitate intermicrobial communication and exchange. Through quorum sensing, bacterial populations can redistribute densities to optimize utilization of nutrient resources. Biofilms also enable the interbacterial transfer of genetic information via plasmids to promote variability and adaptive mutations, such as antibiotic resistance. These factors, in addition to intrinsic nutrient gradients that are integral to the biofilm matrix, minimize the impact of environmental stressors and promote bacterial viability that can contribute to the persistence of infection in spite of prolonged therapy with antibiotics (19). Multiple studies have now shown the presence of both bacterial and fungal biofilms in patients with CRS, although the exact contribution of the biofilm to the pathogenesis of CRS remains to be clarified (20–22).

The pathogenicity of fungus in the paranasal sinuses has been well documented in cases of fungal ball, invasive fungal sinusitis, and allergic fungal sinusitis. However, the extent to which fungus may play a role in CRS at large remains a point of much debate (23).

In much the same way that bacteria can be found in the sinuses of both patients with CRS and healthy controls, fungus has also been found to be widely prevalent in the nose and sinuses of both CRS and normal populations (24). Thus the mere detection of fungus in the nose or sinuses of a patient with CRS does not indicate the pathogenicity of the fungus. The host response to fungus appears to be the differentiating factor between states of sinonasal disease and health. Shin et al. showed that by exposing peripheral blood mononuclear cells to fungal antigens *in vitro*, 89% of CRS patients showed increase in IL-5 and IL-13, but there was no such increase in controls. Interestingly, these results correlated with fungal-specific IgG, not IgE, implicating a nonallergic mechanism (25). However, Orlandi et al. found contradicting results when replicating the Shin study using CRS patients and controls from multiple geographic regions. Orlandi et al. (26) demonstrated elevated IL-5 and IL-13 production in both CRS patients as well as controls, and the IL-5 levels correlated to IgE response instead of IgG, directly contradicting the findings of the Shin study. It appears that more data is needed to make any conclusions about the extent of the association between fungus and CRS (27).

Environmental Factors

Smoking and exposure to secondhand smoke have been identified as morbid cofactors in CRS. Senior et al. found that the most significant risk factor for requiring revision sinus surgery was continued smoking. This was especially true for patients with more advanced disease. Briggs et al. (28) also demonstrated that persistent smoking is significantly associated with worse symptom outcomes after endoscopic sinus surgery. Cohen et al. (29) recently demonstrated decreased ciliary beat frequency as well as impaired transepithelial chloride secretion in both murine septal and human sinonasal epithelial cell (SNEC) cultures when exposed to cigarette smoke condensate. Two

case-control studies have now documented a significant independent association between secondhand smoke and CRS (30,31).

Other environmental pollutants can also have adverse effects on the upper respiratory tract predisposing to CRS. Longitudinal studies of clean-up workers at the World Trade Center disaster site show a clear correlation between environmental pollution exposure and disease in the upper respiratory tract, especially in patients with preexisting atopy (32).

Although there does appear to be a subset of patients with ABRS who have classic IgE-mediated allergic triggers, the association between allergy and CRS, in spite of the strong eosinophilic induction in both processes, is much less defined (33). While allergic rhinitis is a common comorbidity with CRS, the presence of allergy has not consistently been shown to affect the extent of radiographic disease, symptom severity, or the need for surgery (34).

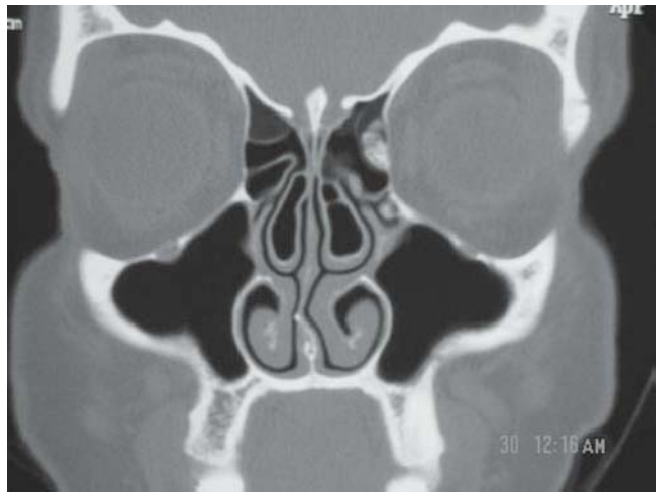

Figure 35.3 Coronal CT scan showing bilateral concha bullosa.

Structural Factors

Structural and anatomic factors were traditionally the main etiologic focus during the early years of endoscopic sinus surgery. Although multiple structural anomalies have been identified and associated with rhinosinusitis, we now know that the anatomic basis of the disease is only one of the categories of inciting factors, and these must be examined in light of other factors as described in this chapter. The term *ostiomeatal complex* (OMC) has been widely described and incorporated into our literature. It should be stressed that the OMC is a functional unit rather than an anatomic structure. It refers to the physiologic arrangement of structures into which the frontal, maxillary, and anterior ethmoid sinuses drain. Anatomically, this corresponds to the area of the ethmoid infundibulum, the middle meatus and its surrounding structures. Classic teaching suggested a pivotal role for the OMC in the establishment of CRS, and a recent study sought to test that hypothesis. Chandra et al. performed a retrospective review in which they found that more than 35% of patients meeting the definition of CRS did not manifest OMC obstruction radiologically. When present, however, OMC obstruction was associated with increased disease burden (35).

Patency of the pathways through which the sinuses drain is crucial for adequate mucociliary function and subsequent sinus drainage. The nasal and sinus mucosa produces approximately 1 L of mucus per day, which is cleared by mucociliary transport. Ostial obstruction may lead to fluid accumulation and stagnation, creating a moist, hypoxemic environment ideal for growth of pathogens.

Sinus obstruction may be caused by multiple anatomic variants, including septal deviation, concha bullosa, paradoxical middle turbinates, and infraorbital (Haller) cells (Fig. 35.3). Scarring from previous surgery or trauma can also anatomically impair sinus drainage. Craniofacial anomalies in which the anatomy of the sinuses is altered may predispose patients to rhinosinusitis. In children, foreign bodies should always be considered as another possible obstructive cause of sinusitis.

The underlying bone within the sinuses may itself also contribute to persistent inflammation or infection. Kennedy et al. demonstrated histologic changes in the ethmoid bone of CRS patients consistent with bony inflammation. Histomorphometry showed increased numbers of inflammatory cells and significantly increased bone turnover, comparable to the rate seen in osteomyelitis. Subsequently, Khalid et al. (36) found evidence of chronic osteomyelitis in the contralateral maxillary sinus of 52% of rabbits that had undergone induced unilateral maxillary rhinosinusitis. With these findings, the authors suggested that inflammation and possibly infectious agents may spread to distant sites through the bony Haversian system. Additional research is needed to determine whether these observed bony changes represent a primary causative phenomenon or a secondary reaction to the overlying inflammatory milieu.

Genetic Factors

The increased prevalence of CRS in patients with certain inherited disorders such as cystic fibrosis (CF) has led to the investigation of possible genetic mutations predisposing to CRS. A landmark study in 2000 showed that mutations in CF genes, in non-CF patients, were significantly more common in CRS patients than in controls (37). In confirmation, a recent genome-wide screen for CRS susceptibility identified a locus on 7q31.1–7q32.1, with the largest linkage signal near the CFTR gene (38). Polymorphisms in the TNF-α, MMP-9, IL-13, IL-33, and IL1A genes have been associated with increased susceptibility to CRS. Furthermore, alterations in the 6p22, 22q13, and 1q23 chromosomal regions have been demonstrated in both CRS and aspirin-sensitive asthma phenotypes, reinforcing concepts of a unified airway pathophysiology (39).

Physiologic Factors

Mucociliary dysfunction has often been cited as a precursor to CRS. Inherited disorders such as CF are associated with abnormal mucociliary clearance from the sinuses. The increased viscosity of nasal secretions in CF patients impedes adequate clearance and leads to ciliary injury, local mucosal edema, and further inflammation. Ciliary dysfunction is the hallmark of a group of disorders known as Primary Ciliary Dyskinesia. Morphologic ciliary defects, such as absent ATPase-containing dynein arms, result in ciliary dysmotility that predisposes patients to both acute and chronic rhinosinusitis. Kartagener syndrome, the most common form of Primary Ciliary Dyskinesia, is associated with a triad of chronic sinusitis, bronchiectasis, and situs inversus. The former term "immotile cilia syndrome" is no longer used in recognition of the fact that true ciliary immotility is far less common than motile but dyskinetic cilia.

Cytokines and other inflammatory mediators, along with respiratory pathogens and particulates released in patients with CRS, have been shown to impact ciliary function and propagate a cyclic loop of inflammation and ciliary dysfunction (40,41).

Acid reflux disease has long been noted by physicians in patients with CRS, but until recently, good data to support a correlation, let alone a causative association, have been lacking. DelGaudio et al. performed a prospective study looking at postsurgical patients with persistent CRS, looking for a possible role for nasopharyngeal reflux. The patients with persistent CRS had more reflux at the nasopharynx, the upper esophageal sphincter, and at the distal esophagus than controls, with the greatest difference at the nasopharynx (42). Wong et al. actively instilled acid into the esophagus of healthy volunteers, looking for a possible reflex arc to the nose. An increase in nasal mucus production occurred with instillation of both saline and hydrochloric acid into the esophagus. Although there was no clear difference between the test groups, the authors still concluded this may have demonstrated a reflex arc via the vagus nerve (43). A provocative study recently published in the gastroenterology literature was a placebo-controlled, double-blind trial in which 75 participants with symptoms of chronic postnasal drainage were randomized to treatment with 30 mg of lansoprazole twice daily or placebo (44). Patients did not have sinusitis or allergy, and they underwent ambulatory esophageal pH monitoring. After 16 weeks, the lansoprazole-treated group was 3.5 times more likely to have symptomatic improvement versus placebo, with absolute symptom improvements of 50% in the lansoprazole group versus 5% in the placebo group. Notably, the presence of heartburn symptoms or abnormal esophageal pH was not predictive of symptom improvement. While this study excluded patients with CRS, the demonstration of a therapeutic effect of proton pump inhibitors on the function of the nasal mucosa opens the door for further investigation.

CRS is a common finding in granulomatous disorders such as sarcoidosis and Wegener granulomatosis, but these are discussed elsewhere in this textbook so will not be expounded upon in this chapter. Briefly, in Wegener granulomatosis, nasal symptoms can be a presenting manifestation and often one of the most common complaints. Autoimmune disorders such as systemic lupus erythematosus, Sjogren syndrome, and relapsing polychondritis can also present with signs and symptoms of rhinosinusitis.

Immune deficiencies, whether inherited or acquired, can also contribute to sinusitis. In a retrospective review, Chee et al. (45) demonstrated immune deficiencies, which included low immunoglobulin levels and deficient T-cell function, in up to half of their patients with medically refractory sinusitis. Although IgG subclass deficiency is the most common deficiency identified, multiple entities including selective IgA deficiency, common variable immunodeficiency, and X-linked agammaglobulinemia can present with ABRS or CRS. In human immunodeficiency virus (HIV)-infected individuals, rhinosinusitis is one of the most common infections and can be more severe and treatment-resistant than in HIV-negative individuals. Hyperimmune states such as is seen in Churg-Strauss and Job syndromes can also predispose to rhinosinusitis. Even though most patients with rhinosinusitis are not immunodeficient, a history of persistent or recurrent infections despite adequate antimicrobial therapy should raise the suspicion of immune deficiency as a contributing factor.

Abnormalities in innate immunity are being increasingly well characterized and appreciated for their potential causative role in CRS. Early on in this past decade, CRS was thought to be mediated primarily by the adaptive immune system, with Th1 cells mediating neutrophilic nonpolypoid subtypes of CRS and Th2 cells driving the eosinophilic inflammatory response typified by polyposis. Recently, the interaction between innate immune functions within the SNEC and the adaptive immune system has come to light. The innate system recognizes certain pathogen-associated molecular patterns via transmembrane glycoproteins known as Toll-like receptors, which in turn switch on a signaling cascade, activating Th1, Th2 or type I interferon profile (46). Multiple antimicrobial peptides, such as lactoferrin, lysozyme, cathelecidins, defensins, SP-A and SP-D, and secretory leukocyte proteinase inhibitor are produced by the SNEC and are a major part of the innate immune system. Mucociliary clearance also plays a key role within the innate immune system, being the first defense against all inhaled particles (47).

DIAGNOSIS

In order to foster effective communication among physicians and researchers and to standardize the reporting of rhinosinusitis, the Task Force on Rhinosinusitis was created in 1996, sponsored by the American Academy of

TABLE 35.1 SIGNS AND SYMPTOMS ASSOCIATED WITH DIAGNOSIS OF RHINOSINUSITIS (1996 RHINOSINUSITIS TASK FORCE)

Major Factors	Minor Factors
Facial pain/pressure[a]	Headache
Nasal obstruction	Fever (all nonacute)
Nasal discharge/discolored postnasal discharge	Halitosis
	Dental pain
Hyposmia/anosmia	Fatigue
Purulence on examination	Cough
Fever (acute only)[b]	Ear pain/pressure/fullness

[a]Facial pain/pressure alone does not constitute a suggestive history for diagnosis in the absence of another major symptom or sign.
[b]Fever in acute sinusitis alone does not constitute a suggestive history for diagnosis in the absence of another major symptom or sign.
Adapted from Lanza, DC, Kennedy DW. Adult rhinosinusitis defined. *Otolaryngol Head Neck Surg* 1997;117:S1–S7.

Otolaryngology-Head and Neck Surgery (AAO-HNS). Their work resulted in the publishing of "working definitions" for rhinosinusitis in 1997 (48). The Task Force proposed a symptom-based format for the diagnosis of rhinosinusitis, with major and minor symptom categories (Table 35.1). According to the duration of the symptoms, rhinosinusitis was defined as *acute* when symptoms lasted 4 weeks or less, *subacute* when symptoms were present for 4 to 12 weeks, or *chronic* for symptoms lasting longer than 12 weeks. The term *recurrent acute* rhinosinusitis was reserved for patients with four or more episodes per year with disease-free intervals in between. An *acute exacerbation of CRS* was defined as a sudden worsening of symptoms in a patient already diagnosed with CRS, with return to baseline symptoms after treatment. A *strong* history consistent with rhinosinusitis would require the presence of either two major factors, or one major and two minor factors. When only one major factor or two or more minor factors were present, this constituted a *suggestive* history in which rhinosinusitis should be included in the differential diagnosis.

While these definitions have largely remained in use to the present day, there have been several efforts to further refine the working definitions of CRS. In 2003 a new task force, the Task Force for Defining Adult Chronic Rhinosinusitis, described objective criteria that must be present in addition to symptoms for a diagnosis of CRS (2). Once again in 2007, these criteria were further codified (49). These objective criteria may take the form of either physical exam findings or imaging studies (Table 35.2). Recently, consensus guidelines have been published jointly by five national societies including the AAO-HNS, the American

TABLE 35.2 DIAGNOSTIC CRITERIA FOR SINUSITIS FROM 2007 TASKFORCE

Acute Rhinosinusitis	Up to 4 wk of purulent nasal drainage (anterior, posterior, or both) accompanied by nasal obstruction, facial pain-pressure-fullness, or both: • Purulent nasal drainage is cloudy or colored, in contrast to the clear secretions that typically accompany viral upper respiratory infection, and may be reported by the patient or observed on physical examination. • Nasal obstruction may be reported by the patient as nasal obstruction, congestion, blockage, or stuffiness, or may be diagnosed by physical examination. • Facial pain-pressure-fullness may involve the anterior face, periorbital region, or manifest with headache that is localized or diffuse.
Acute Viral Rhinosinusitis	Acute Viral Rhinosinusitis (AVRS) that is caused by, or is presumed to be caused by, viral infection. A clinician should diagnose AVRS when symptoms or signs of acute rhinosinusitis are present <10 d and the symptoms are not worsening.
ABRS	Acute Viral Rhinosinusitis that is caused by, or is presumed to be caused by, bacterial infection. A clinician should diagnose ABRS when: a. Symptoms or signs of acute rhinosinusitis are present 10 d or more beyond the onset of upper respiratory symptoms, or b. Symptoms or signs of acute rhinosinusitis worsen within 10 d after an initial improvement (double worsening)
CRS	Twelve (12) weeks or longer of two or more of the following signs and symptoms: • Mucopurulent drainage (anterior, posterior, or both) • Nasal obstruction (congestion) • Facial pain-pressure-fullness • Decreased sense of smell AND inflammation is documented by one or more of the following findings: • Purulent (not clear) mucus or edema in the middle meatus or ethmoid region • Polyps in nasal cavity or the middle meatus • Radiographic imaging showing inflammation of the paranasal sinuses,
Recurrent Acute Rhinosinusitis	Four (4) or more episodes per year of ABRS without signs or symptoms of rhinosinusitis between episodes: • Each episode of ABRS should meet diagnostic criteria above

Adapted from Rosenfeld RM, Andes D, Bhattacharyya N, et al. Clinical practice guideline: adult sinusitis. *Otolaryngol Head Neck Surg* 2007;137:S1–S31.

Rhinologic Society, the American Academy of Otolaryngic Allergy, the American Academy of Allergy, Asthma, and Immunology, and the American College of Allergy, Asthma, and Immunology (7). The guidelines address not only definitions of rhinosinusitis, but also suggest criteria for clinical research and clinical trial designs.

As with any other medical condition, the diagnosis of rhinosinusitis begins with a detailed patient history. Information that should be obtained in the initial history includes the presence of symptoms as outlined by the 1996 Task Force, duration and localization of symptoms, aggravating or relieving factors, and medications used. Any history of allergies or atopy should be addressed in depth. Details of any prior surgical interventions should be carefully elicited. Multiple, sinus-specific, validated symptom questionnaires exist, and have transitioned over the last decade from purely research-oriented tools to a helpful adjunct to patient care. Two of the more commonly used in recent publications have been the Sino-Nasal Outcomes Test-22 (SNOT-22) and the Rhinosinusitis Disability Index (50,51).

The initial portion of the physical exam consists of an anterior rhinoscopy performed with adequate lighting, either with a headlight, head mirror, or the endoscope itself. This should be performed in both the natural and decongested states to assess mucosal edema, turbinate hypertrophy, and response to topical decongestion. With fiberoptic endoscopy, our ability to examine the nasal cavity has been greatly improved (Fig. 35.4). Both rigid and flexible endoscopes may be used for nasal endoscopy, but the rigid scopes have the advantages of a wider field of vision, enhanced clarity, and the ability to use a second hand for instrumentation. In some situations, particularly in postoperative patients, a flexible endoscope may provide greater visualization of the floor of the maxillary sinus or the lateral recesses of the frontal sinus.

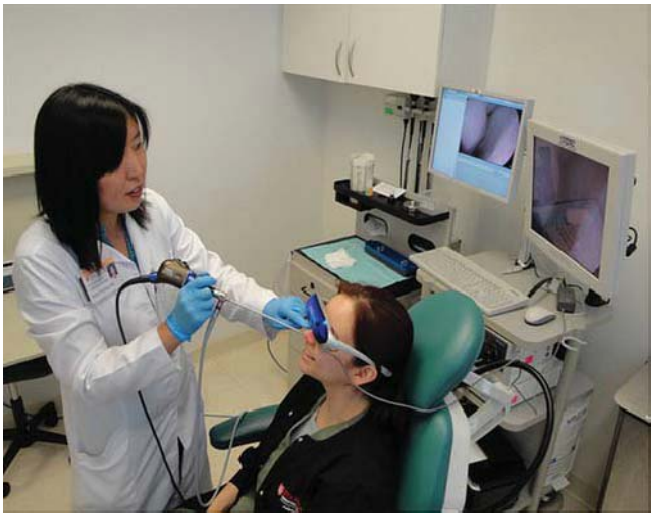

Figure 35.4 The setup for office endoscopy. While the examiner can see the endoscopic view on the monitor behind the patient, the patients themselves can watch along with specialized goggles.

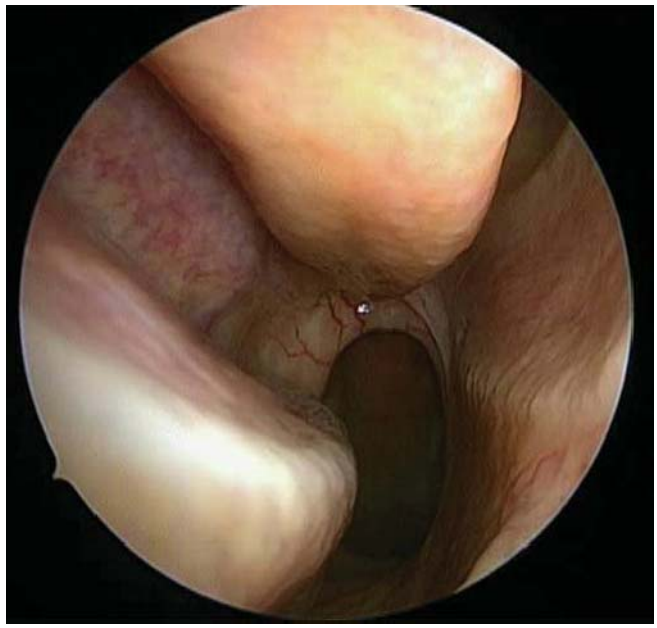

Figure 35.5 View of the inferior endoscopic pass. One can see the posterior aspect of the inferior turbinate, the postero-inferior septum and the choanae. If the endoscope were passed more posteriorly, the Eustachian tube and fossa of Rosenmuller could also be visualized.

Classically described, the nasal endoscopy is composed of three passes of the endoscope. After proper topical anesthesia and decongestion, the scope is first advanced medial to the inferior turbinate along the floor of the nasal cavity to the nasopharynx. Along the way, structures accessible for examination include the inferior septum and maxillary crest, inferior turbinate and inferior meatus, choana, eustachian tube orifice, fossa of Rosenmuller, and nasopharynx (Fig. 35.5). If an angled rigid scope or a flexible scope is used, the contralateral eustachian tube can also be examined. The second pass is performed above the inferior turbinate and medial to the middle turbinate in order to examine the superior septum, middle and superior turbinates, olfactory cleft, sphenoethmoid recess, and sphenoid sinus ostium (Fig. 35.6). The third pass is then directed into the middle meatus itself to examine the structures contained therein.

History and physical exam usually provide enough information to make the diagnosis of rhinosinusitis, especially in ABRS. However, radiologic imaging can be a useful adjunct in establishing objective evidence for the diagnosis of CRS. Plain films have no residual role in the contemporary work-up of CRS (7). Computed tomography (CT) scans are considered the standard for imaging the sinuses. CT scans provide excellent bony anatomic detail, readily depict anatomic variants, and provide a roadmap for presurgical planning (Fig. 35.7). Current multidetector CT protocols enable detailed coronal and sagittal reconstructions from thin section axial cuts. Triplanar imaging can be helpful in evaluating anatomic variations of the frontal recess or sphenoethmoid complex. Intravenous contrast is

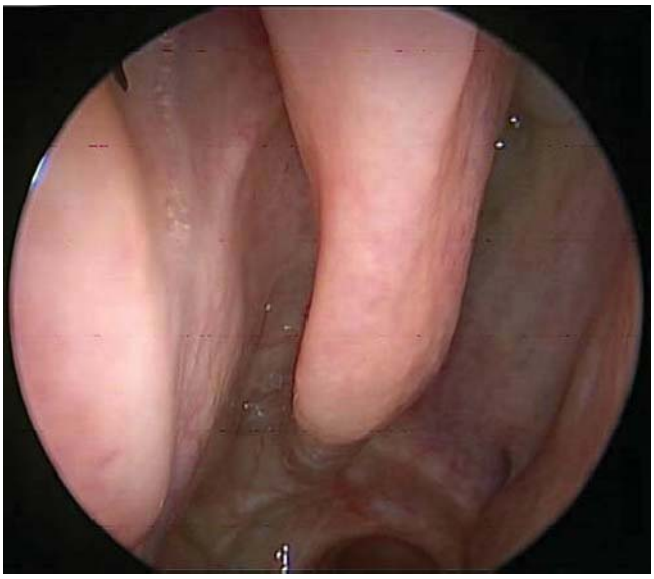

Figure 35.6 The superior pass. One can see the superior turbinate attachment to the face of the sphenoid sinus above the choana and if the endoscope were moved slightly superiorly and medially, the natural ostium of the sinus itself might be visible just medial to the superior turbinate. Sometimes the inferior third of the superior turbinate must first be removed before visualizing the natural ostium.

typically not required unless one is concerned about tumor or infectious complications involving the orbit or brain. Magnetic resonance imaging (MRI) can be a useful adjunct to CT for soft tissue and fluid delineation, but is inferior in imaging of bony detail. Due to recent concerns regarding excessive radiation exposure from radiologic studies, there has been renewed interest in the potential use of MRI as a primary diagnostic imaging tool in CRS (52). Lin and Bhattacharyya have performed the only study to date

Figure 35.7 CT scan demonstrating CRS. This is a coronal CT image showing the maxillary and ethmoid sinuses. Note the complete opacification of the right maxillary sinus and the fluid or mucosal thickening visualized within the left maxillary sinus with a small Haller cell present.

examining the diagnostic accuracy of MRI in CRS relative to CT. They found the results correlated strongly and suggested that MRI may be viable when used as the primary diagnostic tool, although more data need to be gathered and validated (53).

In patients with medically refractory ABRS and CRS, endoscopically obtained culture of purulent secretions with sensitivity profiles is an important tool in diagnosis (54). In a meta-analysis of 126 patients, the yield of endoscopic middle meatal cultures was assessed against the gold standard of maxillary sinus puncture and aspiration performed in the same patient; endoscopically derived cultures were shown to have a satisfactory yield and excellent correlation with sinus puncture (55). These may be performed with sterile suction traps or small wire swabs, as both have been shown to be equally efficacious. In both cases, however, care must be taken to minimize contamination from the nasal vestibule. Nonendoscopic swab cultures obtained from the vestibule or nasal cavity should be avoided, as these are not likely to be accurate and typically only demonstrate contaminant pathogens.

More specialized objective tests of nasal function that are less commonly utilized include olfactory testing, rhinomanometry, and acoustic rhinometry. The Smell Identification Test is a 40-item forced-choice scratch-and-sniff test of olfaction that provides comparative normative data for smell function by age and gender. The test is also designed to detect malingering and has sufficient sensitivity to assess longitudinal changes in olfactory function over time. Rhinomanometry and acoustic rhinometry measure airway resistance and volume, respectively, and are currently used primarily in clinical research.

STAGING

Over the years, multiple staging systems for CRS have been proposed to stratify patients according to severity of disease, but two have remained as the most accurate and widely used, not only in research protocols but in clinical practice as well.

The most widely used system for radiologic stratification is the Lund-Mackay CT staging system, owing to its simplicity as well as its excellent interobserver and intraobserver agreement. Scoring is based entirely on CT findings, and different anatomic regions are given a numeric score: 0, no opacification; 1, partial opacification; and 2, total opacification (Table 35.3). The frontal, maxillary, anterior ethmoid, posterior ethmoid, and sphenoid sinuses are graded separately, and the OMC is also scored, for a total possible score of 24 (56). In the recently published Task Force guidelines, a modification to the Lund-Mackay system is proposed, citing the need to substratify within grade I disease (47).

Soon after the publication of the Lund-McKay radiologic staging system, a modification was suggested, now known as the Lund-Kennedy grading system, which

TABLE 35.3 LUND-MACKAY CT STAGING SYSTEM

Sinus	Right	Left
Frontal	0–2/2	0–2/2
Maxillary	0–2/2	0–2/2
Anterior ethmoid	0–2/2	0–2/2
Posterior ethmoid	0–2/2	0–2/2
Sphenoid	0–2/2	0–2/2
OMC	0 or 2/2	0 or 2/2
Total	Total score/24	

Each individual sinus is scored: 0 = clear, 1 = partial opacification, 2 = total opacification. Scoring for the OMC: 0 = clear, 2 = occluded. Adapted from Lund VJ, Kennedy DW. Quantification for staging sinusitis. The staging and therapy group. *Ann Otol Rhinol Laryngol Suppl* 1995;167:17–21.

incorporates the presence of anatomic variants, type of surgery performed, symptom scores, and endoscopic scores in addition to the CT score (Table 35.4) (57).

DIAGNOSTIC CORRELATES

One of the conundrums in the decision-making process in patients with CRS has been the inability to correlate symptoms with more objective testing such as nasal endoscopy or CT scans. Many well-designed outcomes studies have consistently shown poor correlation between subjective and objective findings in CRS. This discrepancy is often highlighted when evaluating patients for surgery, as surgical decisions are frequently made on a combination of subjective and objective criteria that are not necessarily in agreement.

Multiple studies have attempted to correlate nasal endoscopy findings with the symptom-based diagnostic criteria for CRS. Stankiewicz and Chow (58) analyzed 78 patients prospectively who met the 1997 subjective criteria for CRS with same-day nasal endoscopy and CT scanning. They found that nearly 70% of patients had normal endoscopies. Notably, they found that endoscopy was a good predictor of CT scan findings, with almost 80% of patients with a normal CT scan having a normal endoscopic evaluation. Abnormal endoscopy had a positive predictive value of 74% in predicting positive CT scans, with polyps, purulence, and mucosal edema being the most significant signs seen on endoscopy. Casiano et al. analyzed the correlation between nasal endoscopic findings and CT scans in 247 patients who were undergoing endoscopic sinus surgery. They developed an endoscopic staging system to evaluate their patients and found a relatively high degree of correlation between endoscopy and CT. The sensitivity was 84% and the specificity 74%. When polyps were present, the correlation with CT increased to 94% (59).

Other authors have sought to correlate patient symptoms with CT scan findings. Hwang et al. (60) examined 125 patients prospectively with symptom questionnaires and sinus CT scans. They found that 35% of patients who met symptom-based criteria for CRS had negative CT scans, while 9 out of 10 patients who did not meet the criteria had positive scans. Overall, the subjective criteria had a high sensitivity of 89%, but a very low specificity of 2%. Other authors have confirmed these findings. In one study, up to 53% patients who met the CRS subjective criteria had normal CT scans, with no difference in symptom severity between patients with positive and negative CT scans (61). It was recently demonstrated that there is no better correlation in postsurgical patients. Ryan et al. found that symptoms did not correlate well with either CT findings or endoscopy score. Although endoscopy and CT scores correlated well, a normal endoscopy could not assure a normal CT scan (62). All of these studies together confirm that symptomatology, nasal endoscopy, and CT evaluation are complementary in the evaluation of the patient with CRS.

TABLE 35.4 KENNEDY STAGING SYSTEM FOR CHRONIC SINUSITIS

Stage	Findings
I	Anatomic abnormalities All unilateral sinus disease Bilateral disease limited to ethmoid sinuses
II	Bilateral ethmoid disease with involvement of one dependent sinus
III	Bilateral ethmoid disease with involvement of two or more dependent sinuses on each side
IV	Diffuse sinonasal polyposis

Adapted from Kennedy DW. Prognostic factors, outcomes and staging in ethmoid sinus surgery. *Laryngoscope* 1992;102(12 Suppl):1–18.

TREATMENT

Acute Rhinosinusitis

The overprescribing of antibiotics is an issue affecting primary care providers and otolaryngologists alike. High rates of drug resistant infections have made the judicious, evidence-based use of antibiotics an imperative.

The first determinant in treatment of acute rhinosinusitis is whether the infection is likely viral or bacterial. Clinical guidelines have proposed that acute viral and bacterial sinusitis generally cannot be differentiated until day 10 of symptoms, beyond which the infection is likely to be bacterial (48). At day 10, antibiotic treatment is appropriate, but reliable patients may also be observed, since the rate of spontaneous improvement in ABRS is 40% to 60%. Antibiotic treatment before day 10 of symptoms may be appropriate in patients who have a relapse of symptoms after initial improvement ("double worsening") or in patients with severe symptoms.

Clinical trials for acute rhinosinusitis are difficult to interpret because of highly variable diagnostic inclusion

criteria. Systematic reviews suggest that antibiotics shorten the duration of illness and may increase the rate of cure by 15% compared with placebo. Antibiotics may also decrease the need for concomitant supportive medication (63–66).

If antibiotic therapy is chosen, the treatment regimen should begin with a narrow spectrum antibiotic, broadening coverage in the face of immunocompromise, failure to respond to initial therapy, or specific culture results showing resistance. The 2007 guidelines recommend amoxicillin as an appropriate first line therapy. If patients fail to respond, fluoroquinolones or high-dose amoxicillin-clavulanate (4 g/day) are recommended (1). Regional resistance rates should be considered when prescribing. The duration of therapy is generally recommended to be 10 days, although this is based simply on the duration used in most clinical trials, and has not been validated definitively (53).

As with trials examining antibiotics, studies of intranasal steroid use in ABRS have used broad inclusion criteria, and may not truly reflect the patient population defined by our Task Force guidelines. However, a Cochrane review in 2007 performed a meta-analysis of four double-blind placebo-controlled trials and recommended use of intranasal steroids in ABRS as monotherapy or as an adjunct to antibiotics (67).

Buffered normal saline irrigation can be used via high pressure or low pressure delivery systems to rinse the nasal cavity. Decongestants and mucolytics can also be used as supportive therapy, although care must be taken in patients with high blood pressure when administering oral decongestants, and patients must be counseled to avoid prolonged use of topical nasal decongestants to avoid developing rhinitis medicamentosa. Decongestants and normal saline irrigation are both listed as optional under the 2007 guidelines.

Complications of acute sinusitis are rare (estimated 1 in 1,000 cases of ABRS) but carry the potential for serious morbidity and require urgent treatment. Severe headache, altered mental status, high fever, and prostration should alert the clinician to the possibility of intracranial extension of infection. Meningitis, epidural abscess, cavernous sinus thrombosis, or even frank brain abscess are potential adverse sequelae. The presence of periorbital edema, erythema, impaired extraocular motility, or diminished visual acuity may indicate orbital extension of infection. Prompt imaging with contrast is indicated to characterize the presence and extent of extrasinus spread of infection, and consideration must be given to urgent administration of intravenous antibiotics and surgical treatment.

Chronic Rhinosinusitis

Antimicrobial Therapy

The 2007 guidelines actually offered no specific treatment recommendations for CRS, instead focusing on minimizing symptoms with preventive strategies such as normal saline irrigation, good hand-washing habits, and treatment of underlying exacerbating factors. They also recommended evaluating refractory patients with CRS for contributory factors or disease states such as CF, ciliary dyskinesia, or anatomic variations (48). In keeping with the multifactorial pathophysiology of CRS, the treatment options are equally varied; as in ABRS, the relative lack of published trials comparing treatments in CRS is a barrier to providing truly validated evidence-based care. As discussed above, the role for a microbial effect on inflammation is more likely mediated through superantigens and biofilm formation rather than solely a planktonic infection. Nevertheless, oral antibiotics are the most commonly prescribed agents for CRS. Because of increased prevalence of Staphylococcus species, gram-negative bacilli, and anaerobes in CRS (especially after sinus surgery), broader spectrum antibiotics may be necessary if given empirically (68). Antibiotic selection should be guided by appropriately obtained cultures whenever possible, especially in postoperative patients and those who have failed an initial trial of first-line antimicrobials. Culture-directed therapy may reduce drift toward highly resistant organisms over time, and sinus cultures have been shown to direct a change in therapy in 51.4% patients with CRS (69,70). Parenteral antibiotics have a limited role in the treatment of CRS and are not indicated for routine treatment. Intravenous antibiotics may be indicated in unusual cases of severe or complicated infections, highly resistant organisms, or patient intolerance of other therapies.

The optimal duration of antibiotic therapy for CRS has not been clearly established. Most authors recommend a prolonged course of 4 to 6 weeks of antibiotics; however, the only randomized controlled clinical trial looking at antibiotic therapy in CRS compared macrolide treatment (roxithromycin) to placebo for 3 months (71). The authors found statistically significant improvements in SNOT-20 score, nasal endoscopy, saccharine transit time, and IL-8 levels in lavage fluid in the macrolide group. This study was published in 2006, and by the time a Cochrane review was performed in 2011, it was still the only randomized clinical trial evaluating an antibiotic versus placebo in the literature (72).

Interestingly, it is not the antibiotic effect of macrolides that led to this study, but rather the anti-inflammatory effects of macrolides. Studies have shown that 14- and 15-membered ring macrolides inhibit multiple aspects of neutrophilic inflammation. Not only do they interfere with neutrophil migration and adherence to sites of inflammation, but they also reduce the neutrophil oxidative burst and increase the rate of programmed cell death. They also inhibit IL-1b, IL-8, nuclear factor kB, transforming growth factor B, and granulocyte-macrophage colony stimulating factor, all inflammatory cytokines (73). Multiple studies have demonstrated that macrolides may also inhibit formation of Pseudomonal biofilms, reduce the thickness of airway mucus secretions, and even have a reparative effect on inflamed upper and lower airway mucosa (74).

TABLE 35.5 TRIALS EVALUATING TOPICAL ANTIBACTERIAL THERAPY

Antibacterial Therapy for CRS: Summary of Presented Clinical Studies

Study	Sample Size	Antibacterial/Delivery System	Dose	Duration of Treatment	Placebo Treatment	Conclusions of Study
Desrosiers et al. (80)	20	Tobramycin-saline via large particle nebulizer	240 mg/d	1 mo	Saline-only solution	Few additional benefits when compared with control
Scheinberg and Otsuji (78)	41	One of the following antibiotics via nebulizer: cefuroxime, ciprofloxacin, levofloxacin, or tobramycin	cefuroxime, 285 mg t.i.d.; ciprofloxacin, 90 mg b.i.d.; levofloxacin, 70 mg b.i.d.; tobramycin, 95 mg b.i.d.	3–6 wk	None	Nebulized antibiotics were superior to oral therapies
Vaughan and Carvalho (79)	42	One of the following culture-directed antibiotic via nebulizer: ceftazidine, ciprofloxacin, levofloxacin, ofloxacin, tobramycin, or gentamicin	Information not provided	At least 3 wk	None	Nebulized antibiotics were safe and effective
Uren et al. (81)	16	Mupirocin via nasal lavages	200 mg/d	3 wk	None	Mupirocin was effective in treating patients with *S. aureus* infection

b.i.d., twice daily; t.i.d., three times daily.
Adapted from Comstock RH III, Lam K, Mikula S. Topical antibiotic therapy of chronic rhinosinusitis. *Curr Infect Dis Rep* 2010;12(2):88–95.

Most other published data on antimicrobials in the setting of CRS surrounds their use in topical application (Table 35.5). As discussed above, biofilms are thought to be an important causative factor in CRS, and high concentrations of antibiotic are known to be necessary for eradication. The appeal of topical antibiotic therapy is the ability to achieve high concentrations at the level of the sinonasal mucosa with minimal systemic absorption and adverse side effects. Ha et al. (75) evaluated topical mupirocin, ciprofloxacin, and vancomycin for the treatment of *S. aureus* biofilms *in vitro*, and determined that mupirocin was the only suitable choice for intranasal delivery because of its efficacy and lack of potential side effects. Ciprofloxacin was ineffective even at high concentrations, and vancomycin was only effective at concentrations so high that any absorption would lead to serum levels in the toxic range. Chiu et al. (76) found disappointing results when trying to apply topical tobramycin to eradicate *Pseudomonas* biofilms in the sinuses of rabbits, eradicating only planktonic bacteria with increasing concentrations, but not the biofilms themselves.

Topical therapies are less likely to be beneficial in treating unoperated sinuses, and the efficacy of distribution (nebulizer vs. irrigation) should be considered when assessing antimicrobial efficacy (77). Although early nonrandomized and uncontrolled clinical studies examining nebulized antibiotic therapy suggested it was safe and effective, the only study with a placebo comparison group showed no difference in outcomes between nebulized tobramycin versus nebulized saline alone (78–80). Studies of medicated irrigations have shown greater promise, perhaps related to better efficacy of large volume rinses in reaching the sinuses. Uren et al. (81) studied twice-daily irrigations of mupirocin at 500 μg/mL in sixteen patients with surgically recalcitrant CRS and endoscopic cultures positive for *S. aureus*. Fifteen of the sixteen patients had improved endoscopic findings, 12 of 16 noted improvement in overall symptoms, and 15 of 16 had negative post-treatment cultures for *S. aureus*. Although the current level of evidence is low for the use of topical antimicrobial therapy, promising results from pilot studies will hopefully be validated by larger scale controlled clinical trials.

Research interest in potential fungal etiologies of CRS has led to multiple studies examining topical antifungal therapy as a possible treatment option for CRS. Ponikau et al. (82) first published a prospective open-label trial using topical amphotericin B twice a day for 3 months and found it to be safe and effective. Criticisms of this study included lack of placebo control and randomization. This study was then followed by prospective randomized placebo-controlled studies using topical amphotericin B which failed to show any benefit, although notably these studies used nasal spray as the delivery method in lieu of irrigation (83,84). Ponikau et al. published a follow up randomized, blinded placebo-controlled study of amphotericin nasal lavage. Although the authors claimed beneficial effects of amphotericin B, there was no significant difference in

quality of life improvement between the treatment and control groups, and the study suffered from small sample size. Improvement in the endoscopic exam and a slight radiologic improvement were observed in the treatment group versus control (85). Finally, a definitive multicenter, placebo-controlled, double-blinded study was conducted, using multiple subjective and objective outcome measures, and no difference was demonstrated between the treatment and control arms (86). Recently this same group published a follow up "part two" to the multicenter trial, again examining topical amphotericin B compared with placebo; there was no significant effect on the levels of multiple pro-inflammatory cytokines, chemokines, and growth factors in CRS nasal lavage samples (87). It appears there is not sufficient evidence at this time to recommend topical antifungal therapy.

Multiple studies have been performed on adjunctive topical therapies targeting biofilms. Naturopathic treatments including tea tree oil and manuka honey have proven effective against biofilms through *in vitro* testing, but have yet to show their efficacy in clinical trials (88,89). Surfactants have recently held the most focus in the literature, with the goal of disruption of the biofilm matrix itself. Although neither 1% baby shampoo in saline irrigation or citric acid zwitterionic surfactant (CAZS) have been evaluated in randomized trials, both have shown clinical efficacy in disruption of biofilms on the paranasal sinus mucosa. Studies evaluating baby shampoo have shown symptomatic improvement in greater than half the patient population, but approximately 10% were forced to stop using it due to side effects (90). CAZS disrupted biofilms but at the same time caused ciliary dysfunction, with almost 85% of the cilia denuded compared to the saline controls (91).

Anti-Inflammatory Therapy

Topical steroid therapy is generally accepted as part of the treatment regimen for CRS in the form of nasal spray, with strong evidence supporting its use (92). Topical steroid irrigation has become a commonplace practice among rhinologists, particularly in the treatment of CRS with nasal polyposis, but also it can be used in CRS without polyposis. Uncontrolled case series have been published demonstrating efficacy in CRS patients refractory to more traditional treatments (93,94). Although there have not been any randomized trials looking at efficacy, budesonide irrigation is used frequently enough that studies examining the safety profile have emerged. Two articles to date have published no significant suppression of the adrenal axis in patients using budesonide, at 1 month and 2 month endpoints, respectively (95,96).

As with topical antimicrobial therapy, the efficacy of topical steroid therapy is related to the vehicle of delivery as well as the successful reach of medication to the target site. Saline irrigation alone has been shown to be beneficial in management of CRS symptoms, though the magnitude of the symptomatic improvement was not as large as that observed with topical nasal steroids (97). High volume irrigation in the head-down position appears to be most effective for delivery into the paranasal sinuses.

Systemic steroids have proven valuable in a variety of chronic inflammatory diseases, and their use in CRS is well established, especially in treating CRS patients with nasal polyposis. Although oral steroids are also commonly used by otolaryngologists for CRS without polyposis, a recent systematic review has revealed that the level of published evidence for their use is primarily level 4 and 5 (98). The use of oral steroids may be limited by well known side effects such as insomnia and weight gain, and may be contraindicated in patients with osteoporosis, diabetes, glaucoma, or psychiatric illness.

Other immunomodulating agents have been of increasing interest in management of the inflammatory aspects of CRS. Leukotriene receptor antagonists such as zafirlukast and montelukast have been anecdotally reported to have therapeutic effects in patients with nasal polyps who are being treated concurrently for lower airway disease, but there are no randomized clinical trials supporting its use in nonpolypoid CRS (99). Zileuton, a 5-lipoxygenase inhibitor, has been shown to be effective in nasal polyposis associated with aspirin exacerbated respiratory disease, but no studies have been conducted in nonpolypoid CRS (100).

That same understanding is what has spurred the study of omalizumab, an anti-IgE monoclonal antibody, in CRS. This antibody has had success in treating both asthma and allergic rhinitis (101). Pinto et al. (102) recently published a randomized, double-blind, placebo-controlled trial of omalizumab for patients with CRS, and while improvements were seen on the SNOT-20 at 3, 5 and 6 months compared to controls and reduced inflammation was seen on imaging in these patients, there were multiple other endpoints which showed no statistical difference. The authors concluded that IgE may play a small role in CRS, but that studies with larger enrollment were necessary to determine the clinical significance of these differences.

A number of other candidate therapeutic agents are being evaluated for their potential immunomodulatory effects in CRS. Vitamin D is one such agent, and there appear to be immunomodulatory interactions with the innate and adaptive immune systems (103). Treatment of CRS with vitamin D analogues remains to be studied. Statin drugs have also recently shown promise in decreasing inflammation in the upper and lower airways. Wang et al. recently performed an analysis of sinus tissues collected from patients with CRS. Suppression of highly expressed inflammatory mediators CCL5, CCL11, and IL13RA was found in patients who were on statins, suggesting that statins may induce anti-inflammatory effects (104). *In vitro* studies of cultured primary human airway epithelial cells exposed to ambient air pollution confirmed that expression of these mediators was suppressed by pretreatment with statins. Other compounds being investigated include retinoic acid, L-ascorbate, resveratrol, and bioflavanoids (105–108).

Although medical therapy is always considered first line, endoscopic sinus surgery is the final treatment pathway for many patients with CRS. There have been multiple studies showing that endoscopic sinus surgery improves patient symptoms, quality of life, and nasal endoscopic exam in cases of CRS refractory to medical therapy (109,110). Surgical indications, perioperative management, and surgical technique are discussed in another chapter.

HIGHLIGHTS

- Rhinosinusitis is one of the most common health care complaints with a significant impact on patients' quality of life.
- The pathophysiology of CRS is multifactorial and predisposing factors can be subdivided into microbial factors, environmental factors, and host factors such as genetics, physiology, anatomic structure, and innate immunity. These all interact to produce the endpoint of chronic inflammation.
- The diagnosis of CRS entails a combination of subjective and objective criteria. Nasal endoscopy and CT scanning offer distinct clinical advantages in the evaluation of CRS, and there is poor correlation between subjective and objective parameters in the assessment of CRS.
- The treatment of rhinosinusitis should address the predisposing factors leading to inflammation. This may involve the use of appropriately selected oral or topical antimicrobials, oral or topical steroids, saline irrigations, immunomodulators, and surgical intervention.

36 The Unified Airway

Jeb M. Justice *Richard R. Orlandi*

Otolaryngologists frequently encounter patients with diseases of the upper airways. Patients with upper airway disease present a unique challenge. In addition to having diseases like allergic rhinitis (AR) or chronic rhinosinusitis (CRS) that negatively impact their quality of life, they are at risk of concurrently having or subsequently developing lower airway disease, such as asthma. Although upper airway disease has significant cost and morbidity in and of itself, asthma may have even more associated morbidity and socioeconomic burden. As such, recognition of concomitant lower airway disease and effective management of upper and lower airway disease is paramount.

Recent evidence has shown that the upper and lower airways behave as a single functional unit, with similar histologic characteristics and concurrent inflammation. Worsening of disease in one part of the airway negatively impacts other parts of the airway. Furthermore, effectively managing disease in one part of the airway seems to improve disease in other parts of the airway. This has led to the concept of the unified airway and it has revolutionized the understanding of the relationship between the upper and lower airways.

The concept of unified airway has solidified the need for multidisciplinary care for these patients involving primary care physicians, otolaryngologist, allergists, immunologists, and pulmonologists. Historically, otolaryngologists have less experience in recognizing and managing lower airway disease. Thus it is important for otolaryngologists to understand the concept of the unified airway and apply this to their practice to best manage these patients.

The concept of a unified airway is based on a century-old observation that patients with lower airway disease had a high incidence of upper airway disease as well. In the last 15 years, interest has increased in the relationship between the lower and the upper airways and the shared inflammation between the two. Krouse has proposed three criteria in support of the theory of the unified airway and they are as follows:

1. Patients with upper airway disease such as rhinitis and rhinosinusitis should have a higher prevalence of lower respiratory diseases such as asthma; the corollary, increased prevalence of upper respiratory disease among patients with lower respiratory diseases, also should be present.
2. Interrelated pathophysiologic mechanisms between upper and lower airway diseases should exist to explain the interaction of these two disease processes.
3. Treatment of one portion of the unified airway should improve symptoms in a separate portion of the respiratory system (1).

Asthma may represent the most important aspect of this concept insofar as it carries the most morbidity of all the airway diseases. The presence of AR and CRS are clues to the development of asthma, and effective management of these diseases can positively impact the management of asthma. In this chapter, the evidence and literature that has helped support the concept of a unified airway is reviewed. Furthermore, the disease processes that affect the upper and lower airways are discussed. Finally, treatment modalities and the impact of treatment of one part of the airway on the rest of the airway are reviewed.

ALLERGIC RHINITIS

AR is a common disease affecting 20% of adults and up to 40% children in United States. Its importance lies in its direct and indirect costs to society and its negative impact on quality of life (2,3). AR is characterized by an immunoglobulinE (IgE)-mediated, type 1 hypersensitivity reaction that is triggered by an inhaled antigen. The immunologic response to this inhaled antigen produces

the classic symptoms of AR, which are characterized in Table 36.1 (4).

With regards to the underlying mechanisms of AR, the first phase is known as the priming phase during which one's mast cells are sensitized to a specific antigen. The first exposure to an antigen leads to processing by an antigen presenting cell (APC) or a macrophage. After processing the antigen, the APC interacts with a CD4+ Th2 helper T cell, leading to release of Th2 type cytokines like interleukin (IL)-4 and IL-13, as well as inducing B cells of the immune system to differentiate into plasma cells. The plasma cells produce IgE specific to the initial inciting antigen and attach them to the surface of mast cells rendering the mast cells sensitized. The patient is now primed to have a mast cell degranulation of inflammatory mediators upon subsequent allergen exposure.

The next exposure to the specific allergen will result in the degranulation of the mast cell and release of preformed mediators such as histamine, kinins, and proteases, which lead to the classic symptoms of AR, listed in Table 36.1. This "early phase response" takes place 10 to 30 minutes after exposure to the allergen. This is in contrast with the late phase of the allergic response, which occurs 4 to 8 hours after exposure. This delayed reaction is the result of chemotaxis and migration of neutrophils, basophils, eosinophils, T-lymphocytes, and macrophages across the mucosal endothelium into the nasal submucosa (4).

Supporting the concept of a unified airway, there is a clear relationship between AR and asthma. Over 80% of asthmatics have rhinitis and 10% to 40% of patients with rhinitis have asthma (5). Although there are distinct differences between the two diseases, there are many similarities, especially the hallmark inflammatory response. Later in this chapter, more evidence supporting the link between AR and asthma and how treating AR can retard the progression to asthma is reviewed. The link between AR and CRS is controversial and is examined later in this chapter.

CHRONIC RHINOSINUSITIS

Adult CRS has been defined as a group of disorders characterized by inflammation of the mucosa of the nose and paranasal sinuses of at least 12 weeks duration. It affects more than 30 million Americans and has a significant burden on society from a cost and quality of life standpoint (6). Symptoms of CRS have been divided into major and minor symptoms and are listed in Table 36.2.

For over 70 years, there has been a recognized coexistence and suspected association between asthma and sinusitis (7–9). Much like asthma and AR, the hallmark of CRS is inflammation. Patients who have CRS have a 20% prevalence of asthma, approximately three to four times greater than the 5% to 8% prevalence of asthma in the general population. Multiple mechanisms have been proposed to explain this link. The nasobronchial reflex, the pharyngobronchial reflex, and posterior nasal drainage of inflammatory mediators have been postulated to link CRS with asthma and a lower airway inflammatory response, but none of these hypotheses provides a complete explanation of the relationship between CRS and asthma (10). Multiple studies have demonstrated that a local inflammatory reaction in one portion of the airway can reach the systemic circulation and potentially affect distant airway sites. These are discussed in more detail below.

		Relative annual risk of exacerbation may be related to FEV_1			

Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Heart, Lung, and Blood Institute, Aug 2007.

ASTHMA

Despite the marked heterogeneity of the asthma phenotype, a consensus definition for asthma has been developed that recognizes this condition to be a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role, in particular, mast cells, eosinophils, T lymphocytes, neutrophils, and epithelial cells. The classic symptoms of asthma are recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night and/or in the early morning. These episodes are typically characterized by widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment. The inflammation also causes an associated increase in the existing bronchial hyperresponsiveness to a variety of stimuli. It is the association of asthma with AR and CRS that is one of the central points to the idea of the unified airway, as effective management of AR and CRS may prevent the development of asthma or beneficially impact the severity of asthma and its resultant morbidity.

Diagnostic tests for asthma include pulmonary function tests, such as forced expiratory volume (FEV), peak expiratory flow, and the methacholine challenge test, which provokes bronchial hyperresponsiveness. Furthermore, a diagnosis of asthma is established when a reversible airflow obstruction is confirmed with the above-mentioned tests as well as a response to an inhaled beta-agonist. Asthma severity can be classified clinically as mild intermittent, mild persistent, moderate persistent, and severe persistent. This classification scheme is detailed in Table 36.3, and is useful in guiding management. Management typically consists of anti-inflammatory modulators such as inhaled or systemic corticosteroids as well as short or long acting beta-agonist bronchodilator agents. Other options include leukotriene-inhibitors, methylxanthines like theophylline, and mast cell stabilizers like cromolyn or nedocromil. Anti-IgE monoclonal antibodies are available but reserved for severe cases due to their significant cost (11). Furthermore, pulmonary function tests may be repeated to assess response to therapy, and treatments can be adjusted based on these results.

The impact of asthma on society is substantial. In 2005, roughly 23 million (7.8%) Americans reported having asthma, 6.2 million of whom were under the age of 18. African-Americans are disproportionately affected. The prevalence of asthma under the age of 14 in the African-American population is 13.6%, followed by Hispanics (9.2%) and Caucasians (7.5%) (12). Asthma leads to a significant impact on school and workdays lost, outpatient physician visits, hospitalizations, emergency department visits, and use of newer, more expensive asthma

medications. In 1994, the total direct and indirect costs attributed to asthma were 12 billion dollars (13). If one considers the above statistics in addition to the relationship that asthma has with AR and CRS, one begins to understand the importance of recognizing multiple airway diseases in patients. Otolaryngologists historically may not have considered the diagnosis of asthma in patients with AR or CRS, but with new knowledge of the unified airway, it is imperative to consider this fact in order to effectively manage these patients.

OTHER UNIFIED AIRWAY CONDITIONS

The unified airway model can be extended to include the middle ear cleft and possibly the larynx. Histologically, the middle ear mucosa is lined with the same pseudostratified, ciliated columnar epithelium as found in the upper and lower airways. Furthermore, cellular and cytokine analysis of middle ear effusions from atopic patients with chronic otitis media with effusion (COME) demonstrates findings consistent with a Th2-mediated immune response. This realization has important implications as atopic patients with COME may benefit from new treatment approaches (14). Allergic laryngitis has been described in the literature but insufficient evidence exists to demonstrate a causal relationship between allergen exposure and the subsequent development of laryngitis (15).

EVIDENCE FOR THE UNIFIED AIRWAY

Previous Hypotheses

Several hypotheses previously attempted to explain the link between the upper and lower airways. The first was the nasobronchial reflex, which postulated that there was a direct reflex arc between the upper and lower airways that led to immediate changes in the lower airways after stimulation of the upper airways. Initial studies demonstrated increased lower airway resistance in nonasthmatic patients immediately after application of silica particles to their nasal mucosa. These studies showed that atropine and section of the trigeminal nerve could blunt this effect (16,17). However, more recent studies have not been able to replicate similar findings, that is, immediate changes in the lungs after nasal provocation. In fact, the more recent studies showed delayed changes in the lower airways supporting a different mechanism of cross-talk, and these studies will be detailed below. There is potentially a reflex link between the upper and lower airways but this hypothesis does not provide a comprehensive explanation of the unified airway (1,18).

Others have postulated that the loss of nasal protection of the lower airway could explain the worsening of the lower airways in patients with AR and CRS. Earlier studies demonstrated that mouth breathing led to increased bronchospasm compared to nasal breathing, perhaps because of the loss of the filtering role of the nasal airway. Again, however, subsequent studies have failed to confirm this relationship. Lastly, posterior drainage or aspiration of nasal secretions have been postulated to incite inflammation in the lower airways. Studies looking at this phenomenon do not support it as playing a significant role in the unified airway (1,18).

Allergic Rhinitis and Asthma

The idea that AR and asthma are related originates from the late 19th century (19). Only recently have we begun to develop an understanding of this link. As Krouse (1) has stated, asthma and AR are linked from the standpoint of epidemiology, pathophysiology, and treatment. As such, studies have shown that asthma patients who also have AR tend to have more severe disease with higher treatment costs; treatment of rhinitis may improve asthma control; and early treatment of AR may prevent the development of asthma. In fact, the World Health Organization's Allergic Rhinitis and its Impact on Asthma update in 2008 recommends that "Patients with persistent AR should be evaluated for asthma by history, chest examination, and if possible and when necessary, the assessment of airflow obstruction before and after bronchodilator." Furthermore, their guidelines recommended that all patients with AR be screened by history and questioning for asthma, and that any patient who had concerning history as well as any patient with severe or persistent AR, be sent for formal evaluation with pulmonary function testing (20). Fokkens and Braunstahl (21) stated that AR and asthma may be "manifestations of the same airway disease, rather than two distinct disease of the nose and lung."

As stated previously, over 80% of asthmatics have rhinitis and 10% to 40% of patients with rhinitis have asthma. Furthermore, there may be a temporal relationship in the onset of AR and asthma as suggested by a large Danish study from 1983. In this study, both AR and asthma presented for the first time within the same year in 25% of patients and within 2 years of each other in 75% of patients (22). Going a step further from merely establishing an association between these two conditions, multiple studies, including the Finnish Twin Cohort Study, which followed 11,000 patients for 15 years, suggests that AR is a risk factor for the development of asthma. In these studies, AR typically occurs prior to the onset of asthma, and this progression has been referred to as the "allergic march" (23,24).

AR and asthma have similar pathophysiologic mechanisms. As stated previously, the ciliated pseudostratified columnar epithelium in the nasal cavity is similar to that of the respiratory mucosa. The inflammatory process in both areas is similar. Both sites involve eosinophils, lymphocytes, and mononuclear cells as well as similar cytokines, such as IL-4, 5, and 13, which are typical of Th2 type allergic response. However, there are differences in that the

nasal airway mucosa lacks smooth muscle and therefore does not exhibit the smooth muscle hypertrophy and remodeling that is characteristic of long-term asthma (18).

There is evidence to support that patients who have only asthma or only AR have eosinophilic inflammation in the other uninvolved airway site. For example, Gaga et al. (25) found that asthmatic patients had significant amounts of eosinophils in the nasal mucosa in the absence of a diagnosis of AR. The reverse is also true. Djukanovic et al. (26) demonstrated via bronchial biopsies that atopic nonasthmatics (patient with AR but without the diagnosis of asthma) had basement membrane thickening and eosinophilic inflammation in their lower airways. Other studies have shown that nonasthmatics with AR are prone to bronchial hyperreactivity (27,28). According to Ryan (18), "the finding that patients who have rhinitis without an asthma diagnosis or asthma symptoms have bronchial hyperreactivity lends further support to the notion that asthma and rhinitis are different manifestations of a single respiratory disease".

Several studies by Braunstahl et al. have helped elucidate the common pathophysiology and inflammation shared by AR and asthma. Two studies, in which eight AR patients without asthma were compared to eight normal controls, showed bronchial provocation with allergen-induced nasal inflammation. Specifically, they found that eosinophils, IL-5, and eotaxin were increased in the nasal mucosa after bronchial provocation. Furthermore, mast cell numbers decreased in the nasal mucosa secondary to increased degranulation after provocation, as well as increases in peripheral blood IL-5 (29,30). Another study, with similar groups of patients, showed that nasal allergen provocation in allergic nonasthmatic patients induced increased eosinophilia in the bronchial mucosa as well as increased expression of cellular adhesion molecules, signifying increased inflammatory cell migration (31). These studies demonstrate that inflammation in one part of the airway can lead to inflammation in another site, and based on increased eosinophilia in the blood, it seems as though these inflammatory mediators are disseminated hematogenously.

Treatment of AR helps improve asthma control. Several studies have demonstrated that inhaled topical nasal corticosteroids in asthmatics with AR help reduce bronchial hyperresponsiveness (32–34). Another large retrospective review found that medical treatment of AR in asthmatic patients significantly reduced the risk of asthma-related hospitalization and emergency department visits (35). Conversely, treatment of asthma may improve symptoms of AR. One study of nonasthmatics with AR showed that orally inhaled steroids improved allergic symptoms, blood eosinophil levels, and FEV1 levels. This study also suggests that nonasthmatic patients with AR have some degree of bronchial inflammation when exposed to allergens, as expected in the model of "one airway, one disease" (21,36).

One potentially exciting development is the role of specific immunotherapy for AR and preventing the development of asthma. A study of 205 children aged 6 to 14 without a diagnosis of asthma were randomized to treatment of a birch or grass pollen allergy versus an open control group and followed. At 3, 5, and 7 years, approximately 45% of the control group had developed asthma, while only 26% of the treatment group had developed asthma (37). More studies are needed to confirm this finding, yet the possibility of preventing the development of asthma is important and is one way that understanding the unified airway can lead to better patient care.

Chronic Rhinosinusitis and Asthma

As stated above, there is an epidemiologic connection between asthma and CRS, specifically one of the eosinophilic forms of CRS with nasal polyps. There is also a shared pathophysiology between the two from the standpoint of a similar inflammatory milieu. Both diseases are characterized by a Th2 type immunologic response with increase in mast cells, eosinophils, T lymphocytes, IL4, IL5, IL13, and similar cell adhesion molecules. The underlying mechanism that links CRS and asthma is not completely clear, but seems to involve shared inflammation or systemic signaling where inflammation in one location of the unified airway leads to increased inflammation in another site of the unified airway.

Several studies support the relation of CRS to asthma. Asthmatic patients with CRS have a correlation between the extent of disease on sinus computed tomography scanning and increased sputum and blood eosinophil counts (38). Furthermore, Bresciani et al. (39) found that the severity of sinus symptom scores and the extent of sinus disease were directly correlated with asthma severity. With regards to treatment, Ragab et al. (40) concluded that effective medical management of chronic sinus disease improved asthma symptoms and markers of inflammation. Two different studies reported a decreased need for asthma medications, improved pulmonary function, and fewer asthma exacerbations after sinus surgery in asthmatic patients with CRS (41,42). Therefore, it seems prudent to consider lower airway disease burden when deciding about treatment for CRS. Medical and surgical treatment of CRS seem to improve lower airway disease. Ehnhage et al. (43) recommended considering endoscopic sinus surgery early in the natural course of nasal polyposis in patients with asthma, as their prospective study showed a significant improvement in mean asthma symptom scores as well as mean daily peak expiratory flow rate. This link may also be true in children as a review article by Lai et al. (44) concluded that aggressive treatment of sinusitis can significantly improve asthma symptoms and quality of life in children with CRS and asthma. One should also consider medical therapies that improve CRS and asthma, such as corticosteroids and macrolide antibiotics (45).

Two unique diagnoses that warrant mention are Samter triad and cystic fibrosis (CF). These diseases are additional examples of the upper and lower airways functioning as a

unit, and how lower airway disease burden can be impacted by medical and surgical treatment for CRS. Samter triad (aspirin triad, triad asthma) classically is described as aspirin sensitivity, asthma, and sinonasal polyposis. More recently, Samter triad has also been termed aspirin-exacerbated respiratory disease. It typically starts with rhinitis-like symptoms that eventually progress to persistent rhinosinusitis with polyps, followed later by asthma and aspirin sensitivity. Ingestion of aspirin by these patients leads to exacerbation of asthma symptoms within hours, accompanied by rhinorrhea, orbital edema, conjunctival injection, and cervicofacial flushing. Along with avoidance of aspirin, a combination of medical treatment for the asthma and surgical treatment for the polyps is necessary. Like nontriad asthmatics, sinus surgery leads to improvement in asthma symptoms; however, it should be noted that polyps in these patients tend to recur and often multiple polyp-surgeries are needed. Aspirin desensitization therapy is another option for these patients, but is sometimes limited by gastritis. Intranasal lysine-aspirin or ketorolac may prove to be effective alternatives to oral aspirin desensitization therapy (46,47).

CF is a genetic defect in a chloride-transporting channel that leads to multisystem exocrine dysfunction, most notably in the gastrointestinal and pulmonary systems. It also may have a significant impact on the sinonasal tract, causing mucosal edema, chronic sinusitis, and nasal polyps. Over 90% of CF patients show radiologic evidence of sinus disease, and studies have shown that sinonasal involvement leads to significant morbidity in these patients. 20% to 25% of CF patients require sinus surgery, and surgery is often recommended in CF patients awaiting or preparing for lung transplantation. *Pseudomonas aeruginosa* pulmonary infections in CF patients are often recalcitrant to medical therapy and are a significant cause of morbidity and even mortality (48). Studies have shown that these pulmonary infections likely start in the sinuses and ultimately infect the lungs (49). Therefore, it seems prudent to optimize management of sinonasal disease in CF patients. Multiple studies have shown sinus surgery to be safe and effective in CF patients with sinus involvement. Some patients will have persistent disease, however, and endoscopic maxillary mega-antrostomy is an option in CF patients with recalcitrant maxillary sinus disease as this procedure avoids mucosal stripping yet facilitates mucus clearance and topical sinus irrigation (50).

CONCLUSIONS

Although a link between the upper and lower airways has been suspected for decades, recent evidence has helped establish the concept of the unified airway, that is, "one airway, one disease." AR, CRS, and asthma are similar from an epidemiologic, pathophysiologic, and therapeutic standpoint. Managing disease of the upper airway improves asthma symptoms in patients with asthma, and may retard development of asthma in some patients. It is important that otolaryngologists recognize this association and apply it to patient care, as this may have a significant impact on morbidity and quality of life.

HIGHLIGHTS

- The upper and lower airways function as a single unit, the unified airway.
- Otolaryngologists frequently encounter and manage patients with diseases of the upper airway.
- Because of the shared inflammation between the upper and lower airways, patients with upper airway disease have a higher risk of concurrently having or subsequently developing lower airway disease, namely asthma.
- AR is related to and is an independent risk factor for development of asthma and for increased severity of asthma.
- Treatment of AR improves asthma control in asthmatics, and may delay or prevent the development of asthma in nonasthmatics.
- CRS is related to asthma. Successful treatment of CRS improves subjective and objective measures of asthma.
- Otolaryngologists should consider the diagnosis of asthma in patients with AR and CRS.

FUNGAL RHINOSINUSITIS

Introduction

Fungi are increasingly recognized as etiologic agents in a diversity of disease states in the nose and paranasal sinuses. Over the past 30 years our enhanced understanding of the role of fungi in sinus disease and the complex interactions between host and pathogen has led to a logical classification of fungal rhinosinusitis with improvements in treatment outcomes. At the same time, the development of endoscopic surgical techniques has improved our diagnosis and treatment of all forms of rhinosinusitis. One distinction between fungal rhinosinusitis and other forms of rhinosinusitis is that all forms of fungal rhinosinusitis require some level of endoscopic assessment or surgery.

Basic Mycology

Fungi are eukaryotic organisms ubiquitous in our environment. Scientists estimate the total number of these different fungal species to be between 20,000 and 1.5 million, of which only a fraction of a percent are responsible for human illnesses, perhaps with only a few dozen species responsible for over 90% of infections (1,2). Fungi can exist either as yeast or molds. Characteristically, molds produce *hyphae*, multicellular, branching tubular extensions (2 to 10 µm in diameter), which coalesce as a colony known as a *mycelium*. Yeast are unicellular, from 3 to 15 µm in diameter, and reproduce asexually via budding. Failure of buds to detach can result in a characteristic chain of fungal cells known as *pseudohyphae*. The *spore* represents an evolutionary solution to fungal survival problems posed by unfavorable conditions. These derivatives of sexual or asexual fungal reproduction disperse easily into the environment, can withstand adverse surroundings, and retain their germinative abilities until a more receptive milieu is encountered. Inhalation of spores is thought to be the most common route by which fungal rhinosinusitis is initiated (3). Once the nasal mucosa has been accessed, development of a pathologic condition is determined not only by the inherent characteristics of the fungus, but by the host's immune system and the complex host–pathogen interaction that ensues.

Classification of Fungal Rhinosinusitis

Fungal disease of the nose and paranasal sinuses can be classified based on the clinical, radiologic, and histologic manifestations of the host–pathogen relationship. Most classification schemes divide fungal rhinosinusitis into invasive and noninvasive diseases based on histopathologic evidence of fungus penetrating host tissue (4) (Table 37.1). Recent adjustments to the nomenclature regarding fungal rhinosinusitis reflect the evolving knowledge in this area of Rhinology (5). The full spectrum of invasive and noninvasive fungal rhinosinusitis is considered below.

Invasive Fungal Sinusitis

The unchecked incursion of omnipresent fungal pathogens are among the most impressive infections to which humans are susceptible. While an intact immune system provides sufficient defense against the development of invasive fungal disease, the proliferation of organ transplant procedures and the greater prevalence of diabetes mellitus have led to significant increases in the incidence of invasive fungal infections reported over the last 10 years (6). The growing population of patients with conditions that predispose them to invasive fungal disease, in combination with dramatic disease velocity and considerable morbidity and mortality, has made invasive fungal sinusitis (IFS) a topic of particular interest within the Otolaryngology literature. Previously, tissue-invasive fungal disease was commonly

Fungal rhinosinusitis: a categorization and definitional schema addressing current controversies. *Laryngoscope* 2009;119:1809–1818.

referred to by a variety of terms including "zygomycosis," "mucormycosis" and "invasive aspergillosis," which encompassed almost all of the pathogens associated with human-invasive fungal disease. Revisions of the phylogenetic classification within the kingdom Fungi have eliminated the phylum Zygomycota and therefore the pathologic term Zygomycosis has been made obsolete (7). *Mucor*, *Rhizopus*, and many of the organisms responsible for invasive disease of the Order Mucorales are instead assigned to the subphylum Mucoromycotina until further study better delineates the relationship between these organisms (8). Finally, it has become clear that the various forms of fungal rhinosinusitis are primarily determined by host factors; thus the current classification scheme does not include the names of the organism.

General Description of IFS

IFS is defined by fungal elements invading host sinonasal tissue. A diagnosis of IFS hinges upon histopathologic evidence of fungi invading nasal tissue: hyphal forms within sinus mucosa, submucosa, blood vessel, or bone. Specific histopathologic features, immunocompetence of the host, and disease progression allow further classification of invasive fungal sinus disease into three forms: acute invasive fungal rhinosinusitis (AIFR), chronic invasive fungal rhinosinusitis (CIFR), and granulomatous invasive fungal rhinosinusitis (GIFR) (see Table 37.1). In brief summary, a time course of 4 weeks separates acute from chronic disease, AIFR and CIFR typically occur in patients with some degree of immunocompromise while GIFR is limited to the apparently immunocompetent (see Table 37.2). Accurate classification of these different disease entities is an important step in discussing each with regard to their clinical presentation, pathogenesis, diagnosis, and treatment.

ACUTE INVASIVE FUNGAL RHINOSINUSITIS

Clinical Presentation and Diagnosis

AIFR is almost always seen in patients with some degree of compromised immune function, especially defective neutrophil numbers or function, though it has been reported rarely in patients with normal immune function (9). Ailments associated with impaired neutrophil numbers or function, such as hematologic malignancies, aplastic anemia, hemochromatosis, insulin-dependent diabetes, AIDS, organ transplantation, or those undergoing iatrogenic immunosuppression with systemic steroids

TABLE 37.2 FEATURES OF INVASIVE FUNGAL RHINOSINUSITIS

Syndrome	Histopathology	Immunocompetence
Granulomatous	– Invasive fungal hyphae are sparse and found within noncaseating granulomas	– Immunocompetent
Invasive	– Dense fibrosis and mild inflammatory cell infiltrate in surrounding tissue	– Diabetic cases reported rarely
Fungal Rhinosinusitis	– *A. flavus* is most common	
Chronic Invasive	– Invasive fungal hyphae and necrotic tissue with mixed acute and chronic inflammatory cellular response.	– Diabetes Mellitus
Fungal Rhinosinusitis	– Matted hyphae can resemble sinus FB	
	– *A. fumigatus*, many others	
AIFR	– Invasive fungal hyphae with prominent angioinvasion, thrombosed vessels, and necrotic tissue.	– Immunocompromised as a result of hematologic malignancies, therapeutic immunosuppression, diabetes mellitus
	– Moderate inflammatory cell infiltrate (predominantly neutrophils)	
	– *Aspergillus* and Family Mucoraceae are common	– Immunocompetent cases reported rarely

Modified from Chakrabarti A, Das A, Panda NK. Controversies surrounding the categorization of fungal sinusitis. *Med Mycol* 2009;47:S299–S308; Das A, Bal A. Chakrabarti A, et al. Spectrum of fungal rhinosinusitis: histopathologist's perspective. *Histopathology* 2009;54:854–859; DeShazo RD. Syndromes of invasive fungal sinusitis. *Med Mycol* 2009;47:S309–S314.

or chemotherapeutic agents, are particularly prone to development of AIFR (4,10). A high index of suspicion for invasive disease should be maintained in the immunocompromised patient with symptoms of rhinosinusitis, as early findings are often subtle.

The presenting signs and symptoms of AIFR are not distinctly different from those associated with acute bacterial rhinosinusitis. Patients may complain of rhinorrhea, headache, nasal congestion, or facial pain; however, a fever is the most frequent finding, present in 50% to 90% of patients in the days prior to establishing a diagnosis of AIFR (11). The progression of AIFR leads to extrasinus extension by direct erosion through bone, perineural spread, or perivascular extension through communicating vessels in the surrounding bone (Figs. 37.1 and 37.2). Resultant nasal and/or palate mucosa necrosis, densely anesthetic regions of the face, proptosis, cranial nerve deficits, ophthalmoplegia, decreased vision, and mental status changes are ominous indications of aggressive vascular and neural invasion (12).

Several authors have examined the signs and symptoms of AIFR to better determine which patients will benefit from more aggressive diagnostic investigation. Within the immunocompromised patient population, the presence of a fever in combination with one additional symptom of sinonasal inflammation should prompt both imaging studies and nasal endoscopy (11). DelGaudio reported the success of a multidisciplinary approach for the early diagnosis and intervention for AIFR in neutropenic patients (13). Such patients presenting with fever of unknown origin or symptoms consistent with rhinosinusitis underwent sinus computed tomography (CT) scan and nasal endoscopy with appropriate biopsies in an effort to identify AIFR at an early stage. This surveillance protocol significantly reduced the number of surgical procedures required as

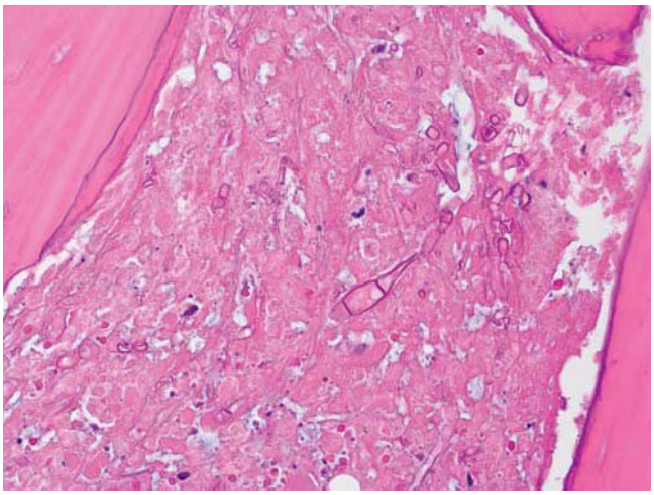

Figure 37.1 AIFR High Magnification (1200×) H&E stained section demonstrates necrotic material between trabeculae of bone removed from the ethmoid sinuses. well as the long-term morbidity of AIFR (13). Endoscopic findings will change dramatically as the disease progresses. Alterations in the visualized nasal mucosa are subtle early in the course of AIFR; however, nasal mucosal changes are the most consistent physical findings and should always be investigated by thorough endoscopy and biopsy in high-risk patients (13,14).

If biopsy of obvious mucosal abnormalities fail to confirm the expected diagnosis, then directed biopsies should be obtained from sites commonly involved in AIFR, such as the middle turbinate (62%) and nasal septum (24%), as well as any other areas of mucosal edema (11). Pale mucosa that does not bleed normally or elicit painful reactions upon biopsy is indicative of tissue ischemia and incipient fungal angioinvasion. The risks of nasal biopsy are small and several authors emphasize the role of early nasal biopsy in the absence of specific mucosal abnormalities as one method of initiating treatment at the earliest stages of disease (14). The risk of hemorrhage from nasal biopsy can be diminished in patients with an underlying bleeding diathesis by replacing any deficient coagulation factors and correcting the thrombocytopenia to a platelet count of greater than 60×10^9/L. Cutting biopsy forceps will limit the resultant mucosal defect and allow the surgeon to accurately sample the leading edges of ischemic or necrotic mucosal lesions, as biopsies from areas of frank necrosis are less likely to provide a histopathologic diagnosis. Middle turbinate biopsy has been shown to have an overall sensitivity of 75% and a specificity of 100% in diagnosing AIFR on frozen section, and this lower-than-desired sensitivity may reflect the inherent difficulties with frozen section studies of fungal disease processes (15).

The utility of frozen section studies in surgery is twofold: to establish a diagnosis and to guide surgical decision making. Management of AIFR with frozen sections has been

studied by several authors, yet a clear consensus is lacking for the role of this type of histopathologic analysis in intraoperative management. Ghadiali et al. report the largest series to date for frozen section analysis in AIFR with an overall sensitivity of 84% for frozen section studies of biopsies to establish disease with no significant difference between the sensitivities of frozen section identification for *Mucor* when compared to that for *Aspergillus* (16). However, the use of histopathologic controls for surgical margins can be misleading and probably does not offer any additional assurance of disease eradication greater than the clinical appreciation of freely bleeding tissue margins (16). Tissue processing during preparation of the frozen section can be compromised by necrosis, hemorrhage, and distortion of the fungi such that even in cases where invasive fungi are identified, morphologic features that allow speciation cannot be appreciated (16,17). While fungal culture remains the gold standard for identifying the culprit fungi and guiding the choice of antifungal therapy, such cultures remain negative in 30% to 50% of cases (18,19), and prior or concomitant administration of antifungal agents also decrease yield on fungal culture. Newer methods such as *in situ* hybridization technology with oligonucleotide probes to identify fungus-specific ribosomal RNA sequences hold promise. This technique has advantages over traditional fungal culture of both greater speed and higher sensitivity in determining the involved fungal species, allowing more rapid institution of targeted antifungal therapy (20).

Radiology

Diagnostic imaging of the paranasal sinuses is often performed in the workup of patients with presumed or proven AIFR. Although no radiographic imaging findings have been found to be pathognomonic for AIFR, such studies assist in the differential diagnosis, treatment planning, and monitoring of the condition. CT images will document the presence of radiographic changes consistent with sinus disease and define the sinonasal anatomy both for surgery and as a baseline exam for future comparison. Fine-cut, noncontrasted CT scans of the sinuses in axial and coronal planes can detect paranasal sinus bony erosion and screen for extrasinus soft tissue involvement. Magnetic resonance imaging (MRI) (with or without gadolinium) delineates the degree of orbital involvement and/or intracranial spread. These findings provide key information regarding the feasibility of surgery and ultimately patient prognosis.

Although bone erosion and extrasinus extension are often cited as classic radiographic findings of AIFR, these results are not typically found in the incipient case of AIFR but instead are ominous signs of advanced disease. The radiographic findings with the greatest positive predictive values are also those that are indicative of late and often irreversible disease: osseous erosion, facial soft tissue thickening, extrasinus involvement. Soft tissue infiltration with loss of the fat planes anterior and posterior to the maxillary sinus is considered an early indicator of AIFR (21). Another subtle finding, severe sinonasal edema without evidence of bone erosion, is emerging as a consistent and early radiographic finding amongst many cases of invasive disease (16,22). Severe unilateral thickening of nasal cavity mucosa is the most consistent CT characteristic suggestive of early IFS, albeit nonspecific for invasive fungal disease (23) (Fig. 37.3).

Physicians should not become overly dependent upon radiographic information alone when considering the diagnosis of AIFR. AIFR may present without significant radiographic evidence of sinusitis and there is poor correlation between surgical specimens and radiographic demonstration of the extent of disease (23). While some studies report a normal CT scan in 12% of patients with histopathologic evidence of IFS, other reviews found no patient afflicted with the disease to have a normal CT scan (11,16). Care should be taken in the interpretation of CT scans in cases suspicious for AIFR as imaging studies are supportive, but not diagnostic, of AIFR.

Pathology

Aspergillus and the members of the Subphylum Mucoromycotina (*Mucor, Rhizomucor, Absidia*) are the fungi most frequently implicated in AIFR, though unusual cases involving *Candida, Bipolaris, Cunninghamella, Conidiobolus, Scytalidium, Fusarium,* and *Exserohilum* have been reported (2,12).

The clinical manifestations of AIFR develop as a result of the propagation of angioinvasive and neuroinvasive fungi within the sinonasal cavity and facial tissues. AIFR

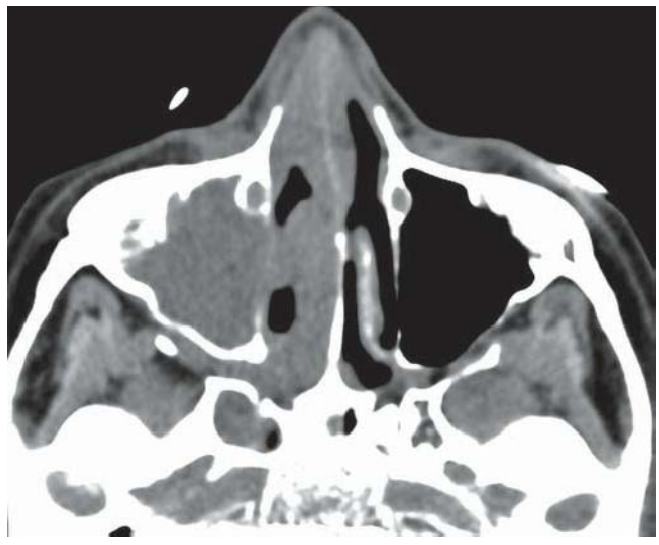

Figure 37.3 AIFR Axial on contrast CT scan shows right maxillary sinus opacification and right nasal cavity mucosal thickening. There is loss of normal fat planes within the pterygopalatine fossa, a sign of invasive disease. Image and caption: Jeffrey Bennett, MD. Department of Radiology, University of Florida College of Medicine, Gainesville, FL.

is defined by fungal forms invading into the submucosal tissue, often associated with angioinvasion resulting in vascular thrombosis, infarction, and necrosis. Areas of coagulative tissue necrosis are extensive and the total numbers of hyphae can be relatively sparse at times, with an associated neutrophilic infiltration (9). The acidotic environment of tissue ischemia and necrosis provide an ideal medium for fungal growth and further propagation of the fungal infestation (12).

Treatment

AIFR is a condition specific to a well-defined patient population, and as such, a high index of suspicion for disease and preventive measures constitute the first step in management in the at-risk population. The most closely monitored of the high-risk population, those with hematologic malignancies or post-transplant patients (AIFR incidence rates from 1.7% to 2.6%), are also most amenable to methods of decreasing environmental exposure to fungi, administration of prophylactic antifungal drugs, and hospital-based screening protocols for IFS. Hospital rooms equipped with high-efficiency particulate air filtration have been shown to reduce fungal burdens, thereby intervening at the initial stage of fungal inhalation (10,14).

Prophylaxis with antifungal medications in high-risk patients should be used with caution, as their side effect profiles, toxicity, and the potential for augmenting drug resistance remain important concerns (10). Nevertheless, prophylaxis is frequently initiated in high-risk patients undergoing additional immunosuppressive therapy. Similarly, prophylactic antifungal medications are indicated for patients with a known history of invasive fungal disease who will require further immunosuppressive therapy (7,10,24).

While secondary prophylaxis with amphotericin B deoxycholate (ABD) is well established and demonstrates a reduction in the rate of recurrent infection, newer, less toxic antifungal agents have supplanted ABD in this role (10). Posaconazole, a second-generation extended spectrum triazole, has been shown to be superior to standard azole therapy in preventing invasive fungal infections in immunocompromised hosts and may soon play a primary antifungal role in the treatment of AIFR (25). While there are no studies that compare prophylaxis regimens with regard solely to AIFR, there is evidence that severely immunocompromised patients, with neutropenia have improved outcomes with posaconazole over earlier generation azoles in the prevention of fungal infections (26). AIFR treatment is most successful when aggressive multimodality therapy can be instituted in the earliest stages of disease. Some hospital-based protocols initiate CT scans of the sinuses in high-risk patients with sinonasal symptoms or unexplained fever, followed by endoscopic examination and intranasal biopsy of all patients with radiographic abnormalities (14,22,23).

Treatment of AIFR relies on medical and surgical therapy directed against the offending fungal pathogen in addition to reversal of the patient's underlying state of immunocompromise. Systemic antifungal medication is instituted immediately while treatment of diabetic ketoacidosis (DKA) or restoration of neutropenia is undertaken. Correction of acidosis and underlying dehydration is associated with an 80% survival rate in AIFR with concomitant DKA (7,9). In transplant patients or those with hematologic malignancies, an absolute neutrophil count (ANC) less than 1,000/mm^3 has been associated with both the onset of disease and reduced survival. White blood cell transfusions and administration of granulocyte colony-stimulating factor that increase the ANC above 1,000 mm^3 have been shown to improve survival in neutropenic patients (14,18).

Systemic antifungal therapy is routinely employed in AIFR. ABD, a polyene macrolide, has been the drug of choice for the systemic treatment of invasive and disseminated fungal infections since its introduction into clinical practice in the 1960s (27). Amphotericin B exhibits fungicidal activity against a wide spectrum of pathogenic fungi; however, its side effects are multiple, serious, and can limit both dosage and duration of therapy in critically ill patients (27). Infusion-related symptoms including fever, chills, headache, nausea, vomiting, thrombophlebitis, and hyperkalemia are seen in 50% of patients and can be managed acutely; however, long-term myelosuppression, ototoxicity, and nephrotoxicity are more problematic (18,27,28). Nephrotoxicity, which occurs in 80% of patients treated with amphotericin B, and the resultant azotemia and electrolyte disturbances (hypokalemia) ultimately mandates halting therapy or switching antifungal agents (27). The negative impact of ABD on the general medical condition of these typically compromised patients has increasingly favored the use of lipid formulations of amphotericin B in lieu of the older and more harmful deoxycholate preparation.

Lipid-based formulations of amphotericin B have improved safety profiles, less renal toxicity, and are effective in treating AIFR (18,27). Though randomized clinical trials of invasive fungal infections in the treatment of AIFR comparing lipid-based formulations with the deoxycholate preparation are not available, evidence derived from treatment of other disseminated and invasive fungal infections favors equal if not greater efficacy and reduced complications in patients receiving the lipid formulation (7). Recently, small case series specifically addressing paranasal sinus disease demonstrate significantly greater survival rates in patients receiving lipid amphotericin B than in those managed with ABD (28,29). The ability to deliver higher total doses (5 to 7.5 mg/kg/day) with reduced toxicity highlights the issue of higher drug cost as the lone remaining obstacle to more widespread utilization of lipid-based formulations of amphotericin B (7,28).

The introduction of extended spectrum azoles, voriconazole, and posaconazole, has expanded the available options both for antifungal therapy of acute disease as

well as prophylaxis of recurrent invasive fungal infections in immunocompromised populations. Voriconazole produces survival advantages with fewer side effects than amphotericin B in the treatment of systemic invasive aspergillosis (30), while posaconazole demonstrates both survival benefits and reduced drug costs over standard therapy with amphotericin B in the management of the same invasive fungal condition (31). Posaconazole is active against the mucoracea while voriconazole is not. Posaconazole has been shown to be a cost-effective medication in the prevention of invasive fungal disease in neutropenic patients (25). The efficacy of posaconazole and voriconazole in treating *Aspergillus* AIFR has been reported. Baumann reported the successful use of voriconazole following sphenoidotomy in four cases of AIFR resulting from *Aspergillus*, while Chirch reported a successful case of combination therapy with caspofungin and voriconazole for *Aspergillus* AIFR in the absence of surgery (32,33). The reduced side effects of these agents may prompt their use both in treatment and prophylaxis within the medically compromised patient population at risk for AIFR. At the present time, however, clinicians should institute voriconazole therapy without hesitancy when either *Pseudoallescheria boydii* or Aspergillosis is identified. *P. boydii* is typically resistant to amphotericin, yet remains susceptible to azole therapy (9,18). While data specific to sinusitis is not available, initial therapy of pulmonary aspergillosis and systemic invasive *Aspergillus* infections with voriconazole (6 mg/kg IV b.i.d. then 4 mg/kg b.i.d. for 7 days, then oral dosage of 200 mg b.i.d.) resulted in significantly greater survival and fewer adverse events than in those treated with ABD (30). Visual disturbances and skin reactions are the most common adverse events in patients treated with voriconazole. While hepatic function abnormality is the most common serious adverse effect in patients treated with voriconazole, significantly fewer serious side effects were experienced in contrast to the group treated with ABD (30). The need for improvements in the medical management of invasive fungal disease is obvious, and a number of therapies including echinocandins, statins, iron-chelating agents, granulocyte transfusions, granulocyte-macrophage colony–stimulating factor, and hyperbaric oxygen have been considered (7,34). Echinocandins are a drug class of large lipopeptides with fungicidal activity against *Candida* and fungistatic activity against *Aspergillus*, suggesting a potential role in the combination therapy of invasive fungal disease. Though clinical trials in AIFR are lacking, a retrospective review comparing liposomal amphotericin B to combination therapy with caspofungin demonstrated a significant survival benefit in the AIFR cases treated with combination therapy (35). The lack of a mammalian cell target for echinocandins endows this therapy with a very favorable safety profile (7,34). Further clinical trials examining the role of eichinocandins in combination therapy for IFS should be forthcoming.

Antifungal medications can be administered through an intranasal route with the potential for greater local activity and fewer systemic toxicities. Intranasal routes have been explored as methods of IFS prophylaxis with varied success; however, as nasal irrigations, nebulizer treatments, and amphotericin B-soaked surgical dressings are of minimal risk and possibly of great benefit, they deserve consideration as adjunctive measures in the management of AIFR (12,14,24).

Surgery plays multiple roles in the management of invasive fungal rhinosinusitis. The first and most important is to secure a diagnosis through tissue biopsy. The second main role of surgery in AIFR is to debride tissue that is obviously involved with fungus, remove devitalized tissue, and establish pathways for sinus drainage and postoperative monitoring of the affected sites. Surgery interrupts the progression of disease by gross removal of the pathogen along with the necrotic tissue in which fungi thrive (12). Debridement is extended until healthy bleeding tissue is encountered. Resection back to vascularized margins favors the host defenses that are required to clear such infections: well-perfused tissue that can deliver systemic antifungal medications, restore a normal tissue pH, and augment local neutrophil numbers (36). There is no demonstrable difference in survivorship between endoscopic and open operations, and therefore open surgical procedures should be limited to those cases where diseased tissue cannot be removed endoscopically, for example orbital, facial, palatal, and intracranial fungal disease (37). The extent of surgery employed needs to be tempered by the patient's overall prognosis and the likelihood of reversing the underlying disease process that led to invasive fungal disease. Surgery facilitates effective antifungal treatment, but is ultimately less important than intact immunity and appropriate medical therapy.

PROGNOSIS OF AIFR

The mortality of AIFR has been cited traditionally as 50% to 80%; however, recent series report mortality rates as low as 18%, perhaps due to earlier recognition and treatment (13,14). Many authors have examined traits of both the host and pathogen to identify elements of prognostic significance. Anatomic extensions of disease with intracranial and/or intraorbital involvement are clinically obvious predictors of poor outcomes, borne out by large case series (17,36,37). The importance of host immune function is highlighted in studies that demonstrate recovery of ANC to be the single feature most predictive of survival in AIFR (9,11,14,18,23).

Chronic Invasive Fungal Rhinosinusitis

Some IFS progresses gradually over time. These cases, labeled CIFR and GIFR, are uncommon conditions with similar clinical presentations and relatively favorable prognosis in comparison to AIFR (38). The sharpest distinction between the two conditions can be made on the

basis of histopathologic features and typical causative organisms (4,5,9). At the present time, CIFR and GIFR are considered distinct disease processes, despite their similar clinical courses and treatment (5). CIFR and GIFR will be addressed separately in the discussion that follows, with particular attention to their distinguishing features.

CLINICAL PRESENTATION

CIFR, formerly known as chronic indolent IFS, was first identified by McGillin in 1980, and is now considered a slowly progressive form of invasive fungal disease (4,9). Symptoms of CIFR are nonspecific and mirror those of chronic rhinosinusitis (CRS): facial pain, headache, nasal congestion. Unilateral blood streaks within nasal drainage have been reported as the most common symptom in a large case series of CIFR (in which a few GIFR cases were included as well) (38). Ocular symptoms are common and are an indication of the extent and aggressiveness of the disease. While proptosis is common both to CIFR and GIFR, orbital apex syndrome with its attendant symptoms of disturbed visual acuity and impaired motion of the extraocular muscles is more particularly associated with CIFR (9).

Typical presentations of CIFR includes nonspecific rhinosinusitis symptoms made remarkable by their long duration, slow progression, and refractoriness to standard antibiotic therapy (39). Cases occur in immunocompetent patients, yet diabetes mellitus remains the comorbidity with which CIFR is most closely associated. Diagnosis of this uncommon infection in a well-controlled diabetic patient may be delayed until the development of vision changes, proptosis, facial deformity, seizures, or altered mental status mandate that the physician consider more ominous possibilities (38).

DIAGNOSIS

The clinical presentation of CIFR is nonspecific. Diagnosis is made by tissue biopsy. CIFR provokes modest sinonasal inflammation and endoscopic exam typically identifies nasal polyps and thick mucus without the eschar or necrosis characteristic of AIFR (39). A diagnosis of IFS can be established only by identification of submucosal invasion of fungal elements on histopathologic examination of tissue specimens, though imaging can narrow the differential diagnosis and better direct surgical biopsies. CIFR evolves over a time course of greater than 4 weeks and may affect normal populations or those with mild immunocompromise (cortico steroid treatment, diabetes mellitus, HIV) (39).

IMAGING

There are no pathognomonic imaging findings of CIFR (40,41). There are, however, radiologic features that are characteristic of CIFR and these are useful when drawing distinctions between an IFS and the less concerning allergic fungal rhinosinusitis (AFRS). In CIFR, paranasal sinus involvement is usually unilateral with a homogenous opacification on CT scan and bone erosion limited to sites of extrasinus extension (40). Neurologic or ophthalmologic deficits warrant a contrast-enhanced MRI of the 1 to delineate involvement of the dura or orbital contents, as intracranial or intraorbital disease significantly impacts treatment planning and prognosis (39). MRI findings particular to CIFR include a T1 intermediate signal intensity with T2 low to very low signal intensity with a homogenous and intense enhancement with contrast, yet these findings are not alone diagnostic of CIFR (40).

Pathology

Histopathologic features of CIFR help distinguish this entity from both AIFR and GIFR. CIFR has been attributed to a wide assortment of fungi; yet *Aspergillus fumigatus* remains the most commonly cultured pathogen across multiple independent case series (38,40). Plentiful submucosal fungal elements are found invading sinonasal mucosa, with only occasional angioinvasion and rare infarction of the surrounding tissue. A paucity of inflammatory cells are recruited and, importantly, fibrotic reactions or giant cell granulomas are absent (4,5,9,42). Dense collections of fungal hyphae and lesser degrees of necrosis distinguish CIFR from both GIFR and AIFR (4,5) (Table 37.2). Nasal polyposis is routinely associated with CIFR as is the recovery of especially viscid mucus within the affected paranasal sinuses (5).

TREATMENT AND PROGNOSIS

The relative rarity of CIFR and lack of controlled treatment trials obliges physicians to base their therapeutic interventions on published case reports and personal experience with cases of IFS. Surgery is required in every case to obtain a diagnostic biopsy and to debride the remaining involved tissue. The need for antifungal therapy in CIFR is less certain. Cure rates of nearly 90% have been reported in a series of surgically managed CIFR for which ABD followed by oral itraconazole was administered (38). Newer generations of antifungal medication with reduced side effect profiles tilt the risk:benefit ratio in favor of their more liberal use in CIFR (7,34,43). Extensive operations that are expected to result in adverse neurologic, functional, or aesthetic impairments are not supported in CIFR (38,39). Surgical debridement should remove all involved tissue and maintain intact natural barriers to infection (dura and periorbita), keeping in mind the more indolent disease course (39). Reexploration in the operating room and further resection of tissue is determined on an individual basis. The general consensus among recent authors recognizes that while surgery alone can successfully treat cases of CIFR, combined therapy using newer, less toxic, systemic antifungal chemotherapy agents is preferred (38,43).

Figure 37.4 **A,B**: GIFR Axial and Coronal CT scans show expansion of the involved right frontal sinus with long-standing invasive fungal infection. Bone of the skull base has become dehiscent and there is direct extension of GIFR into the brain. Image and caption: Jeffrey Bennett, MD. Department of Radiology, University of Florida College of Medicine, Gainesville, FL.

Prognostic features of CIFR are not well characterized; therefore, careful long-term follow-up is recommended. The prognosis for CIFR is far better than what can be expected in other IFS entities. The duration for antifungal therapy for CIFR is not uniformly established. Duration of therapy can be individualized to the severity of the patient's disease process and follow-up examinations. Asymptomatic recurrences of CIFR are not rare and should be treated early in order to prevent intracranial and intraorbital complications. Routine scheduled postoperative CT scans coupled with planned endoscopic surveillance with tissue biopsies as needed are the most effective methods for detection of recurrent invasive disease.

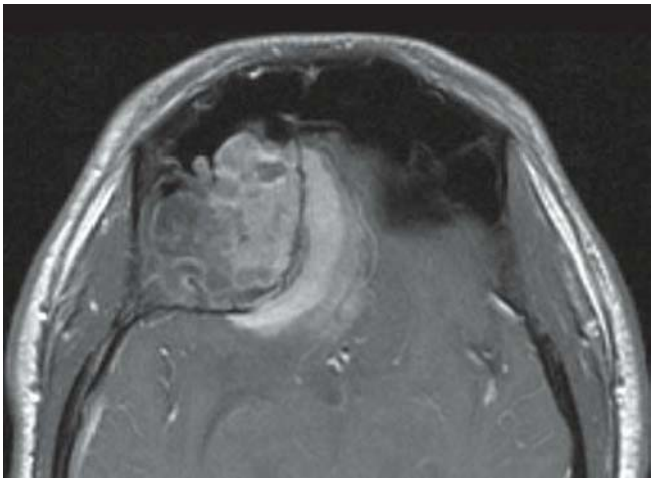

Figure 37.5 GIFR Axial postcontrast T1-weighted MRI of the same patient shown in Figure 37.4 demonstrates enhancement within the granulomatous mass and the adjacent involved brain. Granulomatous Invasive Fungal Rhinosinusitis

GIFR, historically referred to as primary paranasal aspergillosis granuloma in Sudan, is a rare condition whose former name reflects both its geographic predilection and causative organism. Reports of GIFR are mainly circumscribed to the regions of North Africa, India, Pakistan, and Saudi Arabia and *Aspergillus flavus* is uniformly identified when positive cultures are obtained. The symptoms, clinical presentation, exam findings, and imaging studies of GIFR are similar to those of CIFR. Long durations of disease can cause significant remodeling of the skull base and maxillofacial skeleton in response to this slow invasive process (Figs. 37.4 and 37.5). CIFR exhibits a predilection for diabetics that GIFR does not (5). Important distinctions in the clinical features include enlarging granulomatous masses in the paranasal sinuses and adjacent regions of the face that can result in proptosis (5).

PATHOLOGY

Histopathologic study of GIFR shows tissue invasion with few hyphae and a variable inflammatory infiltrate. The presence of a granulomatous response with extensive fibrosis and fungal hyphae within multinucleated giant cells

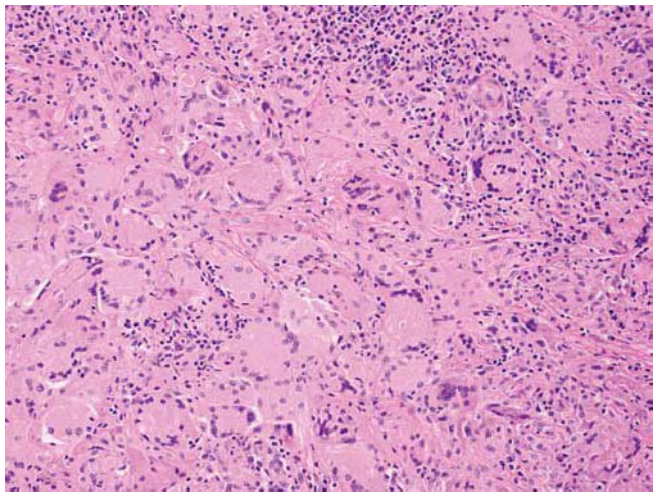

Figure 37.6 GIFR H&E-stained image showing marked granulomatous inflammation with abundant multinucleated giant cells in sinus mucosa. Image and Caption: Anthony T. Yachnis, MD; Department of Pathology, University of Florida College of Medicine, Gainesville, FL.

and noncaseating granulomas distinguishes GIFR from CIFR, which shows more tissue necrosis and purulence (42) (Figs. 37.6 and 37.7).

TREATMENT AND PROGNOSIS

The treatment options for GIFR have closely paralleled those for CIFR. A more sinister clinical course is appreciated for GIFR in comparison to CIFR, with higher rates of relapse and an overall lower survival rate. Aggressive surgery to clear the detectable disease and remove necrotic tissue is recommended in combination with systemic antifungal chemotherapy. Repeat operations for diagnostic surveillance and therapeutic clearance of disease are recommended, as in CIFR. Though specific outcomes data for the antifungal therapy of GIFR are lacking at this time, the reduced toxicity of newer antifungals favors long-term therapy (9).

Noninvasive Fungal Sinus Infections

There are three different forms of noninvasive fungal rhinosinusitis. Localized fungal colonization of nasal or paranasal mucosa, sinus fungus ball, and AFRS are considered below.

Localized Fungal Colonization of Nasal or Paranasal Mucosa

Formerly termed saprophytic fungal infestation, the category of localized fungal colonization of nasal or paranasal mucosa is defined by visible growth of fungus on mucus crusts within the sinonasal cavity and not the presence of fungi demonstrable by culture alone. The condition usually comes to clinical attention during postoperative endoscopic examinations or as a result of a foul odor from the nose. Daily nasal saline irrigation is recommended along with endoscopic examination and debridement until the condition resolves. Imaging studies are not likely to add to the information obtained by a thorough history and physical examination that includes nasal endoscopy. Systemic antifungal medications are not recommended.

Fungal Ball of the Paranasal Sinuses

Fungal ball (FB) of the paranasal sinuses, often erroneously referred to as "mycetoma" is an extramucosal mycosis that fills one or more paranasal sinus with densely tangled, inspissated fungal debris and mucous without invasion of the underlying mucosa.

CLINICAL PRESENTATION

FBs tend to develop in older females who are immunocompetent, nonatopic, and have a prior history of endodontic treatment of the maxillary dentition (44). FB may be asymptomatic or cause the typical symptoms of CRS. Maxillary and ethmoid involvement causes facial pain, nasal airway obstruction, purulent rhinorrhea, and cacosmia while sphenoid disease may cause vertex headache and postnasal drip (45). A prolonged duration of CRS symptoms, unilateral symptoms, and poor response to medical therapy may point to a FB. Nasal endoscopy reveals normal to mild, nonspecific mucosal changes in about half of the patients. Radiographic imaging studies often point to the diagnosis (44).

RADIOLOGY

Fungus balls have characteristic imaging findings. CT scans are the most frequently obtained imaging study of the paranasal sinuses and FB cases will appear as complete or partial

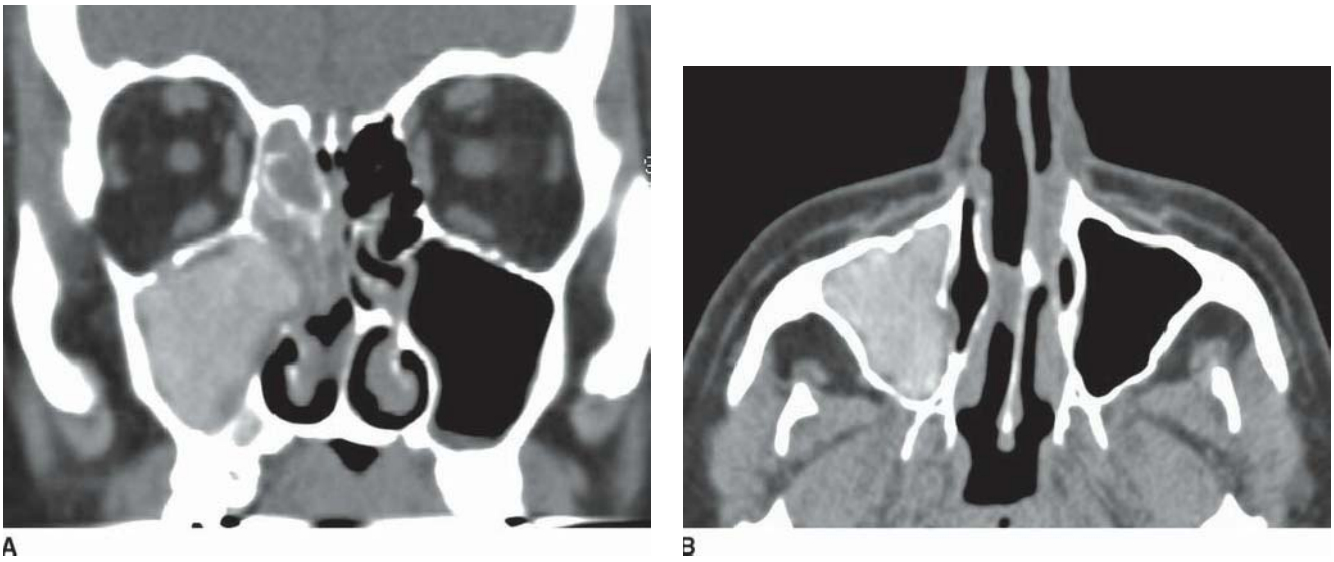

Figure 37.8 **A,B**: Fungus ball of the paranasal sinuses axial and coronal noncontrast CT scans show complete opacification of the right maxillary sinus, higher attenuation densities within the sinus, and thickening of the paranasal sinus mucosa consistent with chronic inflammation. Image and caption: Jeffrey Bennett, MD. Department of Radiology, University of Florida College of Medicine, Gainesville, FL.

sinus opacification (Fig. 37.8). Single sinus involvement is the rule, with less than 10% of cases involving multiple sites (46). Maxillary sinus disease (62% to 84.4%) is reported to be several times more frequent than sphenoid involvement (14.4% to 25%), with the ethmoid site a more rare location (0.6% to 4%) (44,46). Hyperattenuation of the FB on noncontrast CT results from the dense collection of hyphae within the sinus lumen while the inflamed sinus mucosa appears hypoattenuated on CT and hyperintense on T2-weighted MRI (40). The FB itself does not enhance, which can be helpful in differentiating FB from malignant processes or other processes associated with sinus opacification and bone erosion. Maxillary FB is more likely to have microcalcifications seen on CT compared to other paranasal sites (44). Bony erosion or sclerosis occurs in nearly half of cases. The classically described MRI finding of a hypointense signal void in the area of disease on T2-weighted studies as a result of calcifications and chelated paramagnetic metals is present in only 50% of reviewed cases of proven FB of the paranasal sinuses (44).

PATHOLOGY

The pathogenesis of FB is incompletely understood, but epidemiologic features point to possible contributing factors. These include a female predominance (1.87 to 2.97:1), absence of the disease process in children, and a strong association with prior endodontic treatment of maxillary teeth (44,46,47). FB formation requires inhalation of fungal spores and sequestration within the sinonasal passages. A poorly ventilated paranasal sinus favors germination and growth as the fungus evades host immune defenses and avoids clearance from the sinuses by mucociliary transport (4). Bacterial infections may augment fungal growth via purulent secretions that provide valuable nutrient supplies to the fungi (4,46). While culture of sinus contents is often negative, *A. fumigatus* is the most common pathogen isolated (46). Histopathology reveals tightly packed fungal hyphae with a pale center and the thin, septate, acute-angle branching of hyphae that become more apparent at the periphery of the FB (Fig. 37.9). The associated sinus mucosa demonstrates a mild to moderate infiltration of chronic inflammatory cells in the absence of tissue invasion, granulomas, or allergic fungal mucin (42).

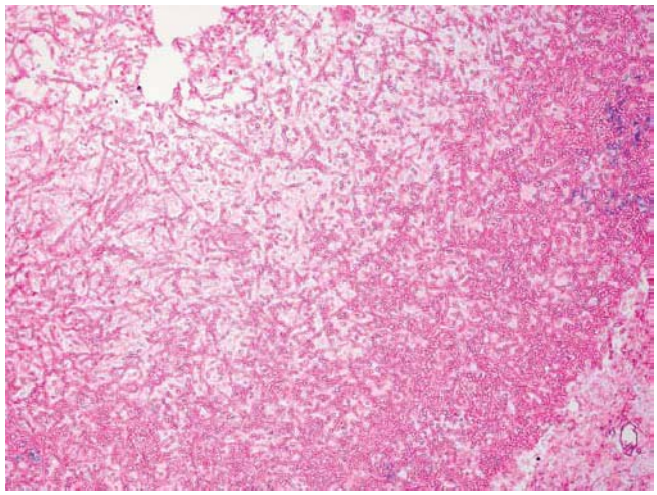

Figure 37.9 Fungus Ball of the Paranasal Sinuses High magnification view of H&E stained material. Enormous abundance of fungal hyphae in a densely matted configuration that is noted to be paler toward the center of the fungal collection. Image and Caption: Anthony T. Yachnis, MD; Department of Pathology, University of Florida, College of Medicine, Gainesville, FL.

FBs preferentially involve the maxillary sinus (61% to 84% of cases), and endodontic treatment of maxillary teeth has been proposed to play a role in pathogenesis (44,46). Zinc oxide-containing materials employed in root-filling during endodontic surgery do promote the growth of *A. fumigatus* and can decrease the protective functions of respiratory epithelium both by paralysis of normal cilia as well as induction of soft tissue hypervascularity and associated edema (47). Park demonstrated endodontic treatment of the ipsilateral maxillary teeth to be a significant risk factor for FB (47). However, FB can involve paranasal sinuses that are removed from the maxillary dentition as well as maxillary sinuses in patients with untreated teeth, so it is clear that other etiologic forces are at play when this disease process occurs in remote paranasal sinus locations.

The average age for patients diagnosed with FB in several studies ranged between 49.4 and 52.7, and given that endodontic procedures increase in frequency with aging, the role of endodontic treatment in maxillary FB is thought to explain the limitation of this disease process to older populations (44,46). The absence of FB in children (less than 19 years old) may reflect the absence of endodontic procedures in this population.

TREATMENT

FBs of the paranasal sinuses are adequately treated by complete surgical removal of the FB and thorough irrigation of the involved sinus. Though traditionally addressed through external approaches, endoscopic techniques are extremely effective in achieving complete extirpation of disease. Trephinations for irrigation, endoscope port placement, or external approaches should be considered in only the most challenging cases. Historical recurrence rates of less than 5% now approach 0% as surgical experience and endoscopic instrumentation have improved (44,45). Postoperative antifungal therapy is never recommended, unless the patient suffers from comorbid conditions with seriously compromised immune function, and then consultation with an Infectious Disease specialist may be warranted.

Allergic Fungal Rhinosinusitis

AFRS is a distinct clinicopathologic entity within the spectrum of CRS that has become increasingly well recognized over the last 30 years. Originally proposed by Millar et al. in 1981 as an upper airway version of allergic bronchopulmonary aspergillosis (ABPA), the newly described allergic Aspergillosis of the sinuses reflected many of the features of the pulmonary disease: a type I hypersensitivity to fungal antigens with production of mucoid impactions (48). By 1983, publication of additional similar cases allowed authors to both describe the histopathologic nature of the mucin that so closely resembles the mucous plugs seen in ABPA and recognize that a significant proportion of CRS patients may have the disease (48). It has been estimated that up to 5% to 10% of all CRS cases undergoing surgery meet modern criteria for diagnosis with AFRS. A complete understanding of this entity is required to optimize the medical and surgical management of this unique subset of CRS patients.

CLINICAL PRESENTATION

Patients with AFRS present with symptoms typical of CRS with nasal polyps: progressive nasal congestion, nasal airway obstruction, hyposmia/anosmia, postnasal drip, periods of exacerbated symptoms with facial pain or pressure, and thick rhinorrhea. Findings that should spur additional inquiry into a diagnosis of AFRS include reports of thick, dark, viscid mucus, recurrence of disease despite appropriate treatment, facial dysmorphia (malar flattening, proptosis, or telecanthus) and asymmetric nasal polyp disease. The clinical presentation may be subtle or dramatic with gross facial disfigurement or complications that have included cavernous sinus thrombosis and visual loss resulting from optic nerve compression (49,50). AFRS cases are more common in the Southern and Southeastern United States (51).

AFRS patients present at a younger age than do those with other forms of polypoid CRS. African Americans and individuals of low socioeconomic status may be disproportionally affected (52). African American patients present at significantly younger ages and with greater degrees of bone erosion than do Caucasian patients (53). Both males and African American patients, across multiple studies, are found to have statistically greater incidences of skull base and orbital erosion in AFRS. Whether this represents a delay in diagnosis resulting from poor access to medical care, a more aggressive course for AFRS in this racial group, or genetic differences in the bony response to inflammatory sinonasal disease is unclear. However, African Americans have been shown to experience a greater improvement postoperatively than Caucasians (54).

DIAGNOSIS

A constellation of clinical, radiographic, and immunologic features are required to establish a diagnosis of AFRS. Although several closely related sets of histopathologic features have been proposed to define the disease,(3) the five criteria set forth by Bent and Kuhn (55) remain the most widely accepted diagnostic criteria. Patients with AFRS demonstrate: (a) type I hypersensitivity to fungi, (b) nasal polyposis, (c) characteristic findings on CT scan including serpiginous areas of high attenuation, (d) gross production of eosinophilic mucin containing noninvasive fungal hyphae, and (e) positive fungal stain. While the disease may be suspected based on physical examination or radiographic findings, a diagnosis of AFRS cannot be established until sinus tissue and mucus obtained during surgery have been reviewed by a pathologist and allergy testing is performed. The retrospective nature by which AFRS is diagnosed has prompted investigators to search for a method of identifying the condition preoperatively.

Dhiwakar et al. (56) found the triad of hyperattenuation on CT imaging, nasal polyps, and elevated titers of anti-*Aspergillus* IgE antibody to preoperatively diagnose AFRS with a sensitivity of 70% and a specificity of 100%. Another study of preoperative diagnosis of AFRS was limited to CRS and noninvasive categories of fungal rhinosinusitis. The combination of type I hypersensitivity, CT findings of hyperattenuation, and bony erosion were shown to predict the diagnosis of AFRS and differentiate this condition from CRS as well as other forms of noninvasive fungal rhinosinusitis (57).

RADIOLOGY

In AFRS, eosinophilic mucin is sequestered within involved paranasal sinus cavities and its accumulation results in typical radiographic findings (Table 37.3). Heterogeneous areas of hyperattenuation on CT scan are noted within the lumen of paranasal sinuses opacified by eosinophilic mucin (40,41). Current evidence points to accumulations of heavy metals (e.g., iron, magnesium, manganese) and calcium salt precipitation within inspissated eosinophilic mucin as the most likely cause of these heterogeneous areas of hyperattenuation. The high protein and low water concentration of eosinophilic mucin in conjunction with heavy-metal precipitate produces a signal void on T2-weighted MR images while the signal intensity is more varied on T1-weighted images (40,41). The loss of signal on T2 helps differentiate AFRS from neoplasms that also produce sinus opacification, bone erosion, and orbital or skull base invasion on CT scan. Inflamed paranasal sinus mucosa is routinely hypointense on T1-weighted images, hyperintense on T2-weighted images, and enhances with gadolinium contrast (40,41) (Fig. 37.10). The combination of CT and MRI findings described above are strongly suggestive of AFRS and can help narrow a patient's differential diagnosis.

CT imaging of patients with AFRS often reveals a surprising degree of paranasal sinus bone erosion with involvement of the orbit and skull base. This common finding is thought to be the result of pressure atrophy from accumulated eosinophilic mucin and bony remodeling that results from the local inflammatory state within the affected sinuses (40). Bone remodeling occurs in 20% to 90% of AFRS cases, with more recent reviews at tertiary care centers indicating frequencies of orbital or skull base erosion occurring in 44% to 56% of AFRS cases (40,53). Orbital involvement occurs more frequently than does skull base erosion, and the ethmoid sinus is the most common site of AFRS associated with bone remodeling.

TABLE 37.3 RADIOGRAPHIC CHARACTERISTICS OF AFRS

CT Characteristics

1. Disease tends toward unilateral or asymmetric distribution
2. Involved sinuses are expanded
3. Bone bordering involved sinuses may demonstrate attenuation or erosion (best demonstrated on bone-weighted algorithms
4. Adjacent anatomic spaces may be displaced
5. Signal heterogeneity within the involved sinuses (best demonstrated with soft tissue algorithm)

MRI Characteristics

T1

1. Involved paranasal sinuses demonstrate variable signal intensity.
2. Enhancement of periphery of the involved paranasal sinuses (mucosal edema)

T2

1. Hypointensity of signal within involved paranasal sinuses (indication of dehydrated state of mucin)
2. Enhancement of periphery of the involved paranasal sinuses (mucosal edema)

Meltzer EO, Hamilos DL, Hadley JA, et al. Rhinosinusitis: establishing definitions for clinical research and patient care. *Otolaryngol Head Neck Surg* 2004;114:S155–S212.

PATHOLOGY

The production of eosinophilic mucin (formerly called "allergic mucin") was formerly considered pathognomonic of AFRS. Grossly, this material is thick, tenacious, highly viscous, and can vary in color from light tan to brown or dark green (3). Examination of sinonasal mucosa and polyps obtained during surgery should confirm the absence of tissue invasion by fungal hyphae amidst a background of mixed inflammatory cellular infiltrates and an abundance of eosinophils (42).

The histologic appearance of the mucin is an important diagnostic criterion for AFRS. Hematoxylin and eosin (H&E) staining accentuates the mucin and cellular components of eosinophilic mucin but fails to stain the fungal hyphae. H&E slides demonstrate accumulations of pyknotic and degranulated eosinophils within a background of lightly staining sheets of mucin (42). More deeply staining Charcot-Leyden crystals are found within the scattered cellular material and, often, the sparse fungal hyphae may avoid detection with H&E staining (42) (Fig. 37.11). It is this difficulty in detecting fungal hyphae in cases of presumed AFRS that provided fuel for some of the controversy surrounding the pathogenesis of AFRS. Silver stains can detect even a single cell and are the most sensitive of the commonly used histologic stains. However, silver stains are not as specific as the periodic acid Schiff stain. The Fontana Masson stain is best to detect dematiaceous fungi. With technologic advancement, more sensitive techniques to demonstrate fungal presence are expected; however, sampling error and inconsistencies in the processing of mucin extracted at surgery may still result in the inability to demonstrate fungal presence within eosinophilic mucin.

Figure 37.10 **A–C**: AFRS Axial noncontrast CT scan shows pan-sinus opacification and expansion, with areas of increased attenuation corresponding to fungal colonization and chelated metals. Axial T1-weighted gadolinium-enhanced MRI shows peripheral mucosal enhancement and internal low signal. Coronal T2-weighted MRI demonstrates areas of signal void within the involved ethmoid sinuses. Image and caption: Jeffrey Bennett, MD. Department of Radiology, University of Florida College of Medicine, Gainesville, FL.

FUNGAL CULTURE

Fungal cultures of eosinophilic mucin may provide supportive evidence for the diagnosis of AFRS but must be interpreted with caution. It is important to realize that the diagnosis of AFRS is neither established nor eliminated based upon the results of these cultures. The variable yield of fungal cultures (64% to 100%) renders AFRS in the presence of a negative fungal culture quite possible (3). Conversely, a positive fungal culture fails to confirm the diagnosis of AFRS, as it may merely represent the presence of saprophytic fungal growth. For this reason, the histologic appearance of eosinophilic mucin in combination with other clinical factors remains an important indicator of AFRS.

THEORIES AND CONTROVERSIES SURROUNDING PATHOGENESIS

The histologic similarities between ABPA and AFRS led to early assumptions about the disease that persist to this day. The dominant theory is that atopic individuals sensitized to fungi produce Gell and Coombs type I and III hypersensitivity reactions to extramucosal fungal antigens within the nose and paranasal sinuses (58). The resultant mucosal edema, polyp formation, and stasis of secretions results in sinus ostial obstruction, intercurrent bacterial infection, retained and concentrated fungal antigens, and collection of the characteristic eosinophilic mucin with eventual sinus expansion and bony erosion (58). The intense eosinophilic response

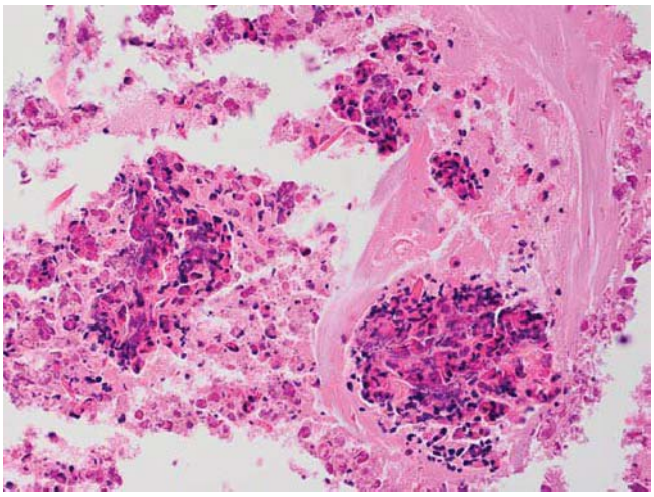

Figure 37.11 AFRS H&E stained section demonstrates clumps of degenerating eosinophils and a background of homogenous, lightly eosinophilic mucoid material, and a few deeply eosinophilic Charcot-Leyden crystals. Image and Caption: Anthony T. Yachnis, MD; Department of Pathology, University of Florida, College of Medicine, Gainesville, FL.

and cycle of inflammation and subsequent sinus obstruction can be attenuated by immunomodulation or surgical therapy to ventilate the sinuses and extirpate the mucin. The most frequently cultured organisms in AFRS include the members of the family dematiaciae (*Bipolaris*, *Alternaria*, *Curvularia*, *Fusarium*, *Exserohilum*, *Helminthosporium*, *Drechslera*) in the United States and *Aspergillus* species in Asia. In AFRS, it is usually possible to detect type I hypersensitivity directed to these fungi (58). The paucity or apparent absence of fungal hyphae in AFRS mucin specimens has led to additional theories regarding the pathogenesis of AFRS.

In 1999, Ponikau et al. (59) suggested that colonizing fungi in sinus mucus play a much broader role in the pathogenesis of CRS. Using an ultrasensitive culture technique, 93% of 101 consecutive patients with CRS demonstrated positive fungal cultures from nasal lavage. Examination of surgical specimens from these patients revealed eosinophils and fungal hyphae within the sinus mucus of nearly all patients. It was also observed that 100% of a group of normal control subjects had positive fungal cultures from nasal lavage (59). Conventional IgE-mediated allergy to fungi was not consistently observed in the CRS patients and many of these patients fulfilled the other criteria required for diagnosis of AFRS. It was proposed that virtually all cases of CRS result from eosinophilic inflammation elicited by certain fungi independent of conventional, allergic, IgE mechanisms, and that the term AFRS be replaced by "eosinophilic fungal rhinosinusitis"(EFRS) (59). The difficulty in demonstrating fungal elements within the eosinophilic mucin of some CRS patients gave rise to the term "eosinophilic mucin rhinosinusitis" (EMRS) to describe those cases in which fungal elements cannot be identified. Ferguson proposed EMRS as a systemic disorder of immune dysregulation with a number of potential pathogenic mechanisms, several of which do not require either fungus or atopy to generate the eosinophilic mucin that characterizes the disease (60). It is not just the absence of fungal elements on histologic examination that encourages categorization of EMRS as a distinct clinicopathologic entity. EMRS patients tend to be older, have bilateral disease, a higher incidence of aspirin sensitivity, greater association with asthma, increased incidence of IgG1 deficiency, and less allergy than those with AFRS (60). In general, nasal polyposis and eosinophilic mucin are prominent in AFRS, EFRS, and EMRS, indicating substantial overlap between the three proposed entities as well as the need for further research to better delineate the conditions. An understanding of the pathogenic roles played by allergy, direct fungal stimulation of the immune system, and the role of humoral immunity will be helpful in generating more specific targets for intervention in the future. At the present time, AFRS is understood to represent a distinct clinicopathologic entity within the spectrum of CRS. While much remains yet to be elucidated regarding AFRS, the understanding of its pathogenesis, clinical properties, and allergic nature are sufficient to guide its medical and surgical management.

TREATMENT

The treatment approach for AFRS is essentially identical to the treatment approach for other forms of CRS with nasal polyposis. There are few treatment studies that have examined AFRS specifically, and treatment recommendations derive from the treatment approach for the analogous disorder, ABPA (58).

Endoscopic sinus surgery (ESS) is the cornerstone of AFRS treatment, but recidivism remains unacceptably high with surgery alone. Modern understanding of the pathogenesis of AFRS as an immunologically mediated hypersensitivity to fungal antigens has prompted a two-pronged attack: (a) utilizing surgery to provide sinus ventilation and thorough mucin removal and (b) medical modulation of the immune response with corticosteroids and immunotherapy to diminish inflammation.

The most important immunomodulatory agents for AFRS are topical and systemic corticosteroids. Preoperative corticosteroids reduce bleeding and facilitate complete surgery. In the early postop period, steroids prevent early polyp recurrence and improve symptoms (61). Patients treated with prolonged course of systemic corticosteroids demonstrate a significant increase in time before revision ESS (62). Brief courses of systemic steroids are used to treat exacerbations or polyp regrowth. The mainstay of medical management for AFRS is topical therapy that consists of saline irrigations and corticosteroids. Saline irrigations help to facilitate mucociliary clearance defense mechanisms, loosen and dislodge inspissated secretions, and reduce mucosal exposure to allergens and other proinflammatory irritants. Daily use of topical intranasal steroids is considered to be safer than long-term oral corticosteroids. There is a dose response effect for nasal steroids in the treatment

of nasal polyp disease, and therefore topical intranasal steroids are often used in an unconventional fashion with high doses delivered via nebulization, irrigation, or drops.

Immunomodulation can also be achieved by means other than corticosteroids. Initial studies addressing the safety of adjunctive immunotherapy for the treatment of AFRS revealed not only that this practice appeared safe, but also lead to a decrease in disease recurrence. In several studies, patients treated with fungal immunotherapy for a period of 1 to 3 years following surgery showed a significant decrease in their rate of recurrence, lower reoperation rates, and a decreased number of office visits. In addition, patients receiving immunotherapy statistically had less mucosal edema as noted on endoscopy and reported better quality of life (62). The efficacy of immunotherapy for the treatment of AFRS has not been substantiated with randomized controlled trials; nevertheless, immunotherapy is a rational treatment approach that may be particularly valuable in patients who have significant allergic symptomatology.

A wide variety of other agents may be employed for their putative anti-inflammatory properties or to eliminate fungal colonization in the sinuses. However, at present there is insufficient data for antifungal therapy, leukotriene inhibitors, or macrolide antibiotics in the medical management of AFRS. Each of these classes of agents has a theoretic rationale and may eventually prove worthwhile in diminishing the overall inflammatory state within the nose and sinuses (63). Topical antifungal agents are clearly ineffective for the treatment of CRS with nasal polyps, but have not yet been studied specifically in AFRS.

HIGHLIGHTS

- ESS is a vital part of the management for all types of fungal rhinosinusitis.
- AIFR is best controlled by the combination of ESS, reversal of the underlying medical morbidities, restoration of normal neutrophil numbers, and systemic antifungal therapy with lipid amphotericin B and azole antifungal medications.
- CIFR has an excellent prognosis and can be treated with surgery alone; however, the reduced side effects of newer antifungal medications favor their use in this infection.
- FBs of the paranasal sinuses are treated with endoscopic surgery and do not require antifungal treatment. Surgical sinusotomies should be large enough to facilitate postoperative surveillance and treatment in the office setting.
- Management of AFRS requires surgical removal of eosinophilic mucin and nasal polyps, creation of wide drainage pathways in addition to long-term medical management with anti-inflammatory medications.

Complications of Rhinosinusitis

38

Carla M. Giannoni

Acute bacterial sinusitis occurs commonly, usually as a sequela of an upper respiratory infection. Symptoms include cough, purulent nasal discharge, headache, facial pain and pressure, nasal congestion, fetid breath, fever, malaise, and lethargy. Spread of infection outside the sinuses results in complicated sinusitis. The incidence of complications from both acute and chronic sinusitis has decreased fourfold since the 1950s but appear to have stabilized in the past several decades (1–3). This has been attributed to the widespread use of antibiotics for rhinosinusitis but clinical data are lacking in this area (see "Prevention of Complications for Sinusitis" later in this chapter for further discussion). Complications of sinusitis can be divided into three categories: orbital, intracranial, and bony. This chapter reviews each of these complications in detail, describing the pathophysiology, evaluation, microbiology, and medical and surgical treatments.

ORBITAL COMPLICATIONS

Anatomic Considerations

The close proximity of the orbit to the paranasal sinuses, especially the ethmoid sinuses, make it the most commonly involved structure in complications of sinusitis. Orbital complications have a seasonal variation indicating a viral role in the initiation of sinusitis. Children appear to be more prone to orbital complications of sinusitis, probably because of their relatively higher rates of upper respiratory tract infections and sinusitis. Gender has not been identified as a risk factor in preseptal disease. Male gender has been identified as a risk factor in postseptal infections in some series (4) but not in others (5–7) and it appears that the gender predilection becomes more dominant in older children.

Orbital involvement primarily results from a thrombophlebitis and interference with the venous drainage of the orbital contents. The superior and inferior ophthalmic veins are valveless, allowing direct communication between the nose, ethmoid sinuses, face, orbit, and cavernous sinus. In addition, congenital or other dehiscences in the lamina papyracea, which separate the ethmoid sinuses from the orbit, expose the orbital contents to direct extension of sinusitis. The combination of phlebitis and direct entry of bacteria into perivascular structures results in what is generally a continuum of inflammatory and infectious changes. The orbital periosteum, the periorbita, is an important structure because it is the only soft tissue barrier between the sinuses and the orbital contents. It comprises loose fibrous tissue that can be easily elevated off the underlying bone. The orbital septum is a reflection of the periorbita at the margins of the orbit and it passes centrally to fuse with the tarsal plates. The orbital septum lacks lymphatic channels and thus forms a barrier limiting infections from passing directly through the eyelids into the orbit. Orbital infections are divided into two groups based on this element of orbital anatomy: preseptal and postseptal infections.

Classification

Chandler et al. (8) classified the orbital complications of sinusitis into five groups: preseptal cellulitis, orbital cellulitis, subperiosteal abscess, orbital abscess, and cavernous sinus thrombosis (Fig. 38.1). The first complication, preseptal cellulitis is a preseptal infection and the latter four are postseptal. Although often thought of as a continuum, each of these complications should be considered separately and treatment individualized (Table 38.1). These infections are not exclusive and multiple complications can occur in the same patient. A number of other classifications schemes have been proposed but the Chandler classification remains the most widely utilized in clinical practice.

PRESEPTAL CELLULITIS

Preseptal infections are far more common than postseptal infections. Preseptal cellulitis can be a complication of ethmoid sinusitis but it can also occur as a result of infection of the eyelids and orbital adnexa, trauma (including insect

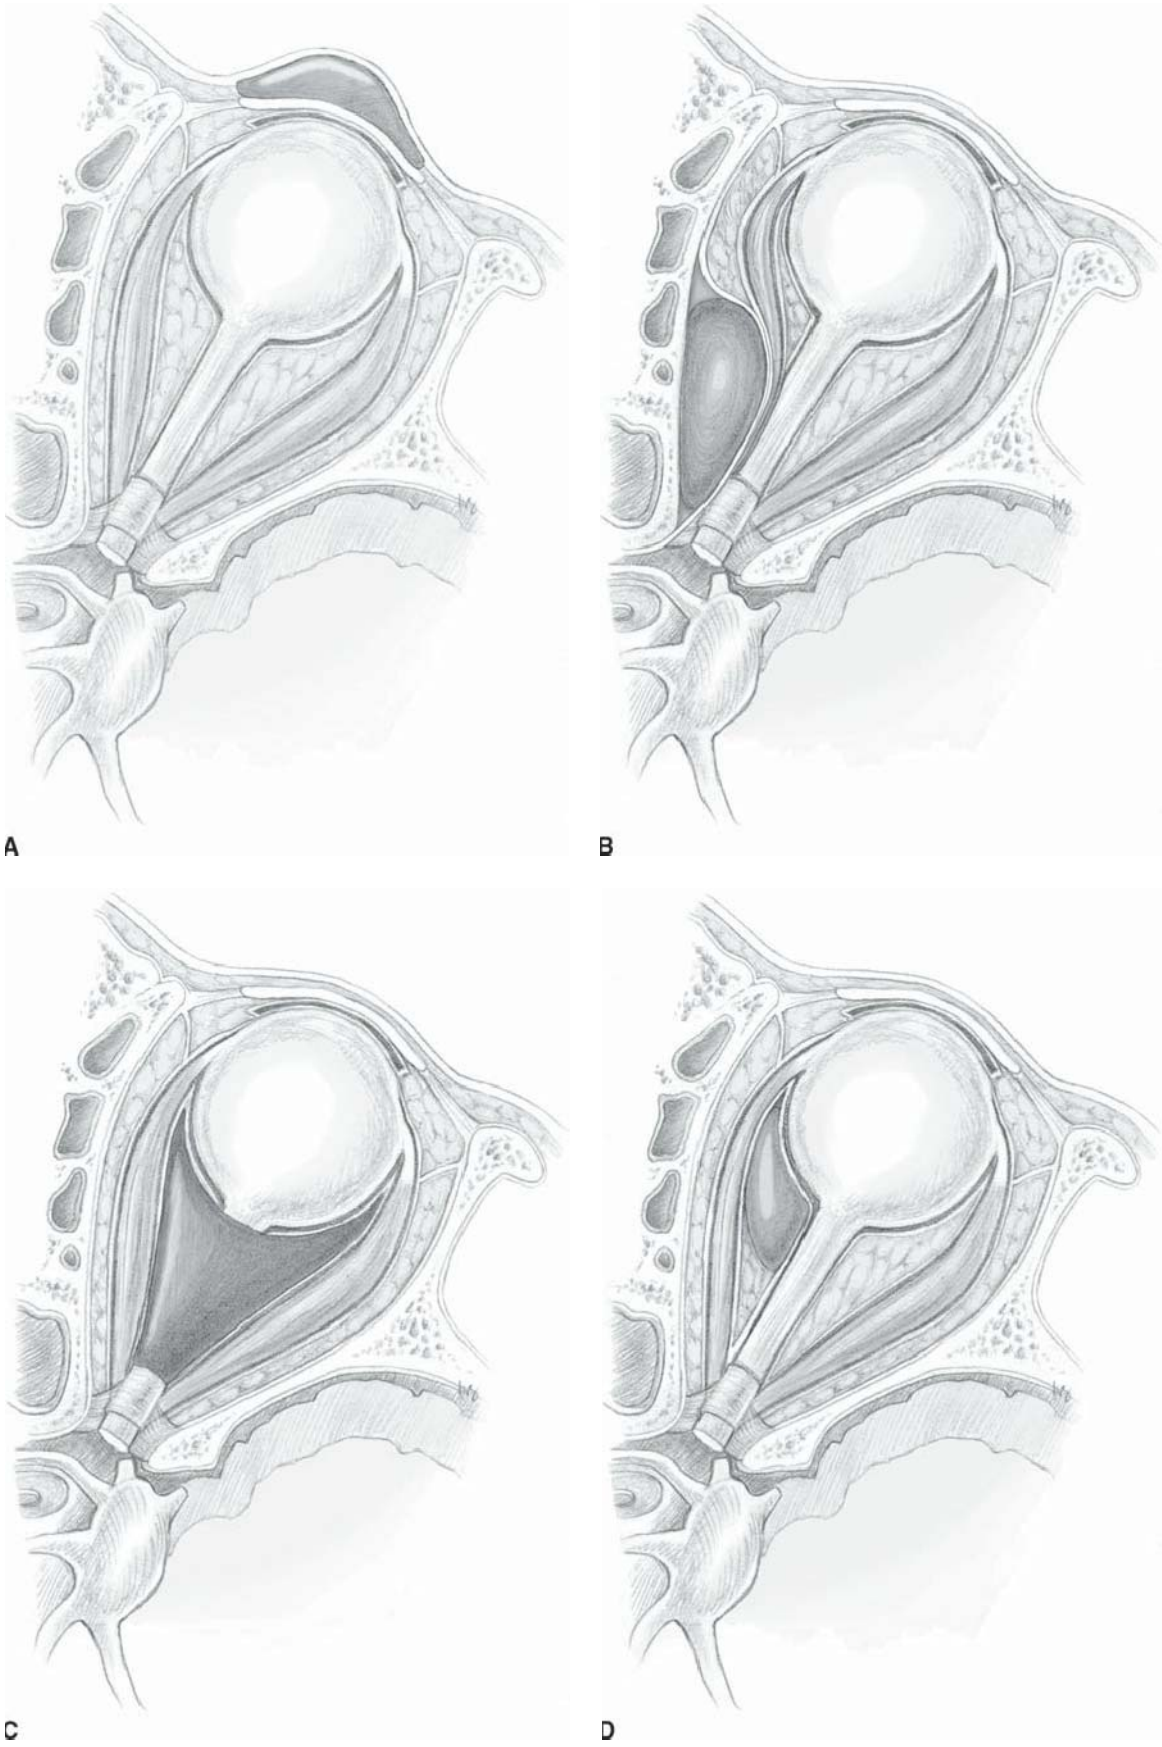

Figure 38.1 Chandler classification of orbital complications of sinusitis. **A**: Preseptal cellulitis (eyelid edema), **(B)** Subperiosteal abscess, **(C)** Orbital cellulitis, **(D)** Orbital abscess,

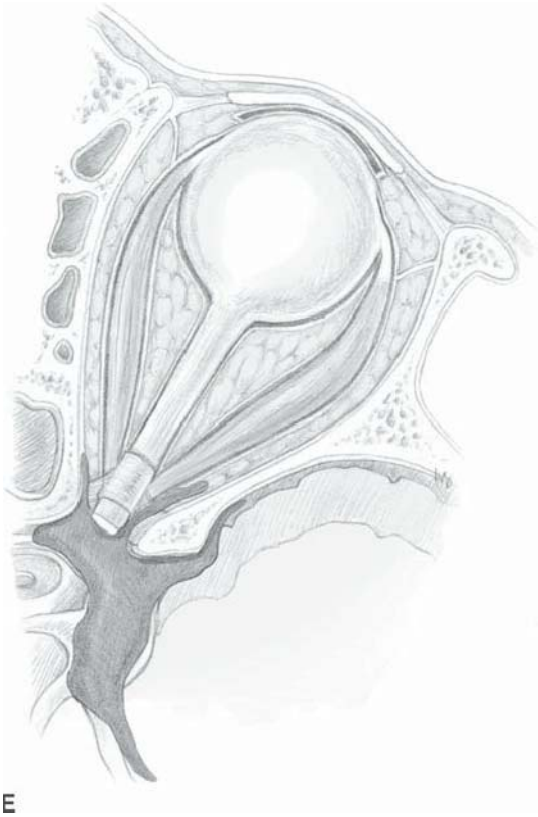

Figure 38.1 *(Continued)* **(E)** Cavernous sinus thrombosis.

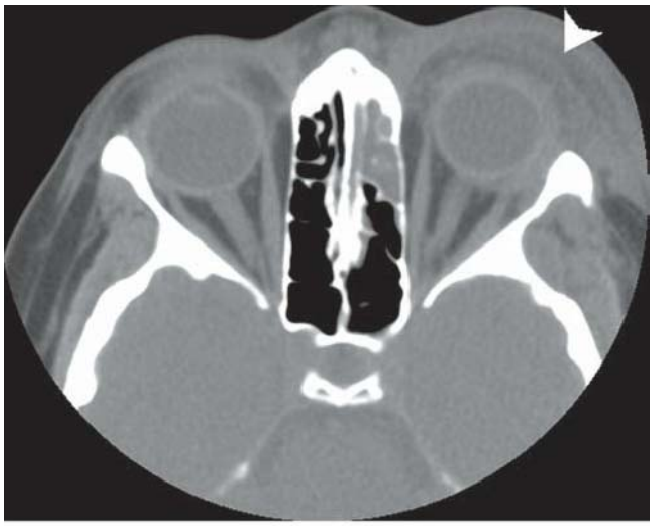
bites), or a foreign body (6,7). In contrast to other orbital complications, medical comorbidities such as cystic fibrosis, HIV, leukemia, diabetes, and other immune deficiencies are risk factors for preseptal cellulitis (7). Preseptal cellulitis manifests as eyelid swelling, erythema, and tenderness. Occasionally these may progress to an eyelid abscess (Fig. 38.2) and can also be associated with edema of the orbital (postseptal) contents. There are no limitations of extraocular movements and no impairment of visual acuity. Sinonasal infections cause periorbital swelling due to impaired venous drainage of the ethmoidal vessels that are obstructed by inflammation and pressure.

SUBPERIOSTEAL ABSCESS

With subperiosteal abscess, a collection of pus forms at the medial aspect of the orbit between the periorbita and the lamina papyracea (Fig. 38.3). This is the second most common orbital complication of sinusitis. In response to inflammation in the ethmoid sinus, an inflammatory tissue collection beneath the orbital periosteum can develop and become a subperiosteal phlegmon (9). This subperiosteal phlegmon can then progress into a discrete abscess. A subperiosteal phlegmon or abscess can displace the orbital contents and globe downward and laterally with normal mobility in the early stages. An abscess may occasionally rupture through the orbital septum and present in the eyelids.

Typically, younger children develop isolated orbital complications, especially medial subperiosteal abscesses associated with acute ethmoiditis. Interestingly, a second, notable subset of patients has been identified: teenage males, who develop simultaneous orbital and intracranial complications (10–14). This phenomenon is likely related to the age-dependent development of the frontal and sphenoid sinuses.



ORBITAL CELLULITIS

Orbital cellulitis is a postseptal infection that manifests as diffuse edema of the orbital contents without a discrete abscess (Fig. 38.4). There is eyelid edema and erythema, proptosis, and chemosis with limited or no impairment of extraocular movements and normal visual acuity early in the disease process. Visual changes and ophthalmoplegia

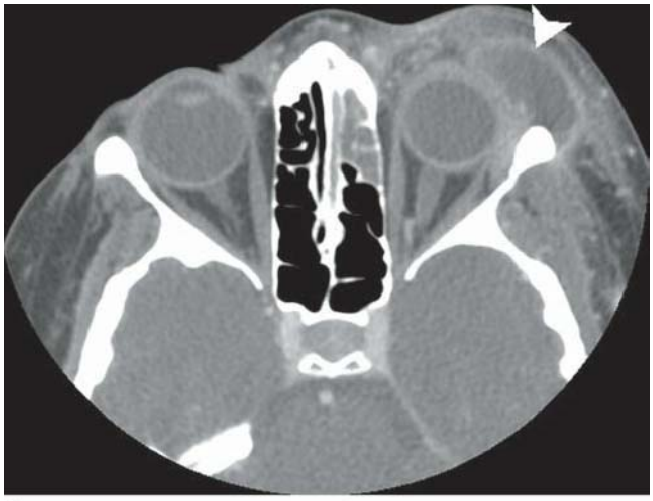


TABLE 38.1 ORBITAL COMPLICATIONS OF SINUSITIS

	Typical Findings	Treatment
Preseptal cellulitis	Edematous, erythematous eyelids Extraocular muscles (EOM) intact Normal vision	Medical therapy (Rarely, drainage of secondary abscess)
Orbital cellulitis	More diffuse orbital edema ± Impaired EOM Usually normal vision until later in disease course	Medical therapy ± Sinus drainage[a]
Subperiosteal abscess	Edematous, erythematous eyelids; Proptosis Impaired EOM Usually normal vision, esp in the case of small abscesses Visual changes more likely with larger abscesses	Medical therapy ± Sinus drainage ± Abscess drainage
Orbital abscess	Severe exophthalmos, chemosis, Ophthalmoplegia, common Visual impairment, common	Medical therapy Sinus drainage, often Abscess drainage, usually
Cavernous sinus thrombophlebitis	Bilateral orbital pain, chemosis, proptosis Ophthalmoplegia CN III, IV, V1, V2, V3, VI can be affected	Medical therapy Sinus drainage, often ± Anticoagulation (controversial)

[a]Surgical sinus drainage may be limited to maxillary sinus aspiration or may include endoscopic or open sinus surgery; its necessity depends on severity of symptoms, physical examination, duration of medial treatment and need for cultures to direct antibiotic therapy.

The patient also developed an orbital subperiosteal abscess, scalp abscess, and small epidural abscess.

indicating optic neuritis and/or ischemia can occur as the disease progresses; these are prognostically worrisome findings. Not all cases of orbital cellulitis are due to sinusitis, however. Patients presenting with pain and diplopia and a history of recent orbital trauma or dental surgery should be assessed for orbital cellulitis. In diabetic patients with ketoacidosis and immunocompromised patients, more severe infections such as invasive fungal sinusitis should be considered. Orbital cellulitis is more concerning than preseptal cellulitis because it can evolve into an orbital abscess.

ORBITAL ABSCESS

An orbital abscess occurs when orbital cellulitis coalesces into a discrete collection of pus within the orbital tissues. This is a serious complication that can be associated with

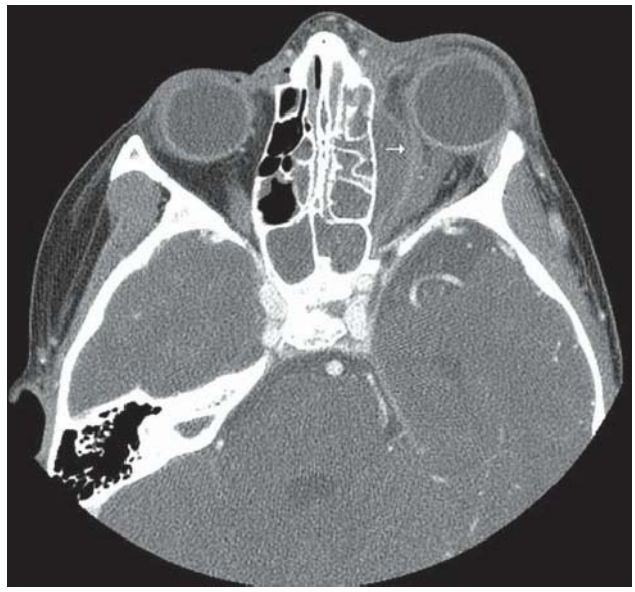

Figure 38.3 Axial CT scan demonstrating a left subperiosteal orbital abscess. The abscess is immediately adjacent to the lamina papyracea (the *arrow* is inside the abscess and identifies the lateral edge of the abscess); note the proptosis and the displacement of the orbital periosteum and medial rectus muscle.

severe exophthalmos and chemosis, complete ophthalmoplegia and visual impairment with a risk for progression to irreversible blindness. On rare occasions there is spontaneous drainage of purulent material through the eyelid.

CAVERNOUS SINUS THROMBOSIS

Cavernous sinus thrombophlebitis or thrombosis is a complication that can be considered an orbital as well as an intracranial complication of sinusitis. Venous congestion

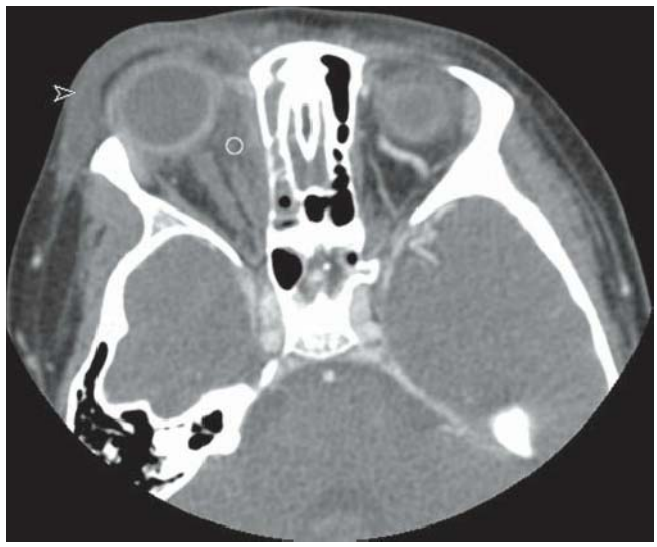

Figure 38.4 Axial CT scan showing right orbital cellulitis with diffuse orbital inflammatory changes that are intra- and extraconal (*open circle*); there is concurrent preseptal edema and inflammatory changes (*arrow*).

in the orbit results in orbital pain, chemosis, proptosis, and ophthalmoplegia. Cranial nerves III, IV, V1, V2, V3, and VI traverse the sinus and can all be affected. Extension of the phlebitis posteriorly into the cavernous sinus results in progression of symptoms in the opposite eye. This contralateral involvement is a distinguishing feature of cavernous sinus thrombosis. It can be associated with sepsis and meningismus or frank meningitis may be present.

DIAGNOSIS AND TREATMENT EVALUATION

A history including recent upper respiratory infection, duration and progression of symptoms, recent trauma (including insect bites and conditions involving the skin such as chicken pox), swimming, ear infection, dental surgery or dental infection, and other systemic illnesses should be obtained when evaluating a patient with orbital findings. Decongestion and examination with anterior rhinoscopy and nasal endoscopy may demonstrate polyps or purulent material under the middle turbinate. The eye must be opened to assess visual acuity, extraocular movements, and proptosis. When orbital infection is suspected, ophthalmologic consultation should be obtained immediately to assess visual status as this may impact the aggressiveness of surgical treatment (5–7). Close follow-up of patients with orbital infections is needed as the infection may evolve or progress during the course of treatment with development of new complications.

Radiography

Imaging is often necessary to appropriately classify orbital complications. Conventional plain film radiography is of limited value in the evaluation of sinusitis because of poor anatomic detail and poor correlation with clinical symptoms. Computed tomography (CT) is considered the gold standard for sinus imaging because it can better depict the anatomy of the globe, retro-orbital tissues, sinuses, and cranium, and provides information for surgical planning. It has been shown to demonstrate good accuracy in diagnosing pediatric chronic rhinosinusitis (9,15). CT of the sinuses and orbits with contrast is indicated when postseptal infection is suspected clinically based on findings of proptosis, gaze restriction or changes in visual acuity, when intracranial complications are suspected, or when symptoms of preseptal inflammation progress in 24 to 48 hours despite treatment (6). The study consists of contrast-enhanced axial and coronal thin cuts of the sinuses and orbits. CT of the brain with contrast and/or magnetic resonance imaging (MRI) may also be indicated if there are symptoms of a concurrent intracranial complication.

In preseptal cellulitis, CT reveals a diffuse increase in density and thickening of the lid and conjunctiva. Postseptal inflammation is characterized by a soft tissue density or low-attenuation area adjacent to the lamina papyracea (9,16). It should be noted that the medial rectus muscle may be displaced, enhanced, or thickened by inflammatory edema in many orbital infectious processes. Abscesses appear as hypodense areas with rim enhancement and mass effect. Subperiosteal abscesses arise adjacent to the lamina papyracea but can also occur in a superior location, adjacent to the orbital roof secondary to frontal sinusitis (17). Extension of the inflammatory process into the intraconal space appears on CT as an ill-defined infiltration of the orbital fat with obliteration of the optic nerve and extraocular muscles. Cavernous sinus thrombosis is better demonstrated on MRI but may be suggested by poor venous enhancement on contrast CT. Contrast-enhanced MRI is performed when intracranial complications are suspected and includes axial and coronal T1 and T2 images (9,16).

Microbiology of Orbital Complications

There is usually little correlation between cultures taken randomly from the nose or nasopharynx and those obtained from sinus aspiration. Culture material can be obtained directly from the sinus by sinus puncture and lavage or during surgical exploration. An exception to this rule is endoscopically directed middle meatal nasal cultures where there may be a more accurate correlation between these nasal cultures and those obtained from the maxillary sinus (18). The organisms responsible for acute suppurative sinusitis are similar for both adults and children and do not always reflect the common causative pathogens of acute and chronic sinusitis (19,20) (Table 38.2). The most commonly identified organisms in acute rhinosinusitis are *Streptococcus pneumoniae, Haemophilus influenzae*, and *Moraxella*, other streptococcal species, and less commonly anaerobes. *Staphylococcus aureus* can be seen in adults and in children with serious sinus infections. Chronic sinusitis in both adults and children is more commonly due to anaerobes as well as alpha-hemolytic streptococci, *S. aureus, H. influenzae*, and *S. pneumoniae*.

Streptococcal organisms play a major role in complicated sinusitis. A thorough understanding of the taxonomy of these organisms is necessary. The majority of streptococci fall into two broad categories: beta-hemolytic and non–beta-hemolytic, which includes alpha-hemolytic and non-hemolytic organisms. The beta-hemolytic group includes Group A and Group B Streptococci. The non–beta-hemolytic group is further subdivided into optochin-susceptible, which includes *S. pneumoniae*, and optochin-resistant, which includes *Streptococcus viridans*. The viridans group includes *Streptococcus bovis* group, *Streptococcus milleri* group and more than 20 other species of viridans streptococci. *S. milleri, Streptococcus constellatus*, and *Streptococcus anginosus* constitute the *S. milleri* group (21).

Excluding preseptal cellulitis, orbital complications are often polymicrobial. *S. viridans*, especially the *S. milleri* group organisms, and *S. aureus* have been implicated as the most common causes of both orbital and intracranial complications of sinusitis in most contemporary

TABLE 38.2 MICROBIOLOGY OF SINUSITIS AND RELATED COMPLICATIONS

Acute sinusitis (children)	More common	*Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and other *Streptococcus* species
	Less common	Anaerobic organisms and *Staphylococcus aureus*
Acute sinusitis (adults)	More common	*S. pneumoniae*, *H. influenzae*, other *Streptococcus* sp., and anaerobic organisms
	Less common	*M. catarrhalis* and *S. aureus*
Orbital complications of sinusitis	More common	*Streptococcus viridans* (including *Streptococcus milleri* group), *S. aureus*, and *S. pneumoniae*; these infections are commonly polymicrobial
	Less common	Anaerobic organisms (especially *Bacteroides* sp., *Peptostreptococcus*, and *Eikenella*), other *Streptococcus* sp., *H. influenza*, and other gram negative bacilli
Intracranial abscesses (intracerebral, epidural, subdural abscesses)	More common	*S. viridans* (including *S. milleri* group), *S. aureus*, other *Streptococcus* sp., other anaerobic organisms (*Peptostreptococcus*, *Bacteroides* sp., others), and *S. pneumoniae*; commonly polymicrobial infections
	Less common	Coagulase-negative *Staphylococcus* and gram negative bacilli (*H. influenza*, others)
Meningitis	More common	*S. pneumoniae*, *S. aureus*, and other *Streptococcus* sp.
	Less common	Anaerobic organisms (*Fusobacterium* sp., others), gram negative bacilli, and *H. influenzae*
Pott's puffy tumor (acute osteomyelitis)	More common	*S. viridans* (including *S. milleri* group) and *S. aureus*; commonly polymicrobial infections
	Less common	Anaerobic organisms (*Bacteroides* sp., etc.) and, much less commonly, gram negative bacilli (*Proteus* sp., etc.)

Note: This compilation represents the observed commonalities and average incidence of groups of organisms identified in series published over the last 10 y; the exact predominance of each organism in the listed disease processes varies among different published series.

series (5–7,22) (Table 38.2). Less common but consistent causes of complicated sinusitis are *S. pneumoniae*, other Streptococci, and anaerobic microorganisms. *H. influenza*, *Eikenella*, and other gram-negative bacilli are also implicated in some cases of complicated sinusitis.

Viridans streptococci are usually facultatively anaerobic organisms but some strains may be microaerophilic. It is important to note that the reporting of these sometimes nonpathologic organisms can vary greatly from one laboratory to another and may be missed if awareness for their pathologic nature in the situation of complicated sinusitis is not understood or if anaerobic cultures are not collected.

Immunocompromised patients may develop sinusitis caused by similar organisms as immunocompetent patients; however, they are also susceptible to atypical pathogens and fungus with development of invasive infections. (Fungal rhinosinusitis is discussed more fully in Chapter 37 of this text).

Treatment

Most orbital infections respond to medical treatment. The mainstay of medical treatment is intravenous (IV) administration of a broad-spectrum antibiotic followed by oral therapy. A nasal decongestant, either topical or oral, mucolytics or saline irrigations may help promote sinus drainage.

Preseptal and orbital cellulitis generally respond to medical management. Preseptal cellulitis is treated with antibiotics, head elevation, warm packs, and management of the underlying cause. Some patients with orbital cellulitis who are not responding to medical therapy, especially those with visual changes may also benefit from surgical drainage of their sinuses despite the absence of a discrete abscess. Incision and drainage of a lid abscess is occasionally necessary.

In general, surgical intervention has been recommended in cases when there is CT evidence of abscess formation, 20/60 or worse visual acuity is observed on initial evaluation, progression of orbital signs and symptoms occurs despite medical treatment, or lack of improvement is seen within 48 hours despite aggressive medical treatment. For subperiosteal abscesses that are large and/or lateral, and for orbital abscesses this remains the appropriate course of treatment. A more conservative approach to the management of small, medial subperiosteal abscesses has been advocated in several contemporary series (5–7). Favorable outcomes have been demonstrated in children with small, medial subperiosteal abscesses when no ocular signs are present.

In these cases, surgical intervention is advocated as in the cases of other abscesses: if ocular signs develop such as worsening visual acuity or ocular motility or if there is failure to improve in 48 hours of medical management. A useful framework for assessing patients was outlined by Oxford and McClay (5): a patient with medial subperiosteal abscess with normal vision (better than 20/40), no ophthalmoplegia, intraocular pressure less than 20 mm Hg, proptosis less than 5 mm, and width of abscess less than 4 mm on CT can be considered for possible medical management. These objective criteria were shown retrospectively to predict successful medical management with good outcomes, even in older children.

Treatment of cavernous sinus thrombosis is primarily medical with high-dose IV antibiotics that cross the blood-brain barrier and consideration of the use of anticoagulants. Surgical intervention consisting of drainage of the affected sinuses may be appropriate to facilitate sinus drainage and obtain cultures.

The mainstay of surgical treatment for sinusitis with complications has traditionally been conventional open surgeries such as external ethmoidectomy and Caldwell-Luc procedures for sinus and abscess drainage. (These external drainage procedures and their indications are described more fully in Chapter 41 of this text.) Functional endoscopic sinus surgery is now more commonly used for sinus drainage in patients with infectious complications. (Endoscopic sinus surgery is described more fully in Chapter 40 of this text.) Endoscopic sinus surgery allows for culture of sinus content and may reduce microbial load and aid in sinus aeration. It should be noted that this technique is not without its limitations; the nasal cavity and sinuses are usually quite inflamed and normal anatomy can be obscured or difficult to navigate due to bleeding and edema. In addition to endoscopic sinus drainage, subperiosteal abscesses can, in many cases, be drained intranasally by endoscopic techniques (see Chapter 43 for additional information). In these cases, surgical intervention should include widely opening the ethmoid sinuses and removal of the lamina papyracea. In cases of orbital abscess, this same endoscopic drainage approach can include incision of the periorbita and drainage of the intraconal abscess if the location and anatomy is amenable to the technique. Newer oculoplastic techniques such as a transcaruncular approach, which utilizes a transconjunctival incision extended medially around the lacrimal caruncle, are finding some favor for draining subperiosteal abscesses (Fig. 38.5) (23). Some patients with orbital cellulitis, particularly in cases where there is disease progression or significant ophthalmologic findings, may also benefit from surgical drainage of their sinuses despite the absence of a discrete abscess.

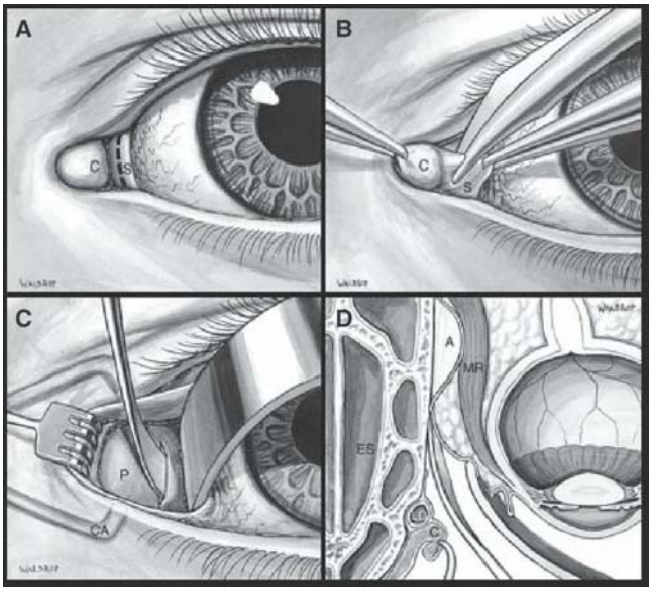

Figure 38.5 Transcaruncular approach to drainage of subperiosteal abscess. **A**: The incision falls between the caruncle (C) and semilunar fold (S). **B**: The tissue between caruncle (C) and the semilunar fold (S) is incised with tenotomy scissors. **C**: While protecting the globe and canalicular (CA) system, the periosteum (P) is incised and elevated with a Freer elevator. **D**: The periosteum is elevated until the abscess (A) is found and drained. ES, indicates ethmoid sinus; MR, medial rectus; LD, lacrimal duct; and C, caruncle. (Adapted from Pelton RW, Smith ME, Patel BC, et al. Cosmetic considerations in surgery for orbital subperiosteal abscess in children: experience with a combined transcaruncular and transnasal endoscopic approach. *Arch Otolaryngol Head Neck Surg* 2003;129:652–655.)

INTRACRANIAL COMPLICATIONS

The paranasal sinuses are an integral part of the anterior and middle skull base. This intimate relationship and the complex venous network that traverses this area result in the occurrence of infectious intracranial complications of sinonasal disease. The incidence, morbidity, and mortality of suppurative intracranial complications secondary to sinusitis have dramatically decreased due to the widespread use of oral antibiotics, improved imaging technology, recognition that involved paranasal sinuses are the primary focus of infection, expeditious treatment of underlying sinusitis, and improved intensive care medicine (4,5).

The risk for developing an intracranial complication in patients requiring hospital admission for sinusitis has been estimated to be 3% (1). Intracranial complications are extremely rare under 7 years of age and appear more commonly in African American and male patients (4,10,13,14). This is presumably related to the fact that adolescents, unlike younger children, have developed their frontal and sphenoid sinuses and also because adolescents are more prone to upper respiratory infections than adults (12). The elderly may form a second, smaller "at risk" group (24).

Intracranial complications do not commonly present with symptoms of acute sinusitis but rather with headache lasting greater than 1 week, often coupled with fever (4,11). Altered mental status, orbital edema, and/or nausea and vomiting are also seen in many patients (11,13,14,25). Focal neurologic deficits can be seen as later findings (4,11,13,14,25). While intracranial complications are often associated with acute or subacute

sinusitis, underlying chronic sinusitis may be a factor in some patients. The presence of a long-standing process characterized by acute exacerbations requiring prolonged courses of antibiotics can result in changes in the mucosa and underlying bone including scarring and polypoid changes. This is theorized to result in hidden foci of infection with poor drainage that have reduced antibiotic penetration (2).

Anatomic Considerations

Routes of spread of infection from the sinuses may be hematogenous or through direct extension. Retrograde septic thrombophlebitis through the valveless diploic veins of the skull and ethmoid bone or communicating veins is the most common route of spread. The intracranial venous system is also valveless, allowing further spread of thrombophlebitis and septic emboli (3,10). Direct extension may occur via preformed routes such as congenital or traumatic dehiscences, through sinus wall erosion or traumatic fracture lines, and by existing neurovascular foramina such as those for the optic and olfactory nerves.

Diagnosis and Classification

The intracranial complications of sinusitis include meningitis, epidural abscess, subdural abscess, intracerebral abscess, and cavernous sinus and venous sinus thrombosis (Fig. 38.6). These infections are all associated with significant morbidity and mortality and warrant immediate attention. Also, multiple complications can occur in the same patient either concurrently or sequentially (10,12,17,24).

A history focusing on recent upper respiratory infection, duration and progression of symptoms, recent trauma, swimming, ear or dental infection or surgery, and other systemic illnesses should be obtained when evaluating a patient with intracranial findings. The patient should be assessed for symptoms of acute or chronic sinonasal complaints such as purulent rhinorrhea and nasal obstruction and symptoms of increased intracranial pressure such as frontal or retro-orbital headache, nausea and vomiting, altered mental status, nuchal rigidity, or papilledema. Intracranial complications may be asymptomatic until late in their course, especially when "silent" areas of the brain are involved such as the frontal lobe. Late findings include seizures, hemiparesis, and other focal neurologic findings; these are associated with a poorer prognosis (11–14,25). While the rate varies widely, review of published series over the last 10 years show that as many as 9% to 38% of patients that do survive have permanent neurologic sequelae and that the mortality averages 4% (10,12,24,25).

Radiographic evaluation is an important component of the diagnosis of intracranial complications. MRI with contrast is considered the study of choice to assess intracranial complications (9,16). CT scan of the sinuses is also generally obtained to assist in treatment planning, especially for possible sinus surgery. Management is multidisciplinary often including an otolaryngologist, neurosurgeon, pediatrician, internist, and critical care and infectious disease specialists.

EPIDURAL ABSCESS

Epidural and subdural abscesses are the most common intracranial sinusitis complications. These abscesses are generally a complication of frontal sinusitis due to venous communications and loosely adherent dura in the frontal region (Fig. 38.7). Initial symptoms include headache, fever, and occasionally orbital edema, local

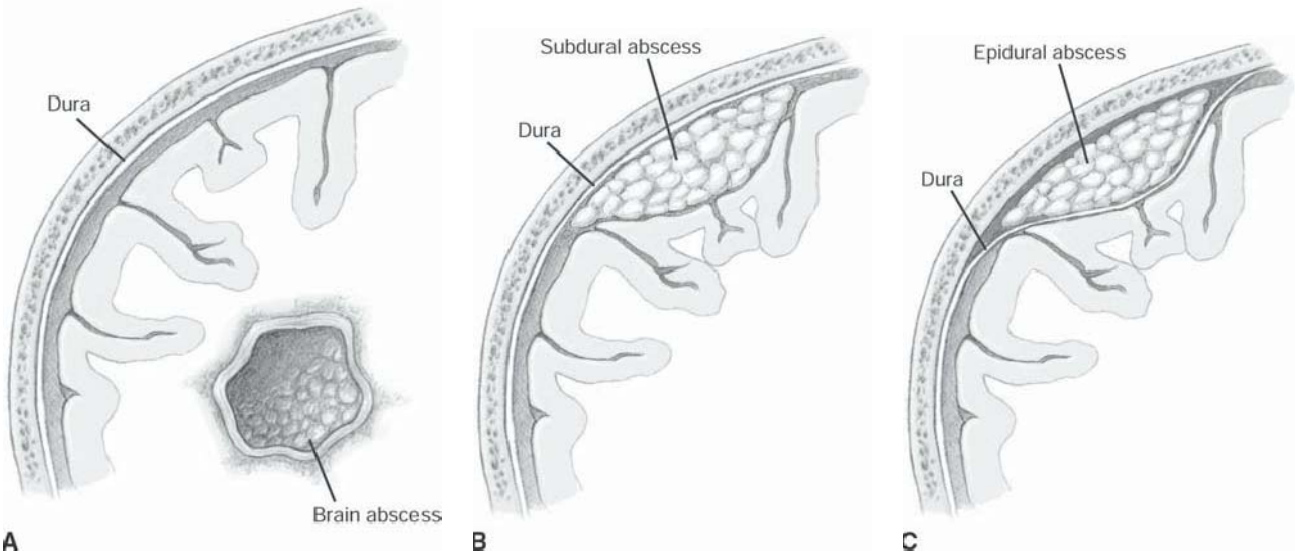

Figure 38.6 Intracranial complications of sinusitis. **A**: Intracerebral (brain) abscess, **(B)** Subdural abscess, **(C)** Epidural abscess.

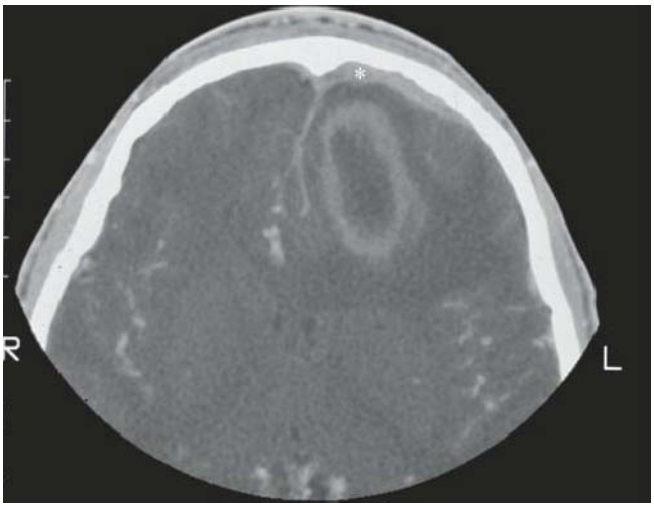

Figure 38.7 Axial CT scan of the brain demonstrating a left intracerebral abscess and epidural abscess (*asterisk*) secondary to frontal sinusitis.

pain, and/or tenderness. The diagnosis can be made using CT or MRI but MRI has greater sensitivity and is the preferred radiologic exam. Unenhanced CT reveals a hypodense or isodense crescent-shaped area adjacent to the inner table of the skull. A curvilinear ring of enhancement may be seen. MRI demonstrates a low-attenuation extraaxial mass (9,16). Outcomes for epidural abscess tend to be more favorable than other intracranial infections (11).

SUBDURAL ABSCESS

As with epidural abscess, subdural abscess is most commonly a complication of frontal sinusitis. Subdural abscesses are usually unilateral. Due to the lack of anatomic barriers, infection can spread over the cortex into the interhemispheric region (Fig. 38.8). Subdural abscesses are notable for having a higher morbidity and mortality than other intracranial complications (4,13,14). A subdural abscess can be a life-threatening emergency because patients can deteriorate quickly. The typical course is headaches, fever, and lethargy followed by coma. Meningismus is often present and the degree of focal neurologic deficits depends on the site of the abscess. MRI reveals a low signal on T1-weighted images and a high signal on T2-weighted images with peripheral enhancement after administration of gadolinium.

INTRACEREBRAL ABSCESS

Intracerebral abscess is a less common complication of sinusitis. These usually involve the frontal and frontoparietal lobes. The most common site of precipitating infection

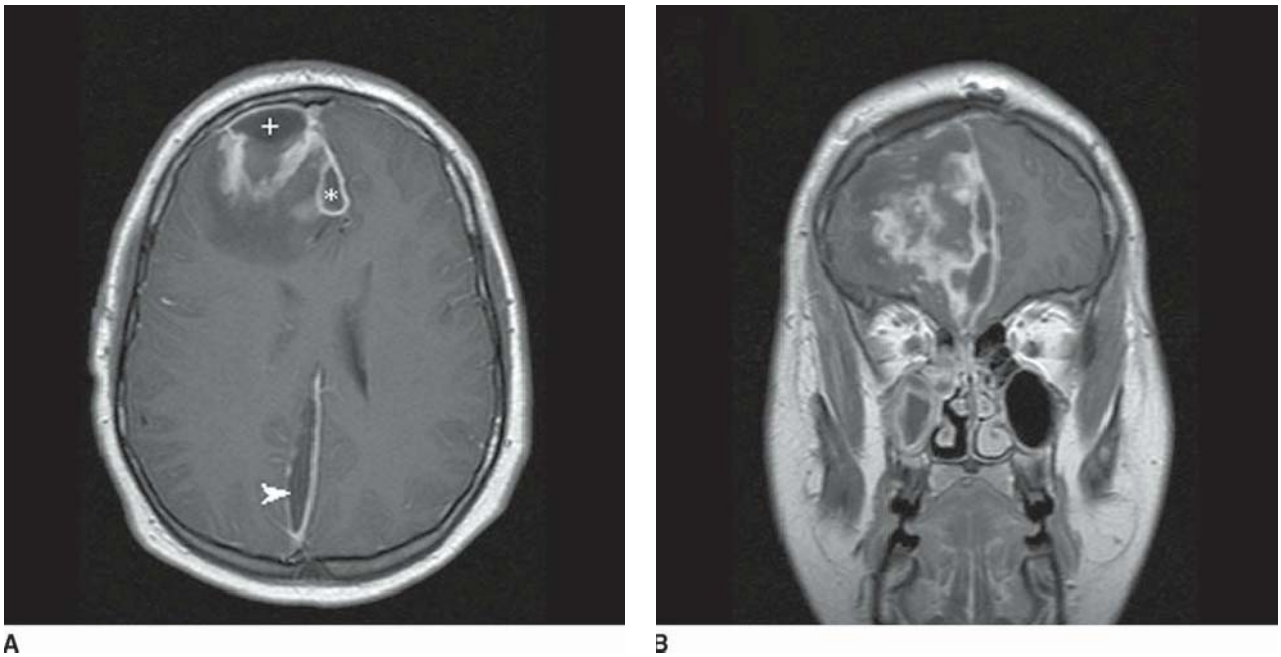

Figure 38.8 MRI images from a 16-year-old male who presented with left leg paresis and was found to have right frontal sinusitis and subdural abscess. Despite aggressive IV antibiotics and immediate treatment with craniotomy and drainage of the subdural abscess, endoscopic sinus surgery, and frontal sinus trephination he had progression of his infectious process. **A**: Axial MRI, taken 12 days after initial drainage procedures, showing a right paramedian falx subdural empyema with a budding abscess (*plus*) that extends into adjacent brain parenchyma with active cerebritis and a right parafalcine subdural collection (*asterisk*) that is located superiorly and centrally near the vertex; this interhemispheric collection extends posteriorly along the right medial parieto–occipital lobe (*arrow*). Local mass effect and shift of the falx due to vasogenic edema is also demonstrated. **B**: Coronal MRI of the same patient showing unilateral right pansinusitis and the interhemispheric subdural collection with frontal lobe involvement.

is the frontal sinus with the sphenoid and ethmoid sinuses less commonly implicated. As with other intracranial abscesses, symptoms include fever, headache, vomiting, and lethargy. Seizures and focal neurologic deficits can also occur, usually as later findings. Frontal lobe abscesses are associated with more subtle symptoms such as mood swings and behavioral changes. Lumbar puncture can be life threatening and should not be performed until radiographic imaging is done and brain anatomy is assessed. MRI demonstrates a cystic lesion with a distinct hypointense strongly enhancing capsule on T2-weighted images (Fig. 38.7).

VENOUS SINUS THROMBOSIS

Sagittal sinus thrombosis develops from retrograde thrombophlebitis from frontal sinusitis. It is usually found in association with other complications such as subdural abscess, epidural abscess, or intracerebral abscess (3). Patients are extremely ill, presenting with meningeal signs or other serious neurologic complications. MRI may reveal focal defects of enhancement after gadolinium administration with decreased cavernous carotid artery flow void. MR angiogram and venogram studies can further delineate the process (2).

MENINGITIS

The frequency of meningitis in series of intracranial complications of sinusitis varies greatly among studies (10–13,17). Isolated meningitis is a relatively uncommon complication of sinusitis. Focal dural enhancement (focal meningitis) associated with other complications of sinusitis is somewhat more common and when these types of meningitis cases are combined, meningitis is seen about as often as intracerebral abscess (11). Meningitis typically results from sphenoiditis or ethmoiditis. As in meningitis due to other causes, initial symptoms include headache, neck stiffness, and high fever. Patients may or may not have complaints of sinusitis but it is demonstrated on CT in affected cases. In severe cases, patients may be septic and demonstrate cranial nerve palsies.

TREATMENT MICROBIOLOGY

Sinogenic meningitis is most commonly due to *S. pneumoniae* and this organism is associated with a higher incidence of neurologic complications such as hearing loss. Cultures from intracranial abscesses are often polymicrobial. *S. viridans* species (including *S. milleri*) and *S. aureus*, other *Streptococcus species* and anaerobes are the most commonly isolated organisms in intracranial infections secondary to sinusitis in both children and adults (Table 38.2) (3,20,22). Even in cases where intracranial abscesses are due to acute sinusitis, this pattern of microbiology is seen. This may in part be due to the fact that although anaerobes and *S. aureus* are not commonly found in acute sinusitis in children they are associated with a higher incidence of complications of sinusitis (19).

Treatment

Upon identification of an intracranial complication of sinusitis, neurosurgical consultation is obtained and multidisciplinary treatment planning is initiated.

Treatment of intracranial abscesses (epidural, subdural, and intracerebral) abscesses includes high-dose, broad-spectrum IV antibiotics with good intracerebral penetration. Neurosurgical drainage of the intracranial abscess is usually performed, although occasionally, patients with small abscesses and mild symptoms are observed for response to medical therapy and drainage performed only if the patient fails to improve or symptoms worsen. Surgical drainage is often eventually required even in these cases due to progression of disease (24). Steroid and anticonvulsant medications may be adjunctively administered to treat any secondary cerebral edema and to reduce the risk of seizures.

In the majority of cases, surgical drainage of the affected sinuses is performed (Table 38.3). Sinus cultures obtained early in the course of the illness can help direct treatment. Endoscopic or external approaches may be used as discussed above in the treatment of orbital complications. Frontal sinus trephination can be used to drain frontal sinusitis. Occasionally, an epidural abscess can be drained via the frontal sinus by opening the posterior table of the frontal sinus. Neurosurgical and otolaryngologic procedures are sometimes performed during the same anesthesia but sinus surgery should only be considered when the patient has been stabilized. It should be noted that while most authors advocate sinus surgery as a component of multidisciplinary treatment for patients with intracranial abscesses, early sinus drainage may not improve outcome or need for neurosurgical drainage procedures (24).

Patients may present with or develop multiple intracranial complications of sinusitis. Repeat imaging of the brain and sinuses can be performed during treatment and prior to hospital discharge to assess response to treatment and identify new complications (13,24). Multiple intracranial drainage procedures are often required to treat new or progressive disease. Antibiotic treatment should be continued for 4 to 8 weeks because as healing takes place, the barriers to drug transport into the central nervous system are repaired (3).

The initial treatment of meningitis is medical with administration of broad-spectrum antibiotics that cross the blood-brain barrier. If the patient has been stabilized, drainage of the affected sinuses may be performed within 48 hours if there is no clinical improvement. Steroid and anticonvulsant medications may be adjunctively administered to treat any secondary cerebral edema. Neurologic

TABLE 38.3 INTRACRANIAL COMPLICATIONS OF SINUSITIS, TREATMENT HIGHLIGHTS

	Sinus Source[a]	Highlights of Disease Process and Treatment
Meningitis	Ethmoid sinus; Sphenoid sinus	High incidence neurologic sequelae (e.g., hearing loss) Medical treatment only, usually
Epidural abscess	Frontal sinus	Aggressive medical treatment; surgical drainage of the abscess, usually Sinus drainage, usually, when medically stable
Subdural abscess	Frontal sinus	Highest rate of neurologic morbidity and mortality Aggressive medical treatment (often includes steroids and anticonvulsants) Surgical drainage of the abscess, usually; sinus drainage, usually, when medically stable
Intracerebral abscess	Frontal sinus (less commonly: ethmoid sinus, sphenoid sinus)	High neurologic morbidity and mortality; usually frontal lobe so symptoms may be subtle Aggressive medical treatment (often includes steroids and anticonvulsants) Surgical drainage of the abscess, usually; sinus drainage, usually, when medically stable
Venous thrombophlebitis	Frontal sinus	Aggressive medical treatment (often includes steroids and anticonvulsants) Anticoagulation is controversial Surgical drainage of the sinuses, sometimes

[a]Most patients with intracranial complications have unilateral or bilateral pansinusitis; the sinus most commonly implicated as the source of intracranial spread of infection is reported.

sequelae are common in patients with meningitis, primarily seizure disorders, and sensorineural deficits such as hearing loss.

Treatment of venous sinus thrombosis includes high-dose IV antibiotics and drainage of the involved sinuses (3). The use of anticoagulants is controversial. When used, the treatment is continued until there is radiologic evidence of resolution of the thrombus (2).

BONY COMPLICATIONS

Frontal sinusitis complicated by osteomyelitis of the frontal bone is known as Pott puffy tumor (Fig. 38.9). It can culminate in an anterior subperiosteal pericranial abscess, a periorbital abscess, or an epidural abscess. The subperiosteal collection of pus in the forehead produces "puffy" fluctuant swelling. It may occur alone but often occurs in combination with other intracranial complications, especially epidural abscess (17). The primary presenting symptoms are severe headache and fever and are not symptoms of sinusitis (17).

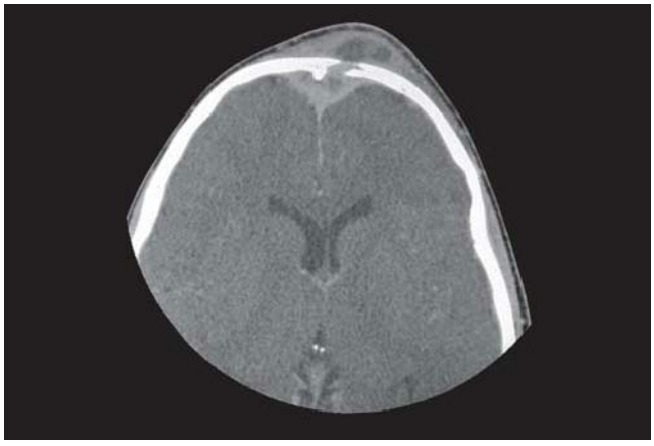

Figure 38.9 Axial CT scan demonstrating a Pott Puffy Tumor secondary to frontal sinusitis. There is bone erosion (due to acute osteomyelitis), a scalp abscess, and a concurrent epidural abscess.

Imaging begins with contrast enhanced CT scan of the sinuses. MRI imaging is the best modality for excluding intracranial pathology and for determining the extent of intracranial involvement and is usually performed when the CT scan identifies or suggests the presence of intracranial infection.

Microbiology

Causative organisms include *S. species, especially S. viridans group and S. aureus* (12,17). These infections are commonly polymicrobial and can include anaerobes and gram-negative rods.

Treatment

Treatment consists of IV antibiotics and drainage of the abscess with removal of infected bone. Surgery should be followed by 6 weeks or more of IV antibiotic treatment (12,17). Definitive endoscopic treatment of the frontal sinuses, frontal sinus obliteration, and reconstructive procedures may then be performed as indicated.

PREVENTION OF COMPLICATIONS OF SINUSITIS

The seriousness of sinogenic complications and the occasionally devastating outcome might cause patients and practitioners alike to question whether or not these

infections could be prevented by early and appropriate use of antibiotics for acute rhinosinusitis. In contrast, high rates of antibiotic use, particularly for upper airway infections that are often viral in nature, are contributing to the dramatic increases in antibiotic resistance seen nationally. In contemporary series, similar complication rates have been seen in patients with acute rhinosinusitis treated with and without prior antibiotics (26). Though the data is limited, early treatment of upper respiratory infections solely in an effort to decrease sinogenic complications is not supported by available clinical data.

Sinogenic intracranial abscesses occur, on average, in only three or four children per million children population (27). The rarity of this condition makes prospective clinical research impractical. An additional challenge to research on early or preventative treatment of acute rhinosinusitis is the fact that the majority of patients with intracranial complications do not have symptoms of sinsusitis at time of presentation.

The conclusions of the audit by the British Rhinological Society of complications of acute rhinosinusitis succinctly summarize the current state of clinical data at this time: "despite prior antibiotic treatment, complications of acute rhinosinusitis seem to occur sporadically… suggesting limited benefit of oral antibiotics in the Primary Care setting" (28). Treatment of complicated sinusitis thus relies on maintaining an index of suspicion for both complications in the setting of sinusitis and sinusitis in the setting of orbital and intracranial infections.

HIGHLIGHTS

- Diagnosing complications of sinusitis requires a high index of suspicion. Presenting symptoms are often not those of sinusitis but rather headache, fever, and/or eye swelling.
- Multiple complications of sinusitis are common, especially in cases of severe orbital or intracranial complications.
- CT scan with contrast of the sinuses and orbits is the study of choice to evaluate orbital complications, whereas MRI with contrast of the brain and orbits is the study of choice for intracranial complications.
- The causative organisms in complicated sinusitis do not always reflect the microbiology of uncomplicated sinusitis.
- Orbital complications are most often caused by *S. viridans* group (including *S. milleri* group). These organisms are facultatively anaerobic or microaerophillic. *S. aureus* and other *S. species* are also common causes of these infections.
- Intracranial complications are often polymicrobial; as in orbital complications, the most common causative organisms in intracranial complications of sinusitis are *S. viridans* group organisms. Other *S. species*, *S. aureus*, and anaerobes are also common causes of these infections.
- All patients with complications of sinusitis require medical management of the underlying sinusitis including appropriate broad-spectrum IV antibiotics.
- Treatment of preseptal cellulitis and orbital cellulitis is primarily medical and rarely require surgical treatment.
- In addition to medical treatment, surgical drainage of subperiosteal and orbital abscesses is usually required although patients with small, medial subperiosteal abscesses without ophthalmologic findings may often be exclusively medically managed.
- An orbital abscess is associated with severe exophthalmos, chemosis, complete ophthalmoplegia, and visual impairment.
- Cavernous sinus thrombosis can progress to bilateral orbital pain, chemosis, proptosis, and ophthalmoplegia. Aggressive medical treatment is needed. Sinus drainage for aeration and cultures may be beneficial.
- Intracranial abscesses can be epidural, subdural, and intracerebral. Multiple abscesses in a patient with complicated sinusitis are common.
- Epidural and subdural spaces are the most common abscess sites. Epidural abscess is associated with a more favorable outcome. Subdural abscesses are especially associated with high mortality and neurologic and developmental sequelae.
- Management of intracranial abscess is usually a combination of medical and surgical treatments.

39 Medical Management of Chronic Sinusitis

Jeffrey D. Suh *Alexander G. Chiu*

Chronic rhinosinusitis (CRS) is one of the more prevalent chronic illnesses in the United States, affecting at least 14% of the adult U.S. population (1). According to recent 2007 data from the National Health Interview Survey, rhinosinusitis continues to be one of the top 10 leading diagnoses of office visits in the United States. It has been estimated that over $5.8 billion dollars is spent each year treating patients with sinus complaints, and that one in every five antibiotics prescribed are for patients with sinusitis (2). The socioeconomic impact of rhinosinusitis is even greater when indirect costs from decreased work productivity and missed work days are considered. CRS not only causes symptoms directly related to the nasal cavity and sinuses, but also has a substantial negative health impact on quality of life with respect to mood, bodily pain, energy level, physical functioning, and social functioning (3,4). Medically recalcitrant CRS can be even more debilitating than other serious medical conditions such as angina, congestive heart failure, chronic obstructive pulmonary disease, and chronic back pain, or sciatica (3).

Despite its prevalence and importance, the etiology and pathophysiology of CRS is poorly understood. CRS was believed at one time to arise, somewhat simply, from sinus ostium obstruction leading to mucus stasis and subsequent bacterial infection. CRS is now thought to arise from persistent inflammation of the sinonasal mucosa, and perhaps the underlying bone, due to a number of factors. Perhaps the most appropriate broad classification of predisposing factors for CRS is grouping into environmental factors (e.g., pollution, allergens, viruses, bacteria, and molds), general host factors (genetic, granulomatous disorders, immune deficiency, cystic fibrosis, and ciliary defects), and local host factors (chronic localized inflammation, anatomic obstruction, polyps, and tumors) (5). It is clear that CRS is not one disease, but rather is a spectrum of symptoms and signs that can arise from multiple different etiologies.

Although multifactorial in origin, CRS is characterized by a consistent set of symptoms and clinical signs. Persistent mucosal inflammation and thickened mucus often leads to symptoms of postnasal drainage, nasal congestion, decreased sense of smell, and/or facial pressure. Given the consistency of these symptoms, initial medical management of CRS is focused on treating mucosal inflammation and purulent mucus. Those that fail this medical therapy are often recommended to consider sinus surgery. But with a 5% to 10% failure rate from surgery (4), there is an additional subset of patients who are recalcitrant to conventional medical and surgical therapies, leading to alternative therapies centered on anti-infective and anti-inflammatory nasal irrigations.

DEFINITION AND DIAGNOSIS

Clinicians treating CRS must be familiar with the criteria used to make the diagnosis. CRS is defined as persistent symptomatic inflammation of the nasal and sinus mucosa lasting for more than 12 weeks. The diagnosis of CRS is based primarily on medical history and is supported secondarily by confirmatory physical findings. In 2007, an updated clinical practice guideline by the American Academy of Otolaryngology—Head and Neck Surgery was developed by a multidisciplinary expert panel based on evidence from the literature (6) (Table 39.1). Briefly, the diagnosis of CRS requires that inflammation be documented on physical examination, in addition to persistent symptoms that usually include at least two of the following: nasal obstruction, facial congestion/pressure/fullness, discolored nasal discharge, and hyposmia.

STAGING SYSTEMS

A variety of staging systems have been used to stratify patients with CRS according to objective radiologic and endoscopic findings. Familiarity with these staging systems can allow the otolaryngologist to better document changes

TABLE 39.1 CLINICAL PRACTICE GUIDELINES, ADULT SINUSITIS (2007)

Diagnosis of CRS: ≥12 wk duration with
Two or more of the following symptoms
- Mucopurulent drainage
- Nasal Obstruction
- Facial pain/pressure/fullness
- Decreased sense of smell

And

Inflammation documented by ≥1 of the following objective criteria
- Purulent mucus or edema in the middle meatus or ethmoid region
- NP in the nasal cavity or middle meatus
- Radiographic imaging showing inflammation of the paranasal sinuses

in physical examination. Two commonly used staging systems found in the literature are described briefly in this section. These staging systems can be helpful to document exam changes following initiation of medical or surgical therapies.

Lund-Mackay Staging

The Lund-Mackay staging system is widely used in the radiologic assessment of CRS (7). The scoring system is based on computed tomography (CT) scan findings that are often obtained after an adequate trial of medical treatment. Each sinus is evaluated on cross-sectional imaging and noted to be completely clear, partly opaque, or completely opaque and assigned a simple numeric score (Table 39.2). The sinus groups include the maxillary, frontal, sphenoid, anterior ethmoid, and posterior ethmoid sinuses. The ostiomeatal complex is also scored. A total score of 0 to 24 is possible, and each side can be considered separately (0 to 12).

TABLE 39.2 LUND-MACKAY STAGING SYSTEM

Sinus System	Left	Right
Maxillary		
Anterior ethmoid		
Posterior ethmoid		
Sphenoid		
Frontal		
Ostiomeatal complex		
Total points for each side		

Scoring: For all sinus systems, except the ostiomeatal complex: 0, no abnormalities; 1, partial opacification; 2, total opacification. For the ostiomeatal complex: 0, not occluded; 2, occluded.
Adapted from Lund VJ, Mackay IS. Staging in rhinosinusitis. *Rhinology* 1993;31(4):183–184.

Lund-Kennedy Endoscopic Scores

In this staging system, the endoscopic appearance of the nose is examined for the presence of polyps (0, none; 1, confined to middle meatus; 2, beyond middle meatus), discharge (0, none; 1, clear and thin; 2, thick and purulent), and edema, scarring or adhesions, and crusting (for each: 0, absent; 1, mild; 2, severe) (8,9,9a).

MEDICAL MANAGEMENT OF CHRONIC RHINOSINUSITIS

The treatment of CRS is based on a number of factors including the type of rhinosinusitis (acute, chronic, or fungal), concurrent medical comorbidities, symptom severity, and response to previous medical treatments (10). In general, the treatment of CRS is intended to reduce symptoms, improve quality of life, and prevent disease progression or recurrence. More specifically, treatments are aimed at reducing mucosal inflammation, controlling infection, and restoring mucociliary clearance. Medical treatment should be considered the cornerstone of disease treatment for CRS, with sinus surgery reserved for medical failures or for patients with complications.

GENERAL TREATMENT STRATEGIES

CRS has recently been simplified to two subgroups; CRS *with* nasal polyps (NP) and CRS *without* NP (9). In the past, these two entities were considered to be a spectrum of a single disease, with NP being considered the end point of the evolution of CRS. Current data suggest that there are distinct differences between patients in the subgroups, and that the groups can have different responses to medical treatment (9,11). This chapter discusses the most common treatment modalities used to treat CRS, and focus on specific recommendations based on the CRS subgroup (CRS with or without polyps) when possible.

STEROIDS

Corticosteroids constitute first-line therapy in the medical management of CRS. Glucocorticoids have wide-ranging effects on the nasal mucosa. Studies of glucocorticoids show that they can suppress many phases of the inflammatory process by inhibiting the release of vasoactive mediators, reducing vasodilation, fluid extravasation, edema, and local deposition of mediators (12). Glucocorticoid-treated NP have demonstrated a down-regulation of proinflammatory cytokines and adhesion molecules that attract and activate eosinophils (13,13a). Studies of asthma and allergic rhinitis (AR) show that glucocorticoids decrease a wide variety of proinflammatory cytokines, chemokines, adhesion molecules, and mediator-synthesizing enzymes such as inducible nitric oxide synthase, cyclooxygenase-2,

and phospholipase-A2 (13,13a,14). Both topical and oral corticosteroids are used frequently for CRS and are discussed in the following two sections.

Topical Steroids

A number of studies have demonstrated the efficacy of intranasal steroids in the management of CRS with NP. These sprays are used most commonly in the management of symptoms associated with seasonal and perennial AR (15). Nasal corticosteroids have been shown to inhibit both immediate- and late-phase reactions to antigenic stimulation in patients with AR (16). In general, nasal steroids with low systemic bioavailability (such as mometasone furoate, fluticasone propionate, or furoate) have not been associated with bone growth or adrenal suppression, which was first noted with more systemically bioavailable agents such as beclomethasone dipropionate (17). There is also no clear evidence that the use of nasal corticosteroids correlates with systemic changes in bone mineral biology, cataracts, or glaucoma. Adverse effects such as nasal irritation, epistaxis, and crusting with nasal steroids are rare, occurring in less than 10% of patients (18). *Rarely, septal perforations have been reported with nasal steroid spray usage. Therefore, to minimize epistaxis and possible perforation, patients are frequently instructed to direct the nasal spray toward the internal lateral aspect of the nasal cavity and not toward the nasal septum.*

Topical steroids are routinely used to treat CRS with eosinophilic inflammation or NP. Guidelines from the 2007 European Position Paper on Rhinosinusitis and Nasal Polyps (19) recommends topical steroids as the first-line medication based on the results of several randomized controlled trials with fluticasone propionate, beclomethasone dipropionate, budesonide or mometasone furoate. Studies have demonstrated that topical corticosteroids are beneficial in the treatment of small to medium-sized polyps, nasal symptoms, and that this effect can be maintained with continued use (20–24). Corticosteroid nasal sprays have also been shown to delay the recurrence of polyps after surgery (24,25). There has also been some recent literature describing the use of budesonide respules (Pulmicort; AstraZeneca, Wilmington, DE) as an adjuvant method of treating eosinophilic or polypoid CRS when the respules are directly applied as a nasal drop or as an additive to nasal irrigation (26,27). In theory, a much higher concentration of corticosteroids can be applied to the sinus mucosa with budesonide respules compared to conventional nasal steroid sprays.

Despite proven efficacy of intranasal steroids for CRS with NP, benefit for nonpolypoid CRS has been harder to demonstrate (28–31). A randomized, double-blind, placebo-controlled study on patients with CRS without NP found no significant improvement on endoscopy and symptoms scores with fluticasone propionate for 16 weeks (32). More research is required to support the use of intranasal steroids for CRS without NP.

Systemic Steroids

Oral corticosteroids are commonly used in the treatment of CRS with and without NP for recalcitrant cases or when a rapid, short-term improvement is needed (33,34). However, despite widespread use among both general otolaryngologists and rhinologists, there is a lack of strong evidence with respect to indication, dose and duration (35,36). In 2007, a Cochrane review found only one randomized, controlled trial (37) on oral steroid therapy for CRS with NP (33). The results of this study and others have shown that oral steroids can dramatically reduce polyp size in patients with CRS, reduce nasal obstruction, improve quality of life scores, and decrease inflammatory chemokines and cytokines (37–40). But without other adjuvant treatments, these benefits are usually short-lived (40). Recent evidence suggests that combination therapy with oral and intranasal corticosteroids can provide long-term reduction in polyp size and improvements in quality of life without significant adverse effects (41).

The most common side effects of oral steroid use include glucose intolerance, hypertension, gastrointestinal bleeding, and altered mood. Adverse effects associated with long-term use of oral steroids include weight gain, glaucoma, cataracts, gastrointestinal complications, adrenal suppression, growth suppression, diabetes mellitus, osteoporosis, and avascular necrosis (most commonly of the hip) (33). These risks must be carefully considered, and patients must be counseled about these side effects prior to initiating long-term therapy.

ANTIBIOTICS

Antibiotics are commonly used in the management of CRS to decrease bacterial load and to treat acute bacterial exacerbations of CRS. There are significant differences in the bacteria present in CRS as compared to acute rhinosinusitis. Antibiotic therapy for CRS has traditionally been aimed at a mixed population of aerobic and anaerobic bacteria. However, despite level 1A evidence of the efficacy of topical steroids in treating rhinosinusitis, no such evidence of antibiotic efficacy in CRS exists and no antibiotic is U.S. Food and Drug Administration (FDA)-approved for the indication of treating CRS. Commonly used agents include amoxicillin-clavulanate, clindamycin, trimethoprim-sulfamethoxazole, or a fluoroquinolone. The optimal duration of therapy has not been studied prospectively, but is typically 3 to 4 weeks long, with longer courses for recalcitrant cases. When treating CRS with antibiotics, it is important that other modalities, such as nasal irrigation and topical or oral corticosteroids, also be included.

The species of bacteria and the incidence of antibiotic resistance vary widely depending on a variety of factors including the chronicity of the disease and the extent of prior antibiotic

therapy. The microbiology of CRS differs from that of acute rhinosinusitis, with a greater incidence of anaerobic bacteria, *Staphylococcus aureus, and Pseudomonas aeruginosa*, all which must be considered before recommending antibiotics. In a study by Finegold et al. (42) the most common anaerobic bacteria in chronic maxillary sinusitis were *Prevotella* species, anaerobic streptococci, and *Fusobacterium* species. The most common aerobic bacteria were *Streptococcus* species, *Haemophilus* species, *P. aeruginosa*, *S. aureus*, and *Moraxella catarrhalis*. The microbiology of chronic frontal sinusitis is slightly different, with 21% *S. aureus*, 21% coagulase-negative staphylococci, 9% *Haemophilus influenzae*, and 26% multiple organisms in one study (43). Anaerobes were present in 3% and fungi in 4%, and there was no growth in 38%. The bacteriology of odontogenic infections tends to mirror that of oral flora. The microbiology of acute exacerbations of CRS is more similar to the microbiology of acute bacterial sinusitis than CRS (44).

When possible, antibiotics for recalcitrant infections should be started after cultures have been obtained and be based on sensitivities. The results of antimicrobial susceptibilities and bacterial presence changed the therapy of almost 50% of patients in a retrospective, consecutive series of patients with CRS or acute exacerbations of CRS (44). If this is not possible, several factors must be considered prior to selecting empiric antimicrobial therapy. The 2004 Guidelines from the Sinus and Allergy Partnership (45) recommend a fluoroquinolone or high-dose amoxicillin-clavulanate for patients who have received antibiotics within the past 4 to 6 weeks, as recent use of prior antibiotics is a risk factor the presence of antibiotic-resistant bacteria. In cases of penicillin allergy, one alternative would be clindamycin and Bactrim (trimethoprim-sulfamethoxazole) as the combination provides strong anaerobic and aerobic coverage. Antimicrobial susceptibility rates vary geographically and by anatomic location. Local hospital antibiograms may be helpful in guiding empiric antimicrobial choices.

Recent investigations have confirmed the presence of biofilms on the mucosa of patients with CRS (46). Bacterial biofilms are highly organized structures composed of communities of bacteria encased within a protective extracellular matrix. Biofilms are notoriously difficult to eradicate, and might explain the high incidence of symptom relapse in some patient with CRS. *P. aeruginosa*, *H. influenzae*, and *S. aureus* are the most common biofilm-forming bacteria seen in sinus infections. Interestingly, persistent symptoms after functional endoscopic sinus surgery and surgical failures have been recently been attributed to the presence of biofilms (47,48). The most common treatments for biofilm-associated sinusitis include topical antibiotics, surgery, mechanical debridement, and surfactants (46,49).

Antifungal therapy for CRS is still controversial at this time. Recent double-blind, placebo-controlled trials have not shown substantial improvement of CRS based on objective and subjective criteria after treatment with amphotericin B (50,51). Another placebo-controlled trial by Kennedy et al. (52) found no improvement with the antifungal terbinafine on symptoms or radiographing findings in patients with CRS. The preceding topical antifungal and oral antifungal studies were not restricted to patients with fungus present on culture or histopathologically. Seiberling and Wormald (53) showed in a retrospective case series, restricted to patients with refractory allergic or nonallergic sinusitis associated with fungus histopathologically that oral itraconazole improved symptoms and endoscopic examination. Better designed studies targeting patients with evidence of fungus histopathologically are required to fully answer the question of the role of antifungals in a subset of patients with CRS associated with fungus.

TREATMENT OF SINONASAL MRSA

The prevalence of methicillin-resistant staphylococcus aureus (MRSA) positive cultures in CRS is increasing (54–56). Prior ESS may be associated with an increased risk of MRSA presence (57,58). However, because there is a high incidence of nasal colonization, the presence of a positive culture does not necessarily require treatment in the absence of symptoms or purulence on endoscopy or anterior rhinoscopy. A sudden worsening of symptoms from baseline and purulence on physical examination implies an acute exacerbation of CRS, which should be treated. These patients are managed by microbiologic culture, determination of antibiotic sensitivities, and appropriate therapy.

Treatment options for MRSA sinonasal infections include oral antibiotics, intravenous antibiotics, and more recently, topical antibiotics (58–60). Outpatient treatment of MRSA sinusitis should be based on sensitivities and until there is a clinical resolution of symptoms and endoscopic findings. Oral antibiotics available to treat MRSA infections include clindamycin, trimethoprim-sulfamethoxazole, tetracyclines (tetracycline, doxycycline, and minocycline), rifampin, and linezolid (60). Rifampin should not be used in monotherapy due to rapid development of resistance (60). In some cases, intravenous antibiotics are required for MRSA sinusitis. One report of a 6 to 8 week course of intravenous (IV) antibiotics for six patients with MRSA sinusitis showed resolution of MRSA on follow-up cultures in 83% of patients, as well as similar improvements in sinus-related quality of life measures (61). However, side effects with IV antibiotics are not insignificant, and require close monitoring to avoid potentially serious morbidity.

Topical antibiotics have also been used to treat MRSA sinus infections. Antibiotic irrigation and nebulized antibiotics have the theoretical advantage of high local levels of drug with minimal systemic absorption, lower costs, and decreased morbidity compared to long-term parenteral therapy (62). Mupirocin nasal irrigation has been used successfully for exacerbations of CRS due to MRSA (63). Vaughan and Carvalho (64) evaluated the use of nebulized antibiotics for acute exacerbations of CRS in patients

who otherwise would have required IV antibiotics. They found that nebulized antibiotics were safe, with few side effects, and a high level (76%) of bacterial eradication, but found changes in the bacterial flora in some of the study patients after treatment. In general, patients who have had sinus surgery are better candidates for topical therapy for sinusitis, since prior sinus surgery enlarges openings into the sinuses permitting improved distribution to the sinus mucosa. However, data suggest that topical therapies are effective for both surgical and nonsurgical patients with rhinosinusitis. For the antibacterial studies, the highest level of evidence currently exists for studies with post-surgical patients and culture-directed therapy. However, despite the increasing use of topical antibiotics for CRS, there is currently only low-level evidence (level III) supporting its use (62).

Saline Irrigation

Saline nasal irrigation has been recommended in the most recent clinical guidelines published in 2007 for CRS and a Cochrane review (6,65). Saline irrigation mechanically removes mucus, crusts, debris, and allergens from the sinonasal cavity, and potentially has the additional benefit of improving mucociliary clearance, ciliary beat frequency, and protecting the sinonasal mucosa (65). Large volume, low-pressure nasal irrigation is more effective than saline sprays or nebulizers in penetrating the sinus ostia (66,67). In eight randomized trials, nasal saline irrigation for CRS improved symptoms, quality of life, endoscopic findings, and was well tolerated and without significant harmful side effects (65).

Saline irrigation may prevent rhinosinusitis. In a randomized trial, daily hypertonic saline nasal irrigation improved disease-specific quality of life after 6 months (68). With 87% adherence to therapy, side effects in this study were minimal and included: nasal irritation, epistaxis, nasal burning, tearing, and headaches. In a follow-up study, a subset of patients reported reduced sinus symptoms and sinusitis-related medication use for an additional 12 months (69). Other recent data suggest that Dead Sea Salt hypertonic saline irrigation may be more beneficial than standard hypertonic saline irrigation for CRS symptoms (70). Studies on the effects of hypertonic saline irrigation on cilia and mucociliary clearance are conflicting. *In vivo* data suggest that hypertonic solutions may improve mucociliary clearance more than isotonic saline (71), however, there are some *in vitro* data suggesting that hypertonic may cause a temporary decrease in ciliary beat frequency (72,73).

Clinicians should work with patients to develop strategies that facilitate incorporating saline nasal irrigations as part of routine sinus care. It is also important to emphasize that rinse bottles be cleaned at least once a week, as there is evidence that irrigation may increase the frequency of gram-negative organisms on culture (74).

OTHER THERAPIES

Irrigation, antibiotics, and anti-inflammatories make up the majority of CRS treatment. This section discusses other classes of drugs or therapies that can either provide additional symptom relief in select patients, or represent promising novel therapies under investigation.

Antihistamines

Antihistamines are commonly prescribed medications for patients with AR. There is a lack of evidence that antihistamines are effective in the treatment of CRS, but these drugs have been used for patients with concurrent allergies. First generation antihistamines, including diphenhydramine, can cause sedation, dry mouth, urinary retention, and potentially drying of nasal and sinus secretions. These side effects are far less common or absent in newer second generation antihistamines.

Some common antihistamines are listed in Table 39.3. Unlike oral antihistamines, nasal antihistamines are not only effective for rhinorrhea, sneezing, and itchy nose, but are also effective for nasal congestion. Combination of an antihistamine nasal spray with a nasal steroid spray may significantly increase symptom control in AR, compared to either spray used alone (75).

Decongestants

Oral and nasal decongestants are used for rhinorrhea and nasal congestion, but side effects prohibit prolonged use (76). Pseudoephedrine is available behind the counter. Phenylephrine is only a weak decongestant, while phenylpropanolamine was removed from the market because of an association with stroke in young women. Common side effects can include anxiety, insomnia, irritability, headache, palpitations, hypertension, and decreased urinary flow. Contraindications include patients with cardiac disease such as coronary artery disease, and concurrent use of monoamine oxidase inhibitors (MAO)-inhibitors. Prolonged and repeated use of nasal decongestant sprays often results in rhinitis medicamentosa, or severe rebound congestion, after drug withdrawal.

TABLE 39.3 COMMON ANTIHISTAMINES

First Generation	Second Generation
Brompheniramine (Dimetane)	Cetirizine (Zyrtec)
Chlorpheniramine (Chlor-Trimeton)	Desloratadine (Clarinex)
Clemastine (Tavist)	Fexofenadine (Allegra)
Diphenhydramine (Benadryl)	Loratadine (Claritin)
Hydroxyzine (Atarax)	
Promethazine (Phenergan)	

Anticholinergics

Ipratropium bromide (Atrovent) nasal spray is generally used two to four times per day to treat rhinorrhea due to allergic and vasomotor rhinitis (77,78). It is an anticholinergic (parasympatholytic) agent that acts by inhibiting vagally mediated reflexes by antagonizing the action of acetylcholine, thus decreasing secretions from the serous and seromucous glands lining the nasal mucosa. To increase the effectiveness in treating rhinorrhea, anticholinergic sprays can be combined with an intranasal steroid spray (77).

Leukotriene Inhibitors

Inhibitors or antagonists of leukotrienes are approved by the U. S. Food and Drug Administration for the treatment of allergy and asthma. Leukotrienes are inflammatory mediators that are produced by a number of cell types including mast cells, eosinophils, basophils, macrophages, and monocytes (79). Activation of specific receptors leads to a variety of biologic effects including contraction of human airway smooth muscle, chemotaxis, and increased vascular permeability. Leukotrienes as well as other arachidonic acid metabolites have been found in high levels in patients with asthma as well as from patients with NP. Studies have demonstrated that leukotriene inhibitors can reduce sinonasal symptoms and NP, especially in patients with Aspirin-exacerbated respiratory disease (79,80). There is also some evidence that leukotriene-receptor antagonists might be useful after ESS in patients with NP to limit polyp regrowth and improve nasal and pulmonary symptoms (81). At this time, more research is required to determine which subset of patients with CRS with NPs will benefit most from leukotriene inhibitors.

Immunotherapy

The association of AR and CRS is unclear, but because many of the symptoms of AR mimic symptoms of CRS, AR should be thoroughly evaluated and treated in patients with CRS.

Rhinitis is common, affecting up to 40% of children and between 10% and 30% of adults (77). Allergen avoidance is the mainstay of management for patients with AR, with antihistamines and topical nasal steroids for symptomatic relief (82). AR causes symptoms similar to those seen in CRS, such as nasal congestion and nasal drainage. Allergy may cause sinusitis by inducing mucus hypersecretion and obstruction of the ostiomeatal complex by mucosal edema.

Subcutaneous immunotherapy (SCIT) is effective for perennial and seasonal AR. SCIT improves symptoms, reduces medication required, and prevents development of new allergies and asthma in children. These effects can persist for at least 3 years after discontinuation of treatment. The mechanism of SCIT is not completely understood but is associated with the generation of allergen-specific T regulatory cells, which are known to be capable of suppressing allergen-induced proliferation and cytokine response. In addition, antibody class switching of B cells from allergen-specific IgE to allergen-specific IgG4 occurs and these allergen-specific IgG4 antibodies may inhibit binding between allergen and IgE on mast cells and basophils (83). A Cochrane review concluded that SCIT is a safe and valid treatment for AR (84).

Sublingual immunotherapy (SLIT) has emerged as a promising alternative to injection immunotherapy (85,86). Although highly effective, SCIT commonly causes pain and swelling at the injection site with a rare risk of severe systemic and life-threatening reactions. A recent review found support for SLIT in children and for use in AR due to seasonal allergens and dust mites (85). However, more study is necessary to optimize allergen dosages, treatment duration, and improve criteria for patient selection.

Macrolide Antibiotics

The only antibiotic to show efficacy in a blinded placebo-controlled trial in CRS was long-term macrolide therapy (86). In Japan, a reduced mortality rate from diffuse panbronchiolitis with long-term, low-dose macrolide therapy, prompted investigation of macrolides for a variety of chronic inflammatory diseases, including cystic fibrosis and CRS, with promising results (87,88). The effectiveness of this therapy is attributed to the drug's anti-inflammatory and immunomodulatory effects, rather than direct antibacterial effects, although macrolides do decrease biofilm formation in certain bacterial species, such as pseudomonas (89,90).

Macrolides inhibit inflammatory mediators such as interleukin (IL)-1B, IL-8, and intercellular adhesion molecule-1 (90). Other effects include protecting bioactive phospholipids, accelerating apoptosis of neutrophils, and increasing mucociliary transport (91). Macrolides decrease airway mucus secretion, and even have a reparative effect on inflamed airway mucosa (92). Wallwork et al. (93) noted statistically significant improvements in the Sinonasal Outcome Test (SNOT)-20 scores, nasal endoscopy exams, saccharine transit times, and IL-8 levels in lavage fluid in patients on long-term macrolide therapy compared to placebo. After 3 months of erythromycin or clarithromycin in patients with CRS with NPNP, IL8 levels in nasal lavage decreased significantly, corresponding with a decrease in the nasal polyp size (94). Low-dose macrolide therapy is worthy of further study in patients with CRS and low or normal IgE levels refractory to other therapies (92).

Mucolytics

Guaifenesin is a mucolytic used to loosen respiratory secretions. Despite widespread use, there is a paucity of evidence for mucolytic use in the treatment of CRS (34). Rosen and Calhoun (95) found no change in mucociliary transport time in human immunodeficiency virus (HIV)+ patients treated with guaifenesin, but did show improvements

in rhinosinusitis symptoms. In a double-blind study involving HIV+ patients, Wawrose et al. (96) reported less nasal congestion and thinner postnasal drainage at doses of 2,400 mg/day at 3 weeks. Nausea was the major reported side effect in doses greater than 1,200 mg/day.

Surfactants

A small prospective uncontrolled, unblinded study of 18 patients treated with twice daily sinus irrigations with 1% baby shampoo in saline for 4 weeks, resulted in subjective improvement in SNOT 22 scores in slightly less than half of these heavily pretreated symptomatic and refractory CRS patients (97). Baby shampoo is thought to act as a surfactant with the ability to thin mucus, disrupt microbial cell membranes, and potentially break up biofilms. The same group recently demonstrated that irrigation with the surfactant solution in buffered saline resulted in a transient increase in ciliary beat frequency *in vitro*, with no evidence of toxicity to the cilia (98). Prospective, blinded, and controlled studies are required to fully evaluate the role of baby shampoo or other surfactants in the treatment of CRS.

SUMMARY

Best evidence suggests that the treatment of CRS comprises a combination of anti-inflammatory, mechanical, and anti-infective therapy. For CRS *with* NP, long-term use of intranasal steroids and saline irrigation is recommended. Short-term, systemic corticosteroids can be used for relief of severe sinonasal symptoms, or for temporary relief of symptoms due to NP. Saline nasal irrigation is safe and effective for managing symptoms associated for CRS with and without NP, and may reduce exacerbations when used regularly. Antibiotics should be utilized in CRS in situations of acute worsening of symptoms associated with purulence. If possible, cultures should be obtained prior to antibiotic initiation, in order to guide subsequent therapy. Low-dose macrolides, leukotriene antagonists, topical antibiotics, and immunotherapy can be considered in select patients.

CONCLUSION

CRS is a common disease that can have a substantial impact on quality of life. Advances in medical therapy have reduced the morbidity associated with CRS, and can provide long-term benefit when effectively combined. The principles involved in treating of CRS include identifying and treating the underlying cause of inflammation. Treatment goals include the reduction of mucosal edema, restoration of paranasal sinus ventilation, and eradication of infectious pathogens. A better understanding of the pathogenesis of CRS will undoubtedly lead to new and novel therapies in the future.

HIGHLIGHTS

- CRS is a common disease that has a substantial negative impact on quality of life.
- CRS treatments are aimed at reducing sinonasal inflammation, symptoms, and re-establishing mucociliary clearance.
- Topical nasal steroids are first-line therapy in the treatment of CRS with NP and AR. Effectiveness of and type of medical management can differ between CRS *with* NP and CRS *without* NP.
- In general, antibiotics should be not be used alone to treat CRS. Rather, antibiotics should be used when there are signs of infection, and as part of a comprehensive treatment regimen in combination with anti-inflammatory medication and sinus irrigation.
- When possible, endoscopically guided cultures should be performed to direct antibiotic therapy in CRS with purulence.
- Sinus surgery should be reserved for patients that fail appropriate medical therapy.

Endoscopic Sinus Surgery for Chronic Rhinosinusitis

40

Barry M. Schaitkin *Kenneth D. Rodriguez*

It is imperative that the chapter on medical treatment of sinusitis be read prior to reading this one, as patients deemed surgical candidates for endoscopic sinus surgery (ESS), must be symptomatic with evidence of chronic rhinosinusitis (CRS) despite a trial of medical therapy. Diagnosis of sinus disorders and proper medical therapy are not reiterated in this chapter. Frontal sinus surgery is covered in chapter 46 and a general review of complications of ESS is covered in chapter 44, and these topics are not covered in this chapter. This chapter highlights the surgical philosophy of the authors, surgical technique, surgical landmarks, pearls, and the avoidance of complications. Instrumentation for endoscopic sinus includes a wide variety of nonpowered and powered tools that are rapidly evolving. Residency training allows for use of a multitude of different instruments and techniques and after residency training, continued attendance at sinus conferences allows for further acquisition of skills and familiarity with the latest technologic trends. As a general rule in ESS, mucociliary transport pathways must be maintained and mucosal preservation of normal tissue is crucial.

PREPARATION FOR SURGERY

1. A history and physical exam including a detailed nasal endoscopy after maximal nasal decongestion is essential. Significant septal deviations that may require septoplasty to allow for complete visualization of the paranasal sinuses are noted on exam and the patient should be informed of the possible need for surgical correction of the septum at the time of sinus surgery.
2. Imaging—Noncontrast thin cut sinus computed tomography (CT) with both coronal and sagittal reconstructions is the first line and gold standard for preoperative evaluation for inflammatory sinus disease surgery. The CT should be obtained if the patient is symptomatic, despite a 4 to 6 week trial of maximal or directed medical therapy, in order to determine irreversible bony and mucosal anatomic obstructions and disease, which may be amenable to surgical correction. Review of the sinus CT should be performed at least three times, once with the patient during preoperative planning, once, the night before surgery, and finally, immediately prior to surgical intervention.
3. The senior author of this chapter advocates a two-handed (person) technique for performing ESS (1). This technique allows for the surgeon to use two instruments with the benefit of endoscopic visualization. The assistant, holding the camera, can use a 60-mL syringe with a blunt 18-gauge needle to clear debris from the camera to reduce the time needed for cleaning outside of the nasal cavity. Alternatives include the use of scope scrubbers and self-irrigating powered instruments.

The patient should be treated with a vasoconstrictive intranasal spray, such as 0.5% oxymetazoline in the preoperative holding area at least 30 minutes prior to the start of the procedure. Upon induction of general anesthesia, pledgets, soaked with the same agent used preoperatively, are placed into the nasal cavity on each side of the intended surgery. One pledget is placed on the floor of the nose and another as superiorly as possible, lateral to the middle turbinate. The patient is then sterilely draped with the eyes visualized within the field and treated with lubricant, but untaped so that they are easily examined and palpated. The pledgets are removed from one side and the nasal cavity is inspected. Local anesthesia with 1% lidocaine with 1:100,000 epinephrine is standardly injected in three locations on each side: above and lateral to the superior attachment of the middle turbinate, the inferior aspect of the uncinate, and the tail of the middle turbinate (Fig. 40.1).

To allow for maximum vasoconstrictive effects of the injected local with epinephrine one must allow 5 to 10 minutes prior to operative intervention. Thus after injecting one side, the pledgets are removed from the contralateral side and repeat injections are performed. Once injections are complete, one side of the nasal cavity can be repacked while operating on the contralateral side.

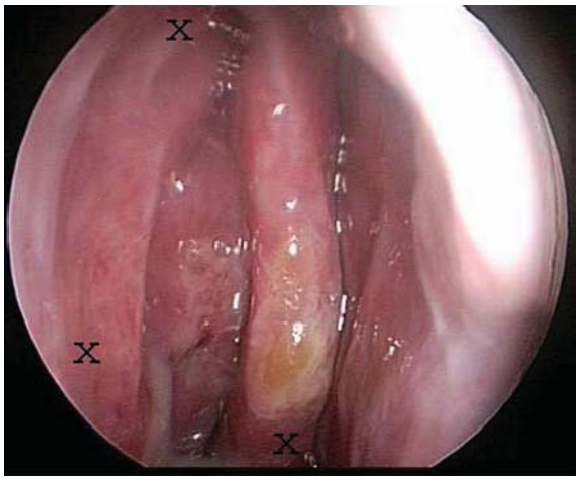

Figure 40.1 Standard three right nasal cavity injection sites.

MAXILLARY SINUS

Key anatomical landmarks:

- Middle turbinate
- Uncinate process
- Lacrimal duct
- Orbit

The first key structure to be identified is the middle turbinate. The middle turbinate should be gently medialized mindful that there is transmission of force to the lateral lamella of the cribriform plate. If a concha bullosa is present, it can be opened in a lateral to medial manner as outlined in the ethmoid sinus section. The middle turbinate can also be reduced in size if it is abnormally bulky or paradoxical in nature again proceeding from lateral to medial sparing as much mucosa as possible. This lateral shaving of the turbinate allows for the preservation of most middle turbinates without risking synechia formation. At all times care should be taken to minimize trauma to the nasal mucosa. The most common minor complication in several series is middle turbinate adhesions along with entry into the orbit (2,3).

Next, the posterior free margin of the uncinate process is identified and medialized with a ball probe, followed by retrograde dissection with the use of a pediatric back-biting forceps beginning approximately one-third of the way above the attachment of the uncinate to the inferior turbinate (Fig. 40.2). This can be efficiently performed by taking multiple bites moving forward as long as the movable tip of the instrument is able to wiggle the mobile uncinate anterior to its path. Moving the uncinate with the tip of the pediatric side biter prior to engaging and biting the bone, can prevent inadvertent nasal lacrimal duct injury, which was more prevalent with the historical technique of anterior to posterior uncinate dissection. The lacrimal duct can be as close as 4 mm anterior to the natural ostium of the maxillary sinus (4).

The uncinate is removed from the superior aspect of the surgically created window up to the level of the agger nasi with a microdebrider. The remaining portion of the inferior uncinate is composed of the medial nasal mucosa, residual uncinate bone, and the lateral mucosa adjacent to the maxillary sinus. The mucosa on the nasal side of the uncinate bone can be removed with the microdebrider and the residual uncinate bone can be dissected and elevated from the sinus side mucosa with a double ball probe. This bone can then be removed with the microdebrider or ethmoid forceps leaving the lateral mucosa in place, thus protecting the natural ostium and preventing the risk of ostium stenosis (Figs. 40.3 and 40.4).

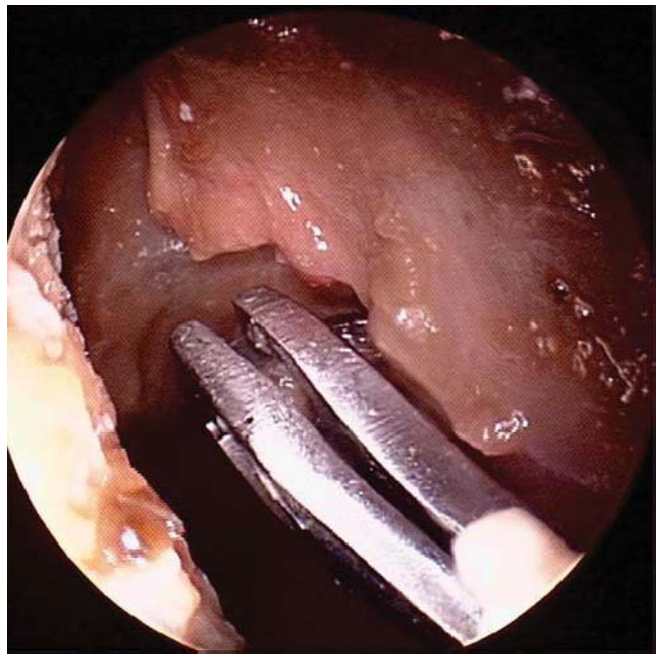

Figure 40.2 Left nasal cavity. Pediatric backbiter removing uncinate process creating the uncinate window.

Figure 40.3 Left nasal cavity. Natural os of maxillary sinus healed following ESS using the technique of the uncinate window. Notice that the natural ostium lies in a parasaggital plane.

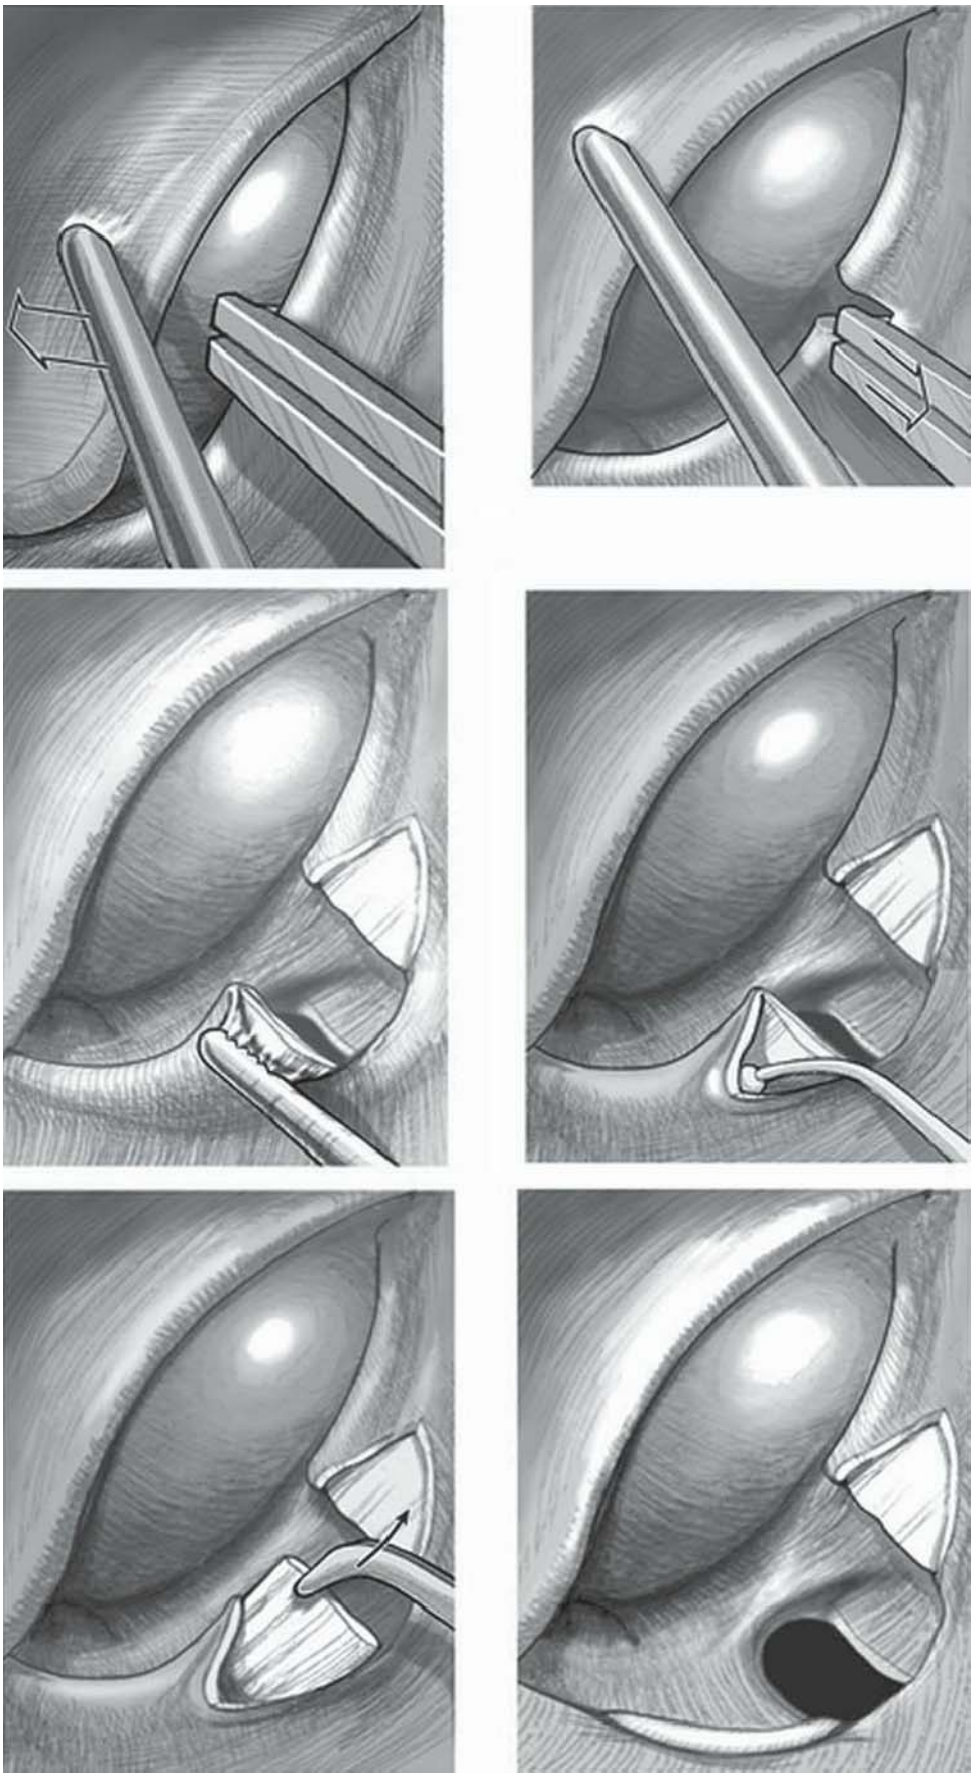

Figure 40.4 Minimally invasive maxillary technique.

Most primary cases do not require a formal antrostomy unless the patient has a mucosal disease process in addition to their chronic or recurrent acute sinus history (i.e., Kartageners, allergic fungal sinusitis, massive polyposis, Samter syndrome, cystic fibrosis, etc.).

Accessory ostia are not universally incorporated into the antrostomy unless they are in the drainage pathway of the sinus putting the patient at risk for recirculation. Haller cells can usually be left in place with just marsupialization into the ethmoid. The opening of the maxillary sinus as described will usually remove any impingement of the Haller cell on the outflow tract.

This procedure is based on the premise that preservation of the mucociliary clearance mechanism is to be maintained whenever possible. Maxillary pathology, such as an antrochoanal polyp will sometimes be accessed via a combination of a middle meatal antrostomy (combining the accessory ostia where the polyp exited to the natural ostia) with inferior meatal instrumentation to improve access and avoid a large antrostomy. This can be done with straight and curved microdebrider tips. It is the senior author's experience that excessive enlargement of the maxillary antrostomy is associated with the development of some of the most refractory cases of maxillary sinusitis, including those with biofilms, and in the senior author's experience, symptomatic biofilms are rare to nonexistent in those with a functioning ostia, normal gas tensions, and normal mucociliary action devoid of surgically introduced scar tissue.

ETHMOID SINUS

Key anatomical landmarks:

- Skull base
- Lamina papyracea
- Ethmoid bulla
- Middle and superior turbinates

Two key anatomic boundaries of the ethmoid air cells are the orbits laterally and the skull base superiorly. The most serious complications of sinus surgery are damage to the globe and cerebrospinal fluid (CSF) leak, and avoiding these complications requires complete understanding of these key anatomic boundaries. Pneumatization patterns of the ethmoid air cells are widely varied and number anywhere from 1 to 2 cells to more than 15 cells. Preoperative review of the patient's CT scan may reveal the presence of an Onodi, Haller, or suprabullar cells. The ethmoid air cells are divided into anterior and posterior at the basal lamella of the middle turbinate. The anterior ethmoid air cells drain into the middle meatus while the posterior air cells drain into the superior meatus. As one proceeds in an anterior to posterior direction, the skull base slopes inferiorly several millimeters, which can lead to entry into the skull base within the posterior ethmoid air cells (Fig. 40.5). As a technical point, while using the microdebrider during an ethmoidectomy, the device should at all times point superiorly, inferiorly, or medially and never laterally when working near the lamina to avoid inadvertent entry and injury to the orbital contents.

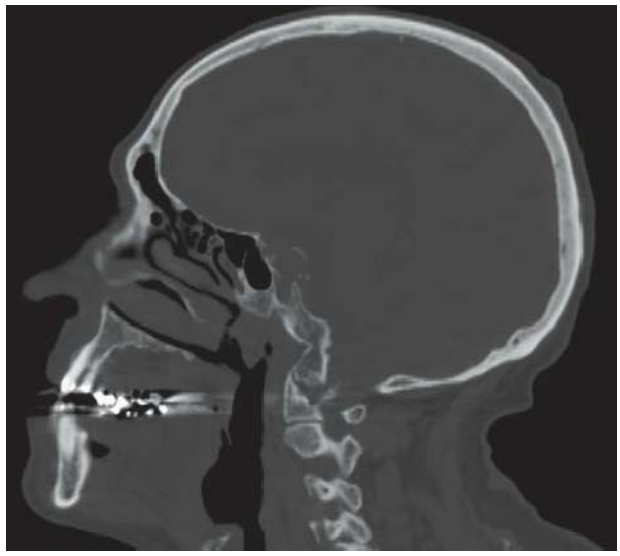

Figure 40.5 Sagittal cut of CT demonstrating the superior to inferior slope of the skull base.

ANTERIOR ETHMOIDECTOMY

A topical decongestant is administered approximately 30 minutes prior to general anesthesia and surgical intervention. The middle turbinate is injected with local anesthesia as described in the maxillary antrostomy section and then gently medialized to identify the ethmoid bulla, which varies from one to several connected cells located just posterior to the free edge of the uncinate. The bulla can be entered in a multitude of ways but the senior author prefers the microdebrider. The bullae are entered medially with the microdebrider inserted between the bulla and the middle turbinate directed laterally which decreases risk to the orbit. If care is taken, one can identify the drainage pathway of the bulla posteromedially into the semilunar hiatus superior, and this natural os should be incorporated into the opening of the bulla (Fig. 40.6).

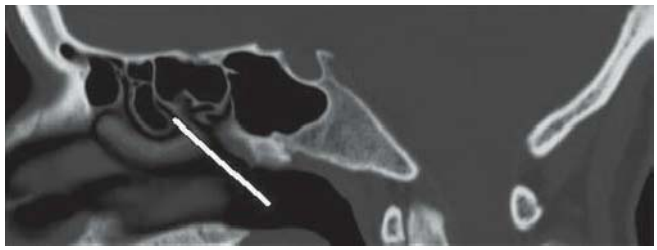

Figure 40.6 Sagittal cut of CT demonstrating drainage of ethmoid bulla between the bulla and the basal lamella in the semilunar hiatus superior (marked by *white line*).

Dissection is concluded at the lamina papyracea although the bulla does not have to be taken flush to this bony plate, it just needs to be opened and adequately drained. Posteriorly, the basal lamella remains intact after anterior ethmoid surgery.

CONCHA BULLOSA

The mere presence of a concha bullosa, or aerated middle turbinate, is not an indication for surgery. However, if an enlarged middle turbinate is causing airway obstruction and/or limited visualization of the surrounding sinuses for planned surgical intervention, it should be reduced at the time of surgery. Lidocaine with 1:100,000 epinephrine is injected into the middle turbinate as described in the maxillary antrostomy section. Multiple options exist for its reduction. The space anterior–lateral to the concha can be entered with the microdebrider and the lateral aspect of the turbinate reduced in a lateral to medial direction with sparing of the medial aspect of the turbinate to prevent scarring to the septum. Damage to the superior medial aspect of the turbinate in some cases can lead to olfactory impairment and this should be discussed with the patient during routine preoperative risk assessment if any middle turbinate surgery is planned. Alternatively, a sickle knife can be used to enter the airspace anteriorly in a vertical fashion. The incision can be extended posteriorly and the lateral aspect of the concha can be removed with a microdebrider or sharp cutting instruments. The concha is a sinus and as such is opened always to include the outflow tract of this intra nasal sinus to enable mucociliary clearance as is done with every sinus procedure.

POSTERIOR ETHMOIDECTOMY

Inspection of the CT scan preoperatively in all three orientations will provide crucial information about the number and orientation of the posterior ethmoid air cells, continuity of the lamina, and height of the skull base. The posterior ethmoid air cells are encountered by entering the basal lamella of the middle turbinate just superior to the point at which the middle turbinate transitions from horizontal to vertical. This can be identified by taking a 0-degree endoscope and passing it under the middle turbinate posteriorly and then withdrawing it anteriorly (Fig. 40.7). The basal lamella is then perforated at the medial and inferior aspect and the posterior ethmoid sinuses are entered. To maintain stability of the middle turbinate the inferior basal lamella should be preserved. Dissection of the basal lamella puts the surgeon into the superior meatus but not the posterior ethmoid air cells that require further dissection to enter. At this point, the resident surgeon is often unclear about their location in the dissection. It can at times be difficult to determine if one is looking at another layer of cells or the skull base. When one is unsure if they are facing another layer of cells or the skull base, one should never enter the next space by pushing through without certainty.

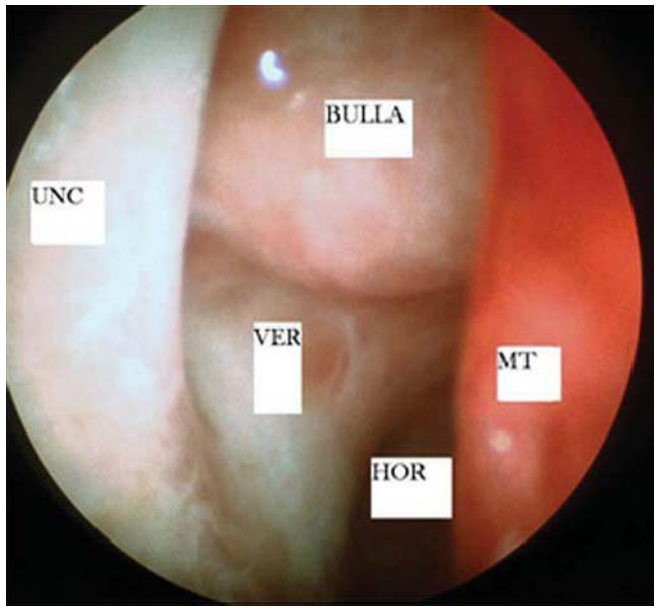

Figure 40.7 Left-sided endoscopic overview. UNC, uncinate; MT, middle turbinate; VERT, vertical basal lamella; HOR, horizontal basal lamella; BULLA, ethmoid bulla.

Possible ways to be certain one is in a posterior ethmoid cell and not at the skull base, include: finding a ledge and opening the posterior cell by pulling rather than pushing on the lamella with a ball probe or kerrison, entering the sphenoid and finding the roof there and coming back anteriorly, using computer navigation, or dropping inferiorly in the dissection and looking for a safe entry point away from the skull base. Dissection can be continued until the superior turbinate and superior meatus are clearly identified.

Identification of the face of the sphenoid and skull base can be facilitated by image guidance and aided by further air cell removal. At the conclusion of this procedure, one should be able to see the lamina papyracea laterally, the skull base superiorly, and the superior turbinate medially. As with all surgery, wide visualization will facilitate safe surgery. While leaving small bony septations anteriorly and at the skull base is acceptable, large overhangs force the surgeon to work in a narrow field and results in an inadequate and less safe ethmoidectomy predisposing the patient to complications.

SPHENOID SINUS

Key anatomical landmarks:

- Nasal septum
- Arch of the choana
- Superior turbinate
- Carotid artery
- Optic nerve

The approach to the sphenoid has been described as transseptal or transnasal. We focus on the latter approach in this text. In addition, pituitary surgery is increasingly being

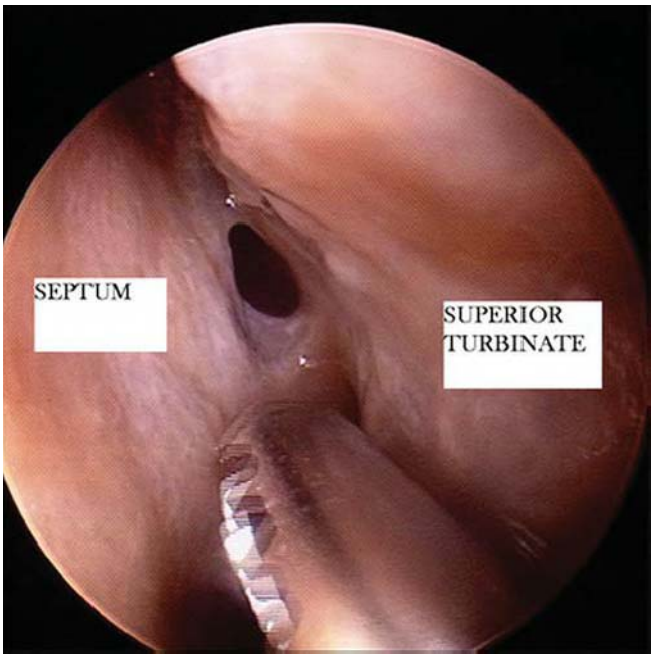

Figure 40.8 Natural os of the sphenoid sinus medial to the superior turbinate.

carried out via endoscopes through an endoscopic transsphenoidal approach. This technique is described in the skull base section of this text. Careful review of imaging should be performed prior to surgical intervention in this region with careful attention to the intimate relationship with the carotid artery and optic nerve in the lateral aspect of the sinus. The carotid artery is partially dehiscent in up to 25% of individuals and the optic nerve in 6% (5). The key anatomic landmark to identify the natural ostia of the sphenoid is the superior turbinate. The natural ostia of the sphenoid sinus can be reached either medial to the middle turbinate through the nasal cavity or lateral to the middle turbinate in a transethmoidal fashion. The middle turbinate is injected in the same fashion as outlined in the maxillary sinus section. Proceeding medial to the middle turbinate, the turbinate is lateralized and the superior turbinate is identified using a 0-degree scope. The natural ostia is identified consistently medial to the superior turbinate (Fig. 40.8) (6).

If needed, the inferior one-third of the superior turbinate can be removed to facilitate identification of the ostia. As advocated for the maxillary sinus, minimal mucosal trauma to the natural ostia should be the goal. A 1 or 3 mm Kerrison (either up or down biting) can be used to enlarge the ostia in an inferior/medial direction. We strongly advocate no use of powered instruments in the sphenoid sinus and complete removal of inflammatory disease is discouraged and is unnecessary when compared with the catastrophic complication of damage to the carotid artery or optic nerve. If the natural ostium cannot be identified using the above technique, providing the sphenoid is well aerated, a point 1.5 cm above the arch of the choana between the septum and superior turbinate can be used as an entry point. This can then be connected to the natural ostia when identified. Of note, inferior opening below the fontanelle with Kerrison forceps will frequently traverse the posterior nasal artery if it is not deliberately avoided, and suction cautery should be used on the artery to avoid postoperative bleeding.

If a total ethmoidectomy has been performed, the sphenoid can be approached as a direct extension of this procedure. The basal lamella is traversed using a ballpoint probe to make a vertical incision just anterior to the superior turbinate that is easily palpated through the basal lamella. This is enlarged slightly with the microdebrider and the lower half of the superior turbinate is removed with through-cutting forceps. The sphenoid ostia can then be seen or easily palpated. It can be gently enlarged inferiorly if necessary exploiting the fontanelle of the sphenoid sinus. For primary cases, if a large sphenoid ostia is required (fungus ball, polyposis, allergic mucin, mucocele, etc.), it is performed inferiorly leaving normal mucosa superior to the sphenoid os.

BALLOON SINUPLASTY

The first U.S. Food and Drug Administration (FDA)-approved dilating balloon catheter system for use in the paranasal sinuses was introduced in 2005. Since that time, more than 88,000 patients have been treated using balloon systems (7). The appeal of this technique is to provide a minimally invasive option to open the ostia of the paranasal sinuses with avoidance of significant mucosal trauma. This method can be used on the maxillary, frontal, and sphenoid sinuses. If combined with an ethmoidectomy performed by traditional means the procedure is termed "hybrid." Depending on the type of balloon system, fluoroscopy may be needed for guidance with associated radiation exposure to both the patient and surgical staff. The advent of lighted guide wires with resultant transillumination or image guidance has reduced the need for fluoroscopy (8,9).

Review of the current literature reveals a minimal number of studies when compared with the prevalence of balloon usage. One of the most frequently cited articles is the CLEAR trial (Clinical Evaluation to Confirm Safety and Efficacy of Sinuplasty in the Paranasal Sinuses), a prospective, multicenter evaluation of balloon sinuplasty published in 2007 (10). One- and two-year follow-ups were subsequently published (11,12). Both follow up studies demonstrated the potential for durable ostial patency over the length of the 2-year follow up with no major complications. However, this remains a single-armed, uncontrolled, observational study and fails to answer many questions about the applicability of balloon sinuplasty. Batra et al. reviewed the current body of balloon sinuplasty literature and concluded that the efficacy and utility of balloon sinuplasty is still unclear and prospective randomized trials are needed (13). The senior author of this text agrees with this conclusion. The use of balloon systems must be evaluated on a case-by-case basis in both a clinical and economic

context. Studies indicate a minimum of complications; however, there is a report of CSF leak following a hybrid sinus case involving balloon sinuplasty (14). This suggests that no matter how safe an instrument is perceived to be, serious complications can ensue.

IMAGE GUIDANCE

There is currently no level-1 evidence for the use of image guidance in endoscopic sinus procedures. That being said, given the low incidence of serious complication that might be decreased by using image guidance, it would require an enormous number of patients to determine a difference and it is likely a study will never be conducted to that end. In 2002, the American Academy of Otolaryngology-Head and Neck Surgery (AAO-HNS) released a consensus statement on indications for the use of image guidance that is listed below (15).

- Revision sinus surgery
- Distorted sinus anatomy of development, postoperative, or traumatic origin, which includes surgery in the absence of normal landmarks or in the presence of anatomical pitfalls
- Extensive sinonasal polyposis
- Pathology involving the frontal, posterior ethmoid, or sphenoid sinuses
- Disease abutting the cranial base, orbit, optic nerve, or carotid artery
- CSF rhinorrhea or conditions where there is a skull base defect
- Benign and malignant sinonasal neoplasms

Fried et al. (16) in a 2008 review on image guidance in sinus surgery emphasized that the core principle of image guidance is as a guide and not a substitute for proper training. In addition, as the boundaries of ESS are challenged through advanced skull base procedures, the role of image guidance becomes more critical. Although this technology is readily available at most institutions, it is the role of the physician to be judicious with its use. Merely having the technology available is not an indication for its use.

REVISION SURGERY

Revision sinus surgery requires forethought and extensive experience. The reason for failure must be addressed in an objective manner and should include that the patient was a poor surgical candidate to start with or medical therapy trial was inadequate. Incorrect diagnosis including failures to send adequate tissue or interpret the pathology can also be a cause for failure. Image guidance can be a useful adjunct but the use of anatomic landmarks and spatial relationships is still the most important component of successful revision sinus surgery. Presented here are six landmarks that can be found in sequence at the time of revision sinus surgery and serve as a guide to progress in a safe manner. Each landmark should be present despite prior surgical intervention (17).

1. The anterior arch of the middle turbinate
2. The maxillary sinus antrostomy
3. The lamina papyracea
4. The ridge
5. The posterior choanal arch
6. The sphenoid sinus roof

The anterior arch of the middle turbinate is formed between the posterior superior aspect of the lacrimal bone and the anterior superior attachment of the middle turbinate. The landmark defines the anterior border and entrance into the ethmoid air cells, and is present even with removal of the middle turbinate. Once within the ethmoid air cells, keeping laterally along the lamina will decrease the risk of penetrating the ethmoid roof, as the frontal bone cap of the ethmoid is thickest laterally.

It is key at the time of revision surgery to ensure that the natural ostium of the maxillary sinus is patent. All retained uncinate must be removed and the natural os identified. Once the maxillary sinus antrostomy has been opened widely, one can identify both the lamina papyracea and "the ridge." The easiest way to identify the lamina is to follow the floor of the orbit medially. The lamina is located just superior to the maxillary antrostomy. It is crucial that the preoperative CT scan be reviewed and careful attention paid to the continuity of the medial orbital wall and any dehiscence, either congenital or iatrogenic identified.

"The ridge" is the bony extension of the orbital floor between the maxillary antrostomy inferiorly and the lamina superiorly. The benefit of this landmark is the posterior ethmoid air cells will be superior to this ridge and the sphenoid sinus inferior (Fig. 40.9). This will play a key role in polyp patients who have undergone multiple prior procedures with dramatic changes to their native anatomy.

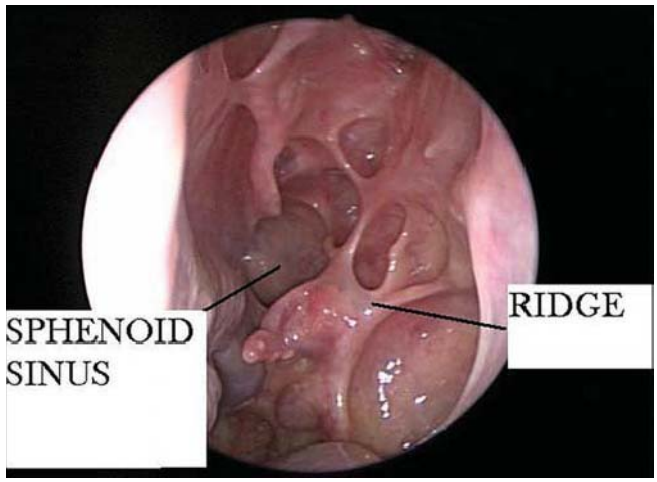

Figure 40.9 Left-sided endoscopic view after maximal endoscopic surgery showing ridge and relation of opened sphenoid sinus extending below the ridge.

The posterior choanal arch allows for identification of the sphenoid sinus and safe entry in the scarred or difficult-to-identify sphenoid ostium. The surgeon, even when using image guidance, can check anatomic coordinates using the posterior choanal arch, the ridge, and the posterior aspect of the nasal septum. The surgeon can grasp the mucosa over the front face of the sphenoid and dissect it inferiorly to displace the posterior nasal branch of the sphenopalatine artery. 1.5 cm above the arch and near the septum, the surgeon can enter the sphenoid safely through the newly exposed bone. The safest point of entry into the sphenoid is medial and inferiorly through the newly exposed bony face of the sphenoid. This opening is then enlarged laterally and superiorly to incorporate the natural ostium. Careful attention should be paid preoperatively to the location and bony covering of the carotid artery and optic nerve within the sphenoid sinus. In the case of stenosis of the sphenoid os, once the sinus is reopened a septal flap can be used to line the floor of the sinus at the conclusion of the revision surgery to prevent stenosis. For revision surgery, a balloon is an excellent option if an opening can be found to dilate or it can be used for initial dilation of a narrow sphenoid os followed by using of a kerrison to continue to widen the os.

On sagittal CT of the paranasal sinuses, one can readily identify that the ethmoid and sphenoid sinuses share a common roof (Fig. 40.5). Once the sphenoid has been entered and opened to the roof, one can proceed in a posterior to anterior direction clearing residual ethmoid air cells to the level of the skull base because the most inferior limit of the skull base has now been defined. This is an effective method for avoiding entrance at the skull base posteriorly.

The method described is one of many revision techniques found in the literature. Regardless of method, if landmarks are identified in order, a safe and effective operation can be achieved. Although all surgeons will face revision work at some time, it is imperative to learn from the mistakes made and think critically about why failure ensued.

OUTCOMES OF FUNCTIONAL ENDOSCOPIC SINUS SURGERY

There are several hundred studies in the past several decades evaluating changes in CRS symptoms following ESS. The assessment of symptoms, outcomes, and techniques vary considerably from study to study making pooling of data a challenge. A comprehensive review is beyond the scope of this chapter but several recent reviews cover the breadth of the literature and demonstrate improvement in symptoms following ESS in appropriate candidates (18,19). ESS failure results from a lack of proper identification of the natural ostium, scarring of the middle turbinate or sinus os, and missed obstructing agar nasi cells. All of the shortcomings listed can cause poor outcomes and therefore should be kept in mind during any sinus operation. The senior author's group reported revision rates following ESS after their first 100 cases. The overall success in relieving sinus symptoms decreased from 98% at early follow-up to 91% at 4-year follow-up (20). Most series report success rates greater than 80%. Failure and recurrence of nasal polyposis is the rule rather than the exception for that pathology. The patient needs to understand the goals of the procedure, and it should always be done as safely as possible.

CONCLUSION

Most patients who undergo routine sinus surgery do not require significant postoperative care or long-term follow up. Clearly underlying allergic disease, malignancies, or patients with cystic fibrosis or primary ciliary dyskinesia require more specialized care over the long-term. Minimizing mucosal trauma and exposed bone along with tailoring the surgery to the needs of the patient will result in minimal morbidity and complications. Careful documentation from initial nasal endoscopy through medical therapy and surgical intervention is also immensely helpful especially if revision surgery by another practitioner is eventually required.

At the resident level, proper patient positioning and placement of the instruments at the nasal valve create an ergonomically favorable beginning. Reading, continued cadaver dissection, and attending course provides an appropriate base of knowledge and continued maturing, which allows more advanced work to be mastered over time. Failure to continue learning in the dynamic field of ESS relegates one quickly to dinosaur status. At the attending level, knowing one's own limits and picking optimal surgical candidates can prevent unwanted surgical failures.

HIGHLIGHTS

- Endoscopic sinus surgery is for those who have failed medical therapy.
- Mucosal preservation is important.
- Anatomical progression of the surgery allows for maximum safety
- Revision surgical landmarks include the "ridge" seen endoscopically as the floor of the orbit, the arch of the choana, the nasal septum, and the anterior superior attachment of the middle turbinate.
- Computer navigation is helpful in complex and revision sinus surgery.
- Balloon sinuplasty is a new technology that will continue to evolve in its role for endoscopic indications.
- Anatomical landmarks for primary sinus surgery case using minimal techniques
- Anatomical landmarks for revision sinus surgery
- Philosophy of current technologies (including balloon and navigation)

41 External Approaches in Sinus Surgery

Carlos D. Pinheiro-Neto *Carl H. Snyderman*

Open approaches to the nasal cavity and paranasal sinuses are based on facial, scalp, and/or sublabial incisions to expose the facial skeleton and provide adequate space for osteotomies. The development of endoscopic endonasal techniques in sinus surgery has dramatically reduced the indications for external approaches. However, persistent indications for open approaches to the facial skeleton include facial trauma surgery, orthognathic surgery, and external anterior ethmoidal artery ligation. In some circumstances, the open approach is combined with endoscopic endonasal techniques to treat sinonasal pathologies and skull base lesions. Therefore, even with the evolution of endoscopic endonasal surgery, it is imperative for a sinonasal surgeon to be familiar with external approaches. In this chapter, the current indications and techniques of open approaches in sinus surgery are presented according to specific anatomic sites.

MAXILLARY SINUSES

In the late 19th century, two surgeons working independently described the external approach to the maxillary sinus. George Caldwell and Henri Luc were the first to describe the procedure to access the maxillary sinus to remove infection and inflamed mucosa (1). According to the authors, a maxillary antrostomy in the inferior meatus was routinely performed to establish a new drainage pathway for the sinus. The Caldwell-Luc procedure remained the principal surgical intervention to treat inflammatory maxillary sinus disease until the advance of endoscopic endonasal techniques in the mid-1980s and the concept of a middle meatus antrostomy at the natural ostium of the maxillary sinus (2). Notwithstanding the procedure is not performed anymore as originally described, the term Caldwell-Luc still remains and is often used to refer to the anterior transmaxillary approach, which requires an incision in the superior gingivolabial sulcus and anterior maxillary antrostomy to access the maxillary sinus.

Indications

The anterior transmaxillary approach is indicated for sinonasal tumors that are not completely accessible using an endonasal approach. This includes tumor involvement of the anterior, inferior, and posterolateral walls of the maxillary sinus. The approach is also indicated in surgeries to address the infraorbital nerve when there is perineural spread of neurotrophic cancers (adenoid cystic carcinoma, squamous cell carcinoma). The anterior transmaxillary approach guarantees access to the posterior wall of the maxillary sinus and can be used as a corridor to reach the pterygopalatine fossa, lateral recess of the sphenoid sinus, masticator space, and infratemporal fossa. Classically, this approach is associated with endoscopic endonasal techniques for resection of selected cases of juvenile nasopharyngeal angiofibromas and inverted papillomas with maxillary sinus involvement (3).

In the field of oral–maxillofacial surgery, the anterior transmaxillary approach is routinely used for the treatment of a variety of dental tumors and for orthognathic surgery. Edentulous patients with insufficient maxillary alveolar bone height for insertion of dental implants may require augmentation of the maxillary alveolus (4). With facial trauma, open reduction and repair of comminuted orbital floor fractures can be facilitated with the use of this approach (2) (Table 41.1).

Operative Technique

Following infiltration with local anesthetic with vasoconstrictor, a sublabial incision is carried from the canine tooth to the first molar. It is important to leave a 5-mm cuff of mucosa above the gingiva to facilitate closure of the mucosa at the end of the procedure. Dissecting in the subperiosteal plane, the soft tissue of the cheek is elevated to the level of the infraorbital nerve. The ideal place to open

TABLE 41.1 SURGICAL INDICATIONS FOR OPEN APPROACHES TO THE SINUSES

Maxillary sinus	Sinonasal tumors (involvement of the anterior, inferior, and posterolateral walls of the maxillary sinus)
	Infraorbital nerve resection (adenoid cystic carcinoma, squamous cell carcinoma).
	Corridor to reach the pterygopalatine fossa, lateral recess of the sphenoid sinus, masticator space, and infratemporal fossa.
	Juvenile nasopharyngeal angiofibromas
	Inverted papillomas
	Dental tumors
	Orthognathic surgery
	Augmentation of the maxillary alveolus.
	Open reduction and repair of comminuted orbital floor fractures
Frontal sinus	Osteoplastic flap for frontal sinus obliteration.
	Osteomyelitis (frontal bone)
	Subperiosteal abscess
	Epidural abscess
	Sinonasal tumors (lateral extension or involvement of the anterior wall of the frontal sinus)
	Displaced fractures of the anterior table
	Posttraumatic CSF leaks
	Displaced fractures of the posterior table
Ethmoid sinus	Resection of malignant tumors
	Repair of complex midfacial fractures
	External ligation of the anterior ethmoidal artery
	Adjunct to frontal sinus surgery
Sphenoid sinus	Microscopic pituitary surgery

the maxillary sinus is the canine fossa, which is an area of thin bone just superior to the root of the canine tooth. A small hole is made with a drill or osteotome and enlarged with a bone rongeur to the margins of the sinus (pyriform sinus, orbital rim, maxillary alveolus). Care is taken to avoid injury to the infraorbital nerve superiorly and dental roots inferiorly. In pediatric patients, unerupted teeth are at risk for exposure. In case an extended lateral exposure is needed, the entire lateral buttress of the maxilla can be removed.

After the anterior maxillary antrostomy is completed, the surgeon can work in the maxillary sinus under direct or endoscopic visualization. Depending on the case, the posterior maxillary wall can be removed providing access to the pterygopalatine fossa and infratemporal fossa. The medial wall gives access to the nasal cavity, and the roof to the orbit. At the end of the procedure, the anterior wall is not reconstructed and the incision is closed in one layer with absorbable suture (Fig. 41.1)

Complications

Facial edema is expected during the early postoperative period and can be minimized with elevation of the head by 30 degrees and application of an ice pack. Complications that can result from the anterior transmaxillary approach include wound infection, wound dehiscence with oroantral fistula, and bleeding with hematoma formation. Removal of the bone around the infraorbital nerve and retraction of soft tissues can injure the infraorbital nerve and cause transient or permanent numbness of the cheek and upper lip. In the presence of a large bone defect, loss of periosteum can result in scar contracture of the cheek. In pediatric patients, elevation of periosteum may affect subsequent facial growth with asymmetry of the facial skeleton. Disruption of dental roots can result in devitalized teeth or delayed eruption of secondary teeth. (Table 41.2)

FRONTAL SINUSES

Because of the complex anatomy of the frontal sinus drainage pathway, surgery to restore frontal sinus function is one of the most challenging aspects of sinus surgery. The frontal recess is a narrow stricture between the frontal sinus and the ethmoidal infundibulum. The recess is limited anteriorly by the *agger nasi* and posteriorly by the bulla ethmoidal and/or suprabullar cells. In 1914, Lothrop described a procedure to enlarge the frontal recess using an external approach. The aim of the Lothrop procedure was to create a common drainage pathway for both frontal sinuses (5). Because of the removal of portions of the lamina papyracea, orbital fat tissue would commonly prolapse medially, obstructing the frontal drainage and contributing to high failure rates (6).

In the 1950s, Montgomery popularized the operation to permanently obliterate the frontal sinus using an open approach (7). Frontal sinus obliteration has been considered the final surgical attempt in cases of refractory frontal sinusitis (8). The principle of this operation is to obliterate the frontal sinus using a variety of autologous tissues and alloplastic materials and block the frontal recess. Although frontal sinus obliteration has a high success rate of 93% at 8 years, complications are relatively high, occurring in over 20% of patients (9,10)

With the advent of endoscopes in sinus surgery, it was feasible to approach the frontal recess and restore the function of the frontal sinus avoiding obliteration. In the 1990s, Draf (11) modified the surgical concept described by Lothrop using endoscopic endonasal techniques to resect the frontal sinus floor and create a common drainage pathway for both frontal sinuses.

Indications

Endoscopic endonasal techniques are ideal to approach the frontal recess and restore the outflow of the frontal sinus in cases of refractory chronic sinusitis. However, intractable disease may require an external approach and osteoplastic flap for frontal sinus obliteration. The open approach is also needed in cases of infectious complications like osteomyelitis and subperiosteal or epidural abscesses. Although

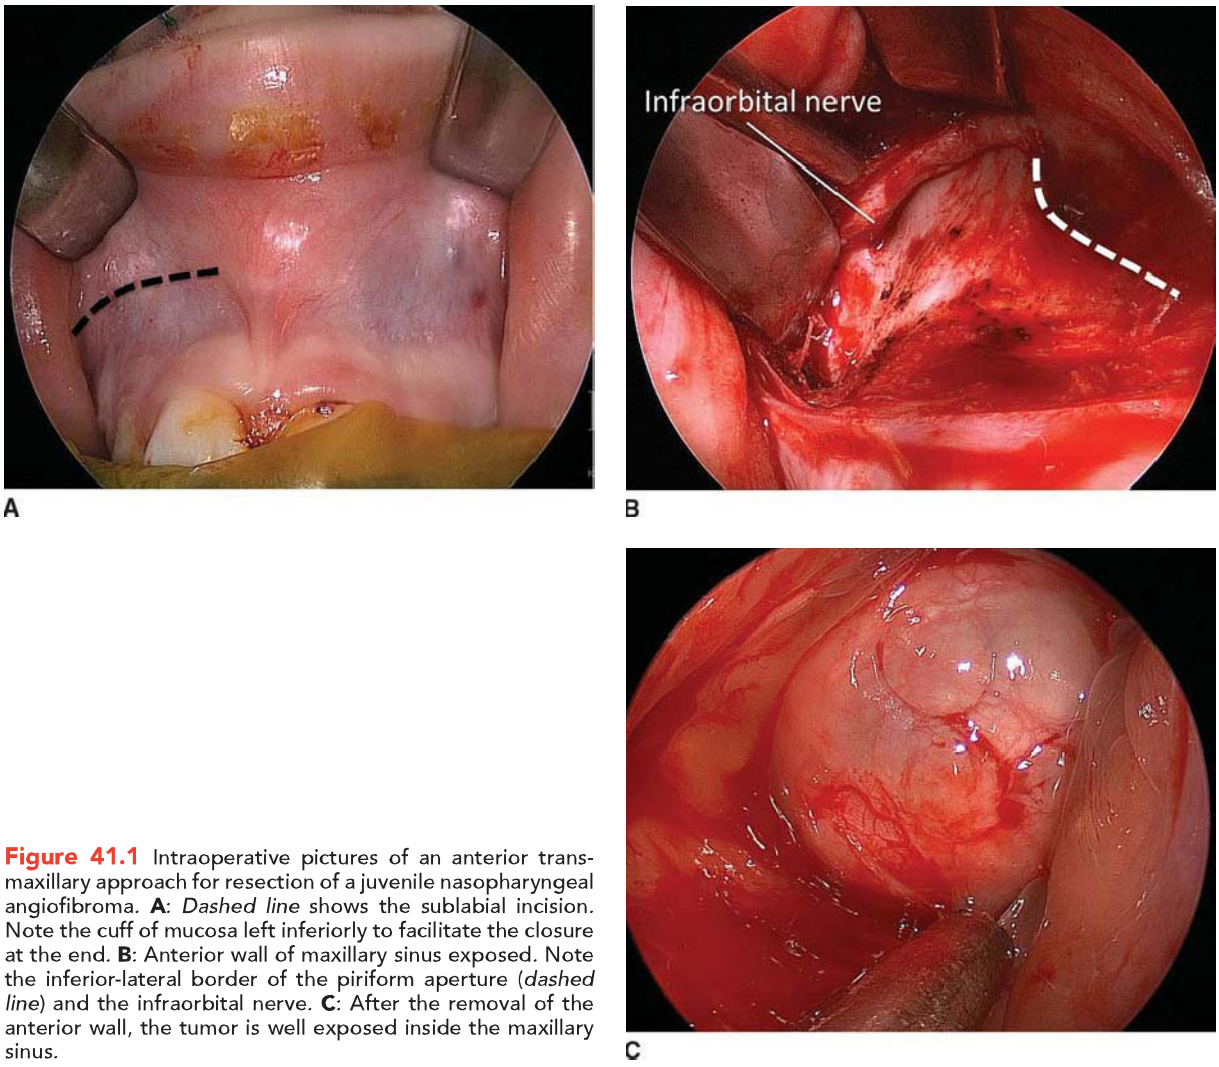

Figure 41.1 Intraoperative pictures of an anterior transmaxillary approach for resection of a juvenile nasopharyngeal angiofibroma. **A**: *Dashed line* shows the sublabial incision. Note the cuff of mucosa left inferiorly to facilitate the closure at the end. **B**: Anterior wall of maxillary sinus exposed. Note the inferior-lateral border of the piriform aperture (*dashed line*) and the infraorbital nerve. **C**: After the removal of the anterior wall, the tumor is well exposed inside the maxillary sinus.

many sinonasal tumors can be removed using endoscopic techniques, lateral extension or involvement of the anterior wall of the frontal sinus will necessitate an open approach.

External approaches to the frontal sinus are indicated in the setting of craniofacial trauma. Displaced fractures of the anterior table of the frontal sinus require open reduction and internal fixation (Fig. 41.2) Posttraumatic cerebrospinal fluid (CSF) leaks and displaced fractures of the posterior table are more easily repaired with an external approach (Table 41.1).

Operative Techniques

Trephination

Frontal sinus trephination is performed through a small incision at the medial aspect of the eyebrow. Because of the elasticity of the skin, the eyebrow incision can be mobilized superiorly and the sinusotomy placed over the frontal sinus. A 4 to 5 mm diameter hole is drilled through the anterior table of the frontal sinus. It is mandatory to assess the pneumatization of the frontal sinus with x-rays or CT scan before the procedure. Direct access to the frontal sinus through a trephination allows collection of material for culture, irrigation of the sinus with saline or antibiotic, and inspection of the sinus with endoscopes. Irrigation of the frontal sinus with saline can be used to localize the frontal recess during endoscopic sinus surgery. However, with the evolution of endoscopic endonasal techniques and intraoperative navigation systems, the applications of the frontal sinus trephination are limited.

Lynch Incision

A Lynch incision extends from the lateral nasal dorsum (level of medial canthus) to the medial brow. It provides access to the medial orbit and ethmoid sinus and the inferomedial aspect of the frontal sinus. Subperiosteal dissection is performed and the orbital tissues are gently retracted. The exposure is bounded inferiorly by the lacrimal fossa and sac. The anterior and posterior ethmoidal arteries traverse the surgical field at the level of the frontoethmoidal suture line. The surgical field is bounded superiorly by the trochlea that anchors the superior oblique muscle and the supratrochlear sensory nerve located superior to the trochlea.

TABLE 41.2 POTENTIAL COMPLICATIONS OF THE EXTERNAL APPROACHES TO THE SINUSES

Maxillary sinus	Facial edema
	Wound infection
	Wound dehiscence with oroantral fistula.
	Bleeding with hematoma formation.
	Infraorbital nerve injury (transient or permanent numbness of the cheek and upper lip).
	Scar contracture of the cheek.
	Asymmetry of the facial skeleton (pediatric patients). Disruption of dental roots
Frontal sinus	Diplopia
	Orbital hematoma
	CSF leak
	Meningitis
	Intracranial hemorrhage
	Cerebral contusion
	Frontalis muscle palsy
	Injury to the supraorbital/supratrochlear nerves (dysesthesia)
	Cosmetic deformity
	Frontal sinus mucocele
Ethmoid sinus	Epiphora
	Diplopia
	Retrobulbar hemorrhage
	Optic nerve injury
	CSF leak
Sphenoid sinus	Septal perforation
	Deviated nasal septum
	Saddle nose deformity
	Optic nerve injury
	Carotid artery injury

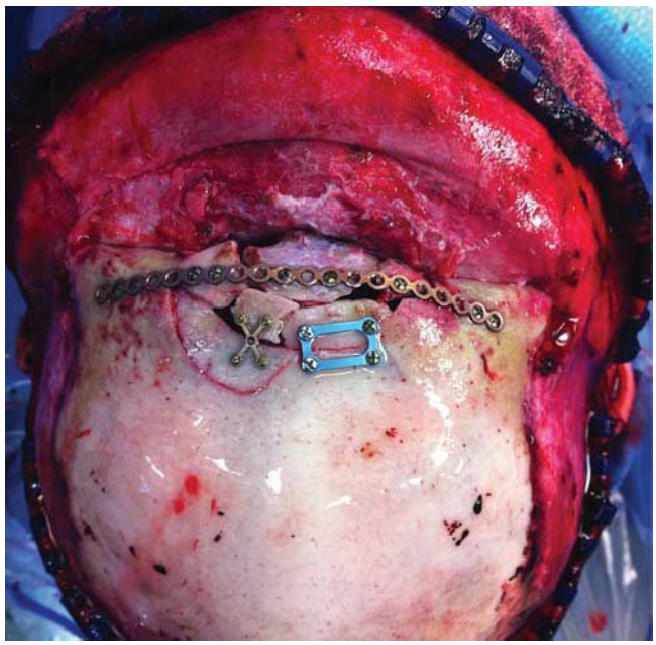

Figure 41.2 Intraoperative picture of anterior wall of frontal sinus repair. Patient had a comminuted fracture of the anterior table of the frontal sinus and bicoronal approach for reduction and fixation of the fragments.

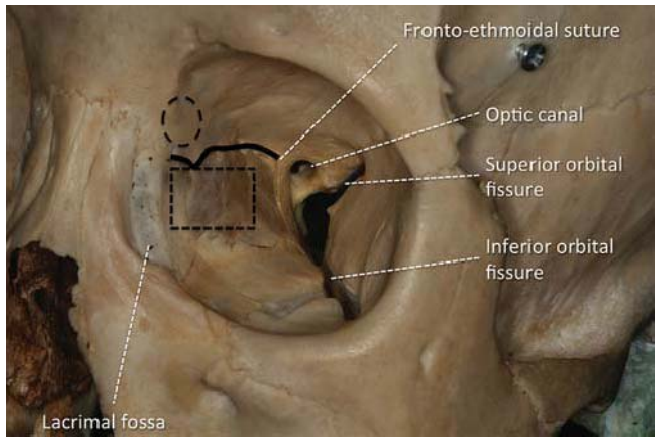

Figure 41.3 Dry skull to show the regions approached through a Lynch incision. The lateral wall of the frontal recess is exposed and the frontal sinus can be accessed (*circle*). External ethmoidectomy is performed after a wide exposure of the medial orbital wall and the ethmoid is entered through the lamina papyracea. The level of the skull base is defined by the frontoethmoidal suture line and bone is removed inferior to this line (*rectangle*).

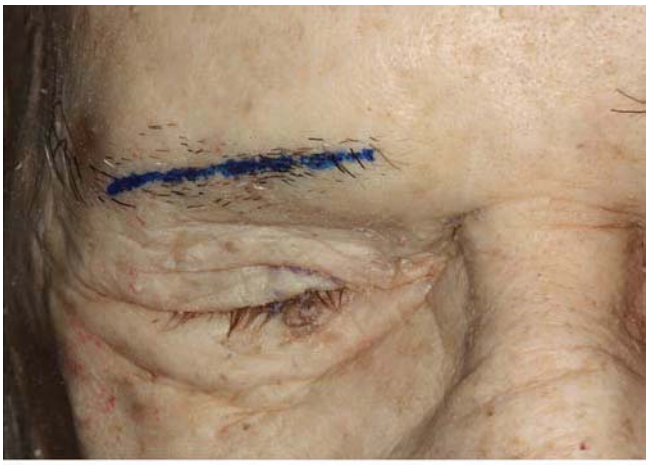
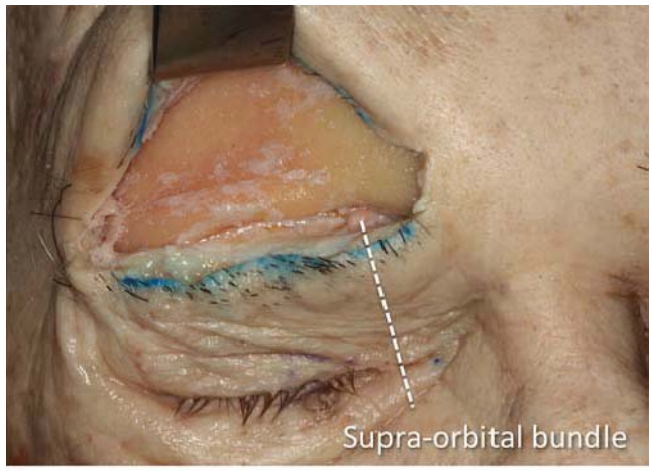


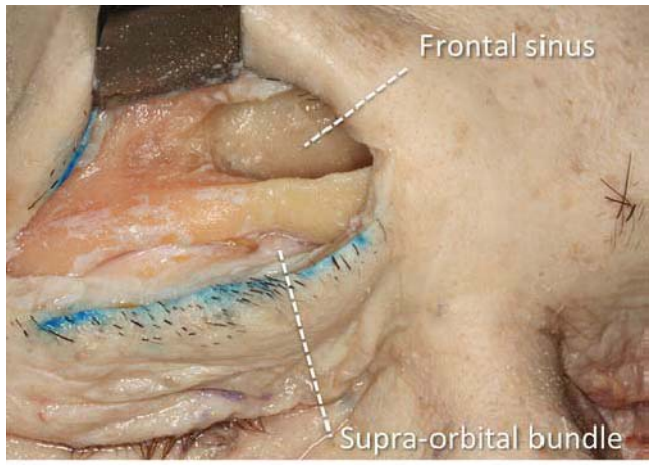
The frontal sinus may be accessed by drilling the bone of the orbital roof medially or by opening the ethmoid sinus below the frontoethmoidal suture line and following the nasofrontal recess to the frontal sinus. The external frontoethmoidectomy provides access to tumors and frontoethmoidal mucoceles. The Lynch incision can also be used to treat infectious complications of sinusitis such as a subperiosteal orbital abscess (Fig. 41.3)

The Lynch incision provides limited access to the frontal sinus and may be complicated by injury to the supratrochlear or supraorbital nerves. Detachment of the trochlea can impair extraocular motion and result in dysconjugate gaze. Injury to the ethmoidal arteries can result in a retrobulbar hematoma, a potential ophthalmologic emergency.



Eyebrow Incision

The eyebrow incision gives direct access to the superior orbital rim and anterior wall of the frontal sinus. The incision can be placed within the brow or immediately adjacent. The incision should be beveled at the angle of the hair follicles to avoid loss of hair and an unsightly scar. Careful dissection in a subperiosteal plane is necessary to identify and avoid injury to the supratrochlear and supraorbital arteries and nerves. In the presence of a complete supraorbital foramen, the inferior bony bridge of the foramen can be removed. This maneuver allows retraction of the supraorbital artery and nerve with the orbital tissues.



The eyebrow approach is useful for lesions localized laterally in the frontal sinus. The anterior table can be drilled or an osteotomy is performed to gain access to the frontal sinus. If the bone is not replaced, the defect is reconstructed with titanium mesh to avoid retraction of the soft tissues and a depression in the forehead. The use of image guidance system is imperative to establish

C

Figure 41.4 Dissection pictures to show the eyebrow approach to the frontal sinus. This approach gives good exposure of the lateral aspect of the frontal sinus when well pneumatized. **A**: Incision. **B**: Exposure of the anterior wall of the frontal sinus. **C**: Frontal sinus open.

the limits of the frontal sinus before the osteotomies are performed to prevent inappropriate opening of the intracranial space (Fig. 41.4)

Mid-Forehead Incision

In patients with a deep forehead crease or trauma patients with a scalp laceration, a transverse incision in a natural skin crease provides excellent access to the anterior table of the frontal sinus with a favorable cosmetic result. Disadvantages of the transverse incision include sensory denervation of the frontal scalp superior to the incision and disruption of the pericranium in case an anteriorly based pericranial flap is needed for repair.

Bicoronal Approach

The bicoronal incision avoids a facial incision and provides wide exposure of the frontal cranium. The incision extends from the tragus of one ear to the other and posterior to the hairline. The scalp is elevated in a subperiosteal plane with separation of the periosteum from the deep temporal fascia along the attachment of the temporalis muscle (superior temporal line). If extra pericranium is needed for a pericranial flap, the posterior scalp flap can be elevated deep to the galea to access additional pericranium. The scalp is elevated to the level of both orbital rims. Careful dissection should be performed close to the superior orbital rim to avoid injury to the supraorbital neurovascular bundles. The supraorbital and supratrochlear arteries are the primary blood supply for a pericranial flap.

Surgical navigation has replaced the use of 6-ft Caldwell x-ray templates for delineation of the boundaries of the frontal sinus. Osteotomies of the anterior table of the frontal sinus are performed with a drill or oscillating saw, staying within the confines of the sinus. After the osteotomies are completed, the single piece of bone is out-fractured and separated from the interfrontal sinus septum. Wide exposure of both frontal sinuses is achieved.

The bicoronal approach is the most versatile approach and allows the resection of benign and malignant neoplasms (osteomas, inverted papilloma, squamous cells carcinoma) as well as treatment of advanced inflammatory disease with infectious complications (Potts puffy tumor or osteomyelitis of the frontal bone with subperiosteal abscess, epidural and subdural abscesses). During a bicoronal approach to the frontal sinus, two options are possible regarding the frontal sinus recess: functional restoration or obliteration. The functional restoration follows the same principle described by Lothrop in 1914. The frontal sinus

floor needs to be removed from orbit to orbit. The interfrontal septum and the superior nasal septum are resected to create a common outflow pathway for both frontal sinuses. The mucosa of the sinus should be preserved, if possible. The medial wall of the orbit should be preserved, because the medial protrusion of orbital fat can cause obstruction and failure of the procedure. In the 1990s, Draf (11) modified this technique applying the same surgical concept through the endoscopic endonasal approach.

Obliteration of the frontal sinus is usually considered when the frontal recess obstruction cannot be relieved by more conservative techniques or when the mucosal disease is diffuse and irreversible. The mucosa of the frontal and supraorbital ethmoid cells must be completely removed. The bone needs to be drilled to eliminate remnants of mucosa, thus minimizing the possibility of mucosal regrowth and mucocele formation. Abdominal fat or pericranium are still the best materials for sinus obliteration. Because the fat is nonvascularized, it may shrink with healing and result in incomplete obliteration. It can be difficult to distinguish fat from scar tissue postoperatively with imaging, and exclusion of ongoing infection is difficult if symptoms persist. The use of pericranium as an osteoplastic flap to obliterate the frontal sinus was popularized by Montgomery in the 1950s (7). The pericranial flap provides vascularized tissue for obliteration and provides an effective barrier for the nasofrontal recesses and coverage of exposed dura. An inferiorly based flap is elevated from the scalp and placed inside the frontal sinus cavity covering the frontal recess. The interfrontal septum should be drilled to allow adequate contact of the pericranial flap to the posterior table of the frontal sinus.

Cranialization is an alternative method of frontal sinus obliteration that consists of the complete removal of the posterior table of the frontal sinus. The frontal recesses are covered with a pericranial flap to separate the nasal cavity from the intracranial space. The anterior table of the frontal sinus is incorporated into the intracranial space and all of the mucosa of the frontal sinus needs to be entirely removed to prevent a mucocele or infection. Cranialization is more commonly indicated for craniofacial trauma, especially with severe comminuted fractures of the posterior table of the frontal sinus.

At the end of the procedure, the anterior table is replaced and fixed with titanium plates and screws. If a pericranial flap was used, a gap in the bone should remain along the inferior aspect of the osteotomy to provide space for the transposition of the pericranial flap into the frontal sinus and avoid compression of the flap pedicle. In cases where the anterior table cannot be used as a bone graft, titanium mesh is a good alternative for reconstruction. In the presence of active infection, reconstruction with synthetic materials should be postponed.

The bicoronal approach can be also used for Riedel's procedure, which consists of the removal of the entire anterior table of the frontal sinus and its floor (12). The procedure allows the frontal scalp to be in direct contact with the posterior table of the frontal sinus or dura and obliterate the frontal sinus, resulting in forehead concavity. This disfiguring procedure is rarely used except as part of a staged reconstructive procedure with infectious complications.

Complications

Because of the proximity, external approaches to the frontal sinus can result in orbital and/or intracranial complications. Loss of periorbita with protrusion of orbital fat can lead to displacement of the globe and diplopia. Orbital hematoma is also a complication, especially if the anterior ethmoidal artery is injured. Placement of osteotomies outside the margins of the frontal sinus can result in a CSF leak and brain injury. Dural lacerations can be repaired directly or with a fascial graft. Other intracranial complications that may occur are meningitis, intracranial hemorrhage, and cerebral contusion. Injury to the frontalis branch of the facial nerve causing frontalis muscle palsy or injury to the supraorbital/supratrochlear nerves resulting in dysesthesia may occur during the approach. Other complications are lack of resolution of symptoms, cosmetic deformity, and frontal sinus mucocele (Table 41.2).

ETHMOID SINUSES

The ethmoid bones are situated between the orbits with close relationship to the anterior cranial base. The natural corridor to approach the ethmoid sinuses is the nasal cavity. Even before the advent of the endoscopes, ethmoid sinus surgeries have been performed transnasally, with or without magnification (microscope). Endoscopic endonasal techniques provide improved access and visualization and are generally preferred. External approaches to the ethmoid sinuses are rarely indicated but can be useful in selected patients for the resection of malignant tumors; repair of complex midfacial fractures; for external ligation of the anterior ethmoidal artery; or as an adjunct to frontal sinus surgery (Table 41.1).

Operative Technique

The external approach to the ethmoid sinuses starts with a Lynch incision. The incision begins at the inferior margin of the medial aspect of the eyebrow and extends inferiorly along the lateral nose midway between the nasal dorsum and the medial canthus to the level of the medial canthus. The angular vessels are controlled with bipolar cautery, and the supratrochlear bundle is preserved superiorly. Subperiosteal dissection is performed and the periosteum is preserved to ensure the integrity of the medial canthal ligament, trochlea, and lacrimal sac as well as to prevent herniation of orbital fat. Herniation of orbital fat interferes with the visualization and dissection of the posterior orbit. As the medial wall of the orbit is widely exposed, the anterior ethmoidal artery is encountered in the frontoethmoidal suture line approximately 24 mm posterior to the anterior lacrimal crest. This vessel is clipped or coagulated with a bipolar

electrocautery and, if necessary, divided. The periorbita is protected with a malleable retractor to prevent herniation of orbital fat into the field. Additional elevation demonstrates the posterior ethmoidal artery approximately 11 mm posterior to the anterior artery and approximately 6 mm anterior to the optic foramen (13). These proportions are not constant, and great care must be exercised in dissecting the area of the posterior ethmoidal artery to avoid retrobulbar hemorrhage and injury to the optic nerve. Periorbital elevation is not routinely performed posterior to the anterior ethmoidal artery. After a wide exposure of the medial orbital wall, the ethmoid is entered through the lamina papyracea. The level of the skull base is defined by the frontoethmoidal suture line and bone is removed inferior to this line. Remember that the cribriform plate is often lower than the roof of the ethmoid sinus; careful dissection is necessary to prevent injury to the lateral lamella of the cribriform and a CSF leak. Further dissection of the ethmoid sinus can be performed with a headlight or endoscopic assistance (Fig. 41.3)

Complications

Complications related to the external approach to the ethmoid sinuses include epiphora, diplopia, retrobulbar hemorrhage, optic nerve injury, CSF leaks, and postoperative neuralgia. Persistent epiphora from injury to the nasolacrimal apparatus is an unusual but significant complication and may necessitate a dacryocystorhinostomy. Temporary diplopia is common and usually self-limited as edema resolves. Horizontal gaze diplopia, however, may result as a consequence of trauma to the medial rectus muscle with subsequent fibrosis. Blindness is a potential consequence of retrobulbar hemorrhage or direct injury to the optic nerve. Leakage of CSF and intracranial hemorrhage can occur if the fovea ethmoidalis or cribriform plate is disrupted. Inappropriate placement of the incision or poor surgical technique can cause hypertrophic scar formation, medial canthal scarring, or rounding of the medial canthus. Anesthesia, hypesthesia, or neuralgia of the median forehead can occur if the supratrochlear nerve is injured (Table 41.2).

SPHENOID SINUS

The sphenoid sinus is located deep in the central part of the head and is surrounded by all three cranial fossae. The roof of the sphenoid sinus is the planum sphenoidale and forms part of the anterior cranial fossa. The posterior wall is part of the clivus and is related to the posterior cranial fossa. The lateral wall borders Meckel's cave in the middle cranial fossa. Important structures that are related to the sphenoid sinus include the optic nerves, internal carotid arteries, cavernous sinus, and pituitary gland.

External approaches to the sphenoid sinus include superior, lateral, and anterior approaches. A superior approach through the planum sphenoidale is usually part of a craniofacial resection for sinonasal malignancy. A bifrontal craniotomy with subfrontal approach provides access to the planum sphenoidale and is limited posterolaterally by the optic nerves. A lateral skull base approach (infratemporal) provides access to the sphenoid sinus between the second and third divisions of the trigeminal nerve. This opening into the lateral recess of the sphenoid sinus is very limited in exposure. The sphenoid sinus can be accessed through a transseptal route or through craniofacial translocation.

Anterior approaches to the sphenoid sinus include transethmoidal and transseptal approaches. The sphenoid sinus can be reached through an external ethmoid incision. Dissection along the medial wall of the orbit and below the roof of the ethmoid sinus leads to the anterior wall of the sphenoid sinus. Transseptal approaches to the sphenoid sinus are less morbid and still used by microscopic pituitary surgeons. However, with the development of endoscopic endonasal techniques, external approaches to the sphenoid sinus are disappearing.

The transseptal approach is based on exposure of the anterior face of the sphenoid through submucosal tunnels in the septum. With a transnasal route, a hemitransfixion incision is extended across the nasal floor and a subperichondrial/subperiosteal dissection of the septum and nasal floor is performed to the rostrum of the sphenoid. With a sublabial route, a mucosal incision in the superior gingivolabial sulcus provides similar access to the nasal septum and nasal floor for a subperichondrial/subperiosteal dissection. The nasal septum is disarticulated from the maxilla inferiorly and from the bony septum posteriorly. Bilateral subperiosteal dissection of the ethmoid and vomer bones is then performed until the rostrum and anterior sphenoid are exposed. A "pituitary" speculum is placed into the tunnel on both sides of the septal bones to displace the tissues and expose the sphenoid rostrum. The bone of the posterior septum, rostrum, and anterior sphenoid wall is removed with a drill or rongeurs and the sphenoidotomy is widened to the margins of the sinus. Once the sphenoid sinus is open, the visualization can be enhanced using the operating microscope or endoscope.

Other anterior approaches to the sphenoid sinus that may be employed in selected patients include midfacial degloving associated with Le Fort I osteotomies; maxillary translocation; and transoral associated with palatal split.

Complications

Complications of transseptal approaches to the sphenoid sinus include injury to nasal structures and the skull base. Dislocation of the nasal septum can result in septal perforation, deviated nasal septum, or loss of vertical height with tip rotation or saddle nose deformity. Placement of the speculum into the sphenoid sinus can result in fracture of the lateral sphenoid with injury to the optic nerves or carotid arteries. The biggest risk of external approaches to the sphenoid sinus, however, is limited access with poor visualization (Table 41.2).

CONCLUSIONS

Although endoscopic endonasal techniques have dramatically decreased the need for external approaches to the paranasal sinuses, there is still a need in selected patients. Factors to be considered in choosing the optimal approach include the site and extent of the pathology, prior treatment and reconstruction considerations, patient comorbidities and preferences, and the experience of the surgeon.

HIGHLIGHTS

- The transmaxillary approach is indicated in surgeries to address the infraorbital nerve when there is perineural spread of neurotrophic cancers (adenoid cystic carcinoma, squamous cell carcinoma).
- The ideal place to open the maxillary sinus is the canine fossa, which is an area of thin bone just superior to the root of the canine tooth.
- The approach provided by the Lynch incision is bounded inferiorly by the lacrimal fossa and sac and superiorly by the trochlea that anchors the superior oblique muscle and the supratrochlear sensory nerve located superior to the trochlea.
- The anterior and posterior ethmoidal arteries traverse the surgical field at the level of the frontoethmoidal suture line.
- In the presence of a complete supraorbital foramen, the inferior bony bridge of the foramen can be removed. This maneuver allows retraction of the supraorbital artery and nerve with the orbital tissues.
- During external ethmoidectomy, the level of the skull base is defined by the frontoethmoidal suture line and bone is removed inferior to this line. The cribriform plate is often lower than the roof of the ethmoid sinus.
- A lateral skull base approach (infratemporal) provides access to the sphenoid sinus between the second and third divisions of the trigeminal nerve. This opening into the lateral recess of the sphenoid sinus is very limited in exposure.
- The transnasal transseptal approach to the sphenoid provides similar exposure as the sublabial approach without the need for a sublabial incision.

42 Septoplasty, Turbinate Reduction, and Correction of Nasal Obstruction

Neal C. Gehani *Steven M. Houser*

Nasal obstruction is one of the most common complaints in an otolaryngology practice. The differential diagnosis for this symptom is broad and can be multifactorial. There are a variety of both mucosal and structural abnormalities that can alter the sensation of nasal airflow, including septal deviation, turbinate hypertrophy, nasal cartilage deformity, sinus infections, sinonasal neoplasms, and systemic diseases. It is important for the otolaryngologist to be aware of the various etiologies of nasal obstruction while evaluating a patient and recommending appropriate treatment options.

EVALUATION AND ASSESSMENT

History

It is essential to obtain a thorough history when assessing a patient with nasal obstruction. The clinician should pay particular attention to unilateral versus bilateral symptoms, onset, seasonal variation, and associated nasal symptoms. The nasal cycle is a periodic alteration of engorgement of the erectile tissue in the inferior turbinates, typically cycling every 2 to 7 hours, with subsequent changes in nasal airflow. Mucosal inflammation caused by rhinosinusitis or allergic rhinitis may exacerbate the normal nasal cycle. Unilateral nasal obstruction, especially with epistaxis, could be a symptom of a sinonasal neoplasm. Obstruction, either unilateral or bilateral, following nasal trauma may indicate a fracture or structural abnormality of the nasal septum or pyramid. Obstruction that fluctuates seasonally or with environmental exposure indicates a reversible mucosal abnormality rather than a fixed structural obstruction. Associated symptoms, including facial pain or pressure, nasal discharge, and hyposmia may indicate rhinosinusitis. Nasal obstruction, associated with serous otitis media requires evaluation of the nasopharynx for possible neoplasm. Nasal obstruction can also cause nonnasal symptoms such as dry mouth, sore throat, snoring, halitosis, and decreased appreciation of taste sensation, presumably from impaired smell.

In addition to eliciting subjective complaints, one must also review the patient's past medical and surgical history, current medications, and social habits. Numerous systemic diseases may have a nasal manifestation of obstruction, including aspirin-exacerbated respiratory disease, cystic fibrosis, Wegener granulomatosis, sarcoidosis, rhinoscleroma, fungal infections, and lymphoma. Normal fluctuations of estrogen during the menstrual cycle and pregnancy can also lead to temporary nasal obstruction. A prior rhinoplasty may cause nasal valve collapse, while a prior aggressive turbinectomy or reduction may lead to subjective nasal obstruction due to atrophic rhinitis or empty nose syndrome. Medications that may induce nasal obstruction include aspirin and other nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, alpha-adrenoceptor antagonists, methyldopa, beta-blockers, and oral contraceptives. Lastly, alcohol can produce vasodilation with nasal obstruction, while smoking impairs mucociliary clearance, exacerbating rhinitis, and cocaine abuse can cause extensive destruction of nasal support structures, leading to obstruction (1).

Physical Examination

The physical examination of nasal congestion includes evaluation of the external framework of the nose, with attention to any bony or cartilaginous deformity or nasal dorsal deviation. Rarely, pyriform aperture narrowing or stenosis contributes to obstruction. A horizontal nasal crease at the supratip area usually indicates chronic nose wiping, as in the "allergic salute." Tip ptosis contributing to obstruction can be assessed by pushing the nasal tip superiorly. The Cottle maneuver, in which the cheek skin and nostril are retracted laterally to assess changes in subjective nasal airflow, detects contributions to congestion at the nasal valve. In a modification of the Cottle maneuver,

an ear curette is used to selectively retract the upper lateral and then lower lateral cartilages to detect their contribution individually to nasal obstruction. The presence of alar collapse with inspiration indicates dynamic external nasal valve collapse, while supra-alar pinching indicates internal nasal valve collapse. Turbinate contribution to nasal obstruction can be assessed before and after topical decongestants with anterior rhinoscopy. Significant improvement following topical decongestants, indicates primarily a potentially reversible cause of nasal congestion such as allergy. Reddened, ulcerated, or friable nasal mucosa may indicate exposure to toxins, rhinitis medicamentosum, food allergy, or systemic disorders. Septal spurs, deviations, or perforations are the most common septal findings. Nasal polyps, purulence, excessive secretions, tumors, choanal stenosis, eustachian tube or nasopharyngeal pathology can usually be visualized with thorough rigid or flexible nasal endoscopic evaluation.

Investigations

Further investigations to determine the etiology of nasal obstruction will vary depending on the suspected differential diagnosis. Blood tests, such as angiotensin converting enzyme level (for sarcoidosis), cytoplasmic-antineutrophil cytoplasmic antibodies (C-ANCA) level (for Wegener granulomatosis), erythrocyte sedimentation rate, and syphilis serology, may be helpful if systemic inflammatory disorders are suspected. *In vitro* assessment of specific immunoglobulin E (IgE), intradermal testing, or skin prick testing may be useful if allergy is considered. Subjective complaints of anosmia or hyposmia may be quantified using validated testing kits, including the University of Pennsylvania Smell Identification Test (Sensonics, Haddon Heights, NJ), the alcohol smell test, and Sniff'n sticks. Further assessment of smell is discussed in more detail in the chapter on olfaction. A directed nasal swab is considered if purulent drainage is noted during anterior rhinoscopy or nasal endoscopy to direct medical management.

Acoustic rhinometry and rhinomanometry have been used for many years to objectively assess nasal airway resistance and obstruction. Acoustic rhinometry measures the cross-sectional area (CSA) of the nasal cavity by presenting a shock wave to the nasal airway and measuring the reflected sound. The CSA is measured while the patient is apneic and during inspiration. Normally, the inspiratory to apneic CSA ratio should be around 1. A ratio significantly lower than 1 indicates nasal valve collapse during inspiration, while significantly low CSA during both apnea and inspiration may indicate a fixed obstruction. The limitation of acoustic rhinometry is the wide variation of normal CSA and therefore difficulty in interpreting results. Rhinomanometry, which was first described by Coutade in 1902, is a method of simultaneously measuring nasal airflow at a fixed pressure differential during the nasal respiratory cycle. A pressure-flow curve is then generated, yielding another objective assessment of nasal obstruction. Both acoustic rhinometry and rhinomanometry are obtained for experimental purposes; however, they are not considered standard of care when evaluating a patient for nasal obstruction (2).

Imaging is considered in certain patients presenting with nasal obstruction. Plain x-rays of the sinuses may be helpful in evaluating particular clinical entities, such as a nasal fracture; however, it has largely been replaced by computed tomography (CT) scan due to wide availability, rapidity of the study, and superior anatomic detail of structures. A CT scan is considered in patients with concern for rhinosinusitis, trauma, inflammatory disease, sinonasal neoplasm, or congenital abnormality. If malignancy is considered, magnetic resonance imaging may be obtained to provide enhanced soft tissue information.

Differential Diagnosis

Patients with a variety of conditions may present with a chief complaint of nasal obstruction. It is important for the otolaryngologist to keep the differential diagnosis in mind when obtaining further diagnostic studies or recommending therapeutic interventions (Table 42.1).

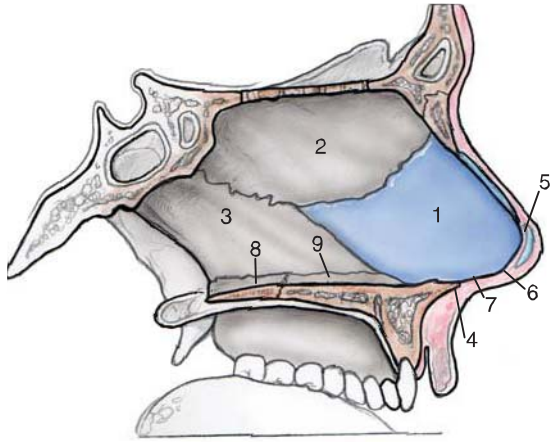
Treatment Options

The management of patients with nasal obstruction can be divided into medical or surgical interventions. In general, patients with an anatomic abnormality, such as septal deviation, inferior turbinate hypertrophy, nasal valve collapse, choanal atresia, or nasal polyposis will require surgical intervention; however, they may also benefit from medical

TABLE 42.1 DIFFERENTIAL DIAGNOSIS OF NASAL OBSTRUCTION

Diagnosis	Symptoms
Septal deviation	Usually unilateral nasal obstruction, deviated nasal septum on examination
Turbinate hypertrophy	Turbinate enlargement on examination
Nasal valvular collapse	Nasal valve collapse on deep inspiration
Polyps	Unilateral or bilateral nasal obstruction, altered sense of smell
Sinusitis	Infectious mucopus on anterior rhinoscopy
Adenoid hypertrophy	Unilateral or bilateral nasal obstruction, mouth breathing, snoring
Neoplasm	Unilateral nasal obstruction, epistaxis, nasal mass on examination
Choanal atresia	Unilateral or bilateral nasal obstruction, clear or purulent rhinorrhea
Allergy	Bilateral nasal obstruction, history of seasonal obstruction, pale or bluish nasal mucosa
Vasomotor rhinitis	Clear mucous
Nasal foreign body	Unilateral or bilateral purulent drainage

TABLE 42.2 TREATMENT OPTIONS



Diagnosis	Treatment
Septal deviation	Septoplasty
Turbinate hypertrophy	Nasal decongestants, inferior turbinate reduction
Nasal valvular collapse	Adhesive supporting strips, nasal valvular reconstruction
Polyps	Endoscopic sinus surgery
Sinusitis	Antibiotics, topical or systemic steroids, endoscopic sinus surgery
Adenoid hypertrophy	Adenoidectomy, topical steroids
Neoplasm	Resection
Choanal atresia	Transpalatal or transnasal repair
Allergy	Avoidance of or desensitization to the allergen, topical steroids and antihistamines, leukotriene modulators

treatment before and after surgery to optimize outcomes. Patients with physiologic etiology, such as allergy, rhinosinusitis, and systemic inflammatory diseases, should be treated with medical therapies including local or systemic corticosteroids or avoidance, prior to considering surgical intervention (i.e., endoscopic sinus surgery) (Table 42.2).

DEVIATED NASAL SEPTUM

Surgery for correction of a deviated nasal septum has evolved over the course of the years. Submucous resection of septal cartilage was initially described by Ingals in 1882, followed by Freer, who described resection of both the bony and cartilaginous portions of the deviated septum in 1902. Killian further modified the procedure in 1904; however, both Freer and Killian advocated not addressing deflections of the dorsal and caudal portions of the septum to prevent postoperative nasal deformities. In 1946, Cottle and Loring described removal of all deviated portions of the septum and replacement of bone and cartilage in the intramucosal space to prevent postoperative saddle nose deformities and a retracted columella (3). More recently, endoscopic septoplasty was introduced as a technique to address the deviated nasal septum for enhanced visualization during endoscopic sinus surgery.

A thorough understanding of the anatomy of the nasal septum is important when performing a septoplasty. The bony portion of the nasal septum is composed of the perpendicular plate of the ethmoid bone superiorly and the vomer inferiorly. Posteriorly, the bony septum defines the medial aspect of the nasal apertures, or choanae. Superiorly, the perpendicular plate of the ethmoid bone is contiguous with the cribriform plate of the skull base and the posteriosuperior aspect fuses with the sphenoid rostrum. Inferiorly, the vomer fuses with the maxillary crest. Anteriorly, the bony septum fuses with the cartilaginous

septum. The cartilaginous nasal septum, also known as the quadrangular cartilage due to its shape, has attachments to the upper lateral and lower lateral cartilages anteriorly and maxillary crest inferiorly (Fig. 42.1). The keystone area, the junction of the quadrangular cartilage, perpendicular plate of the ethmoid, and paired nasal bones (4), is critical to the support of the nasal dorsum and should be preserved when performing a septoplasty.

Indications

There are numerous indications for the surgical correction of a deviated nasal septum, which are listed in Table 42.3.

Operative Procedure

Many techniques and variations of septoplasty have been described in the literature. Although the procedure can be performed under local or general anesthesia, the latter is

TABLE 42.3 INDICATIONS FOR SEPTOPLASTY

Deviation of the nasal septum with partial or complete nasal obstruction

CPAP, continuous positive airway pressure; OSA, obstructive sleep apnea.

preferred, especially in anxious patients or those undergoing additional procedures, such as sinus surgery. The procedure is initiated with the infiltration of a hemostatic agent, such as 1% lidocaine with 1:100,000 epinephrine, in the subperichondrial plane to assist in raising submucosal flaps and maintaining hemostasis throughout the procedure. The nasal cavities are then packed with pledgets soaked with a decongesting agent such as 4% cocaine, oxymetazoline, or neo-synephrine.

An incision is then made through the mucosa of the septum. The side of the incision depends on the patient's anatomy or surgeon preference (e.g., a right-handed surgeon may prefer a left-sided incision). The authors prefer making an incision on the side with the convex aspect of the deviation to assist in raising an intact mucosal flap. If a prominent septal spur is located anteriorly, then dissection may be best achieved from that side even if it is not the convex side. A Freer's hemitransfixion incision (on the caudal aspect of the cartilaginous septum) may be used for caudal deviations (Fig. 42.2) or a Killian incision (1 cm posterior to the columella at the mucocutaneous junction) may be used for more posterior deviations. Once the incision is made, a mucoperichondrial–mucoperiosteal flap is carefully raised on the side of the incision over the cartilaginous septum, posteriorly over the bony septum, and inferiorly onto the maxillary crest (Fig. 42.3). An incision through the quadrangular cartilage is then usually made 1 cm posterior to the dorsal and caudal portions of the cartilaginous septum ("L-strut"), and a mucoperichondrial–mucoperiosteal flap is then raised on the contralateral side of the septum. The cartilaginous septum is then disarticulated from the bony septum and the posterior cartilaginous septum is removed and preserved for reimplantation later. Alternatively, the cartilage can be left essentially intact if the bony septum is the main area of deflection. The keystone area should not be disrupted during this portion of the procedure. The bony septum is then carefully removed.

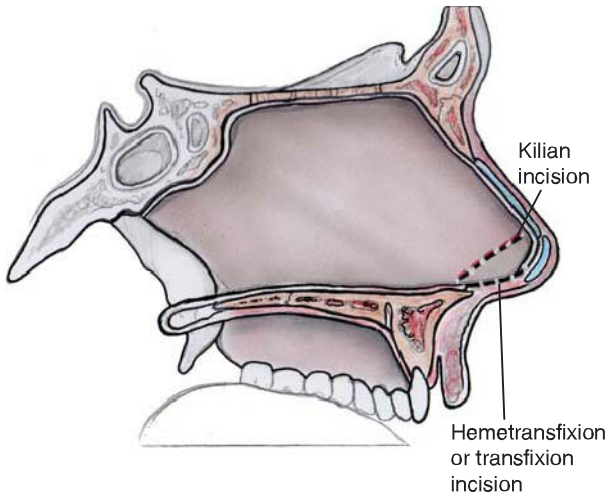

Figure 42.2 Hemitransfixion incision.

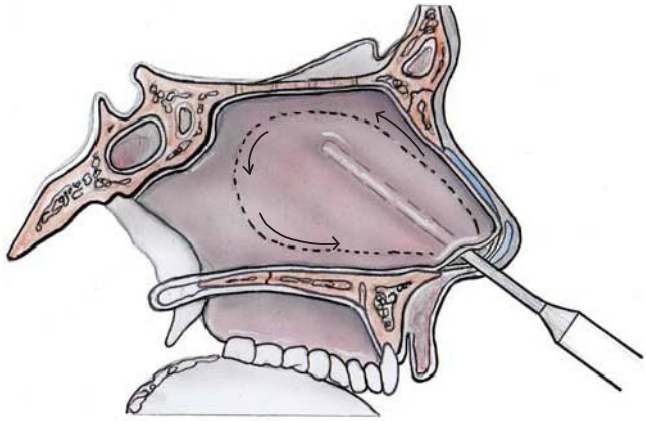

Figure 42.3 Elevation of mucoperichondrial flap.

Care is taken not to rock the perpendicular plate of the ethmoid bone, as rocking may lead to a fracture of the cribriform plate and cerebrospinal fluid (CSF) rhinorrhea. Redundant bony or cartilaginous septum over the maxillary crest can be removed using an osteotome. The mucosal flaps are then inspected. Ideally, the flaps should remain intact, since tears will delay healing and increase the risk of septal perforation postoperatively. Large or bilateral mucosal tears should be repaired. The removed cartilage is either morselized, scored, or crushed to remove memory and reinserted between the mucosal flaps to maintain integrity of the septum and nasal support. The incision is then closed with absorbable suture. A unilateral mucosal incision is then made in the ventral portion of the septum to allow for drainage of blood, preventing postoperative septal hematoma. Silastic nasal splints are then inserted and secured in place to prevent synechiae formation as well as eliminate dead space between mucosal flaps. Quilting sutures may also be used instead of splints.

Endoscopic septoplasty is a technique which was developed as a result of limited nasal access during endoscopic sinus surgery. Commonly, the surgeon's endoscopic view is obscured due to septal spurs or deviations. Endoscopic septoplasty is initiated by injecting the nasal septum with local anesthetic with vasoconstrictive properties under endoscopic guidance. An incision is then made either over the spur or just anterior to the deviation and a mucoperichondrial–mucoperiosteal flap is raised above and below this area with an instrument, such a suction Freer elevator (Fig. 42.4). The deviated cartilage or bone is then resected as described earlier, however, with endoscopic guidance. The mucosal flaps usually do not need to be closed; however, this is considered if the incision is large.

Since the dorsal and caudal septum provide support for the middle and lower third of the nose, correction of deviation of this portion of the septum can be most challenging. Removal of the deflection will result in external collapse. The simplest technique to correct caudal deflection involves vertically scoring, incising, or morselizing the caudal strut to reshape it. Overaggressive manipulation

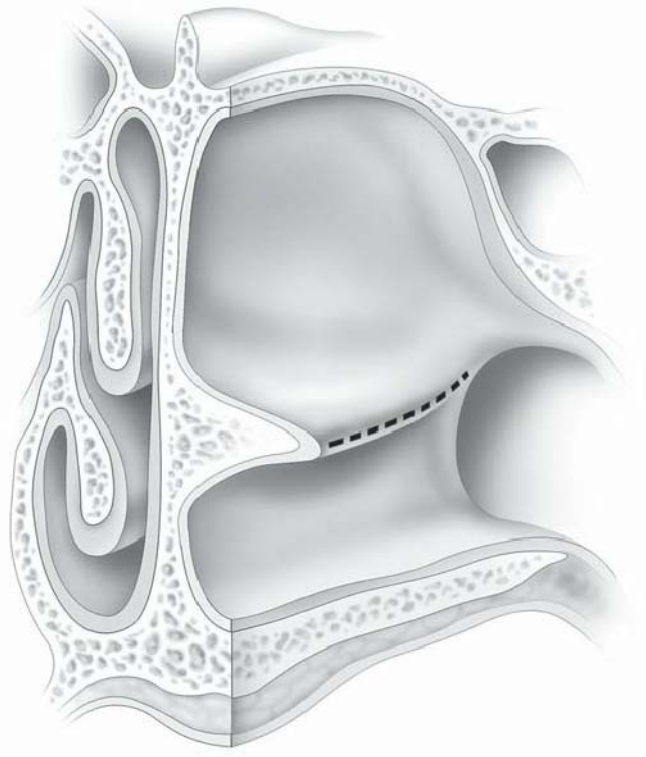

Figure 42.4 Endoscopic septoplasty: Mucoperichondrial flaps are elevated above and below the septal spur.

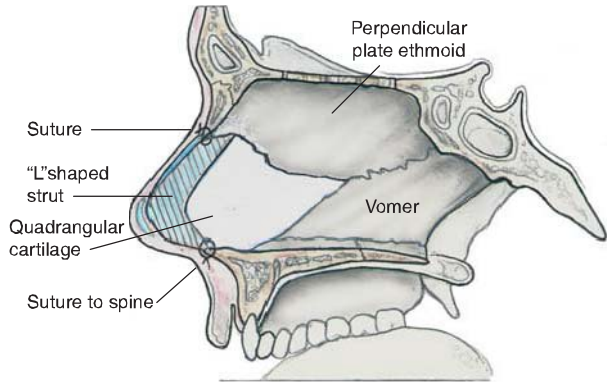

Figure 42.5 Explantation and reimplantation of L-shaped strut during extracorporeal septoplasty.

will result in loss of tip support and tip ptosis. Graft material, such as septal cartilage, ethmoid perpendicular plate, or vomer bone, may be used as a splint to prevent repeat deviation as well as provide support to the caudal septum. The graft material is placed on both sides of the straightened caudal septum and sutured into position. Another technique introduced by Metzenbaum in 1929 and subsequently modified by others involves removing a vertical wedge of cartilage on the convex side of the caudal deformity and suturing the remaining cartilage to the anterior nasal spine. A modification of this technique involves wedge resection followed by translocation and securing the caudal septum to the other side of the anterior nasal spine to prevent the septum from returning to its native position (4). Finally, extracorporeal septoplasty has been employed for severe deviation of both the caudal and dorsal septum. This technique involves separation of the cartilaginous septum from the upper lateral cartilages, perpendicular plate of the ethmoid bone, vomer, and maxillary crest, followed by en bloc removal (5). The appropriate dimensions of the desired dorsal and caudal strut is then measured and carved from the straight segments of the previously removed quadrangular cartilage. The strut is then placed between the mucoperichondrial flaps and sutured into appropriate position (Fig. 42.5). For isolated caudal deviation, a 1 cm dorsal strut of quadrangular cartilage is left *in situ* and the remainder of the cartilaginous septum is removed. The caudal strut is reconstructed with a straight piece of resected cartilage and sutured to the dorsal strut and maxillary crest. The remaining resected cartilage is then morselized or scored and placed between the mucoperichondrial flaps prior to closure.

Outcomes

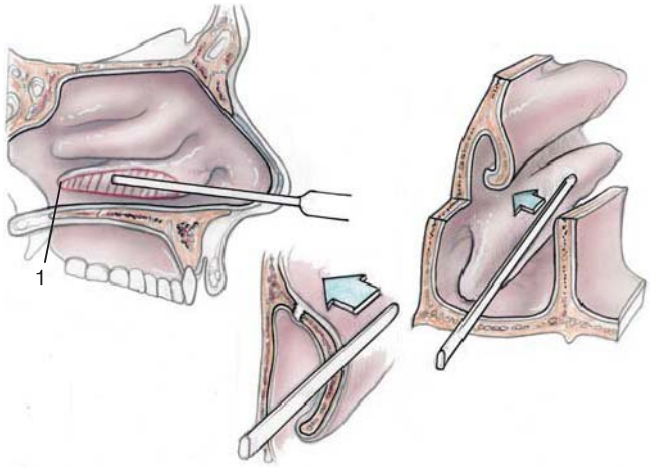
The American Academy of Otolaryngology-Head and Neck Surgery Foundation supported a multicenter study investigating outcomes after septoplasty. Fifty-nine patients completed a validated survey (the Nasal Obstruction Septoplasty Effectiveness scale) before and 3 and 6 months after septoplasty. Only 6% of patients reported they were not pleased with the procedure. The remaining patients in the study reported improvements in nasal obstruction, which remained stable 6 months postoperatively (6). More recently, another study reviewing 86 patients after septoplasty using the same survey reported 89.5% of patients with subjective improvement in nasal obstruction postoperatively (7).

Complications

Complications from septoplasty are rare, but most significantly include septal hematoma, epistaxis, and very rarely CSF leak and anosmia, and more commonly septal perforation and occasionally dorsal saddling. Septal hematomas are usually prevented by hemostasis prior to closure, a quilting stitch, and placement of small perforations in septal mucosa. A postoperative septal hematoma, should be treated in the standard manner as soon as it is recognized, with evacuation of the hematoma, and usually resplinting for several days. Epistaxis is best avoided by recognition of coagulopathies preoperatively and meticulous operative hemostasis. Topical fibrin and thrombin products may be helpful in achieving hemostasis. CSF leak is best treated by preventing its occurrence using appropriate techniques discussed in the prior operative section on septoplasty. Once recognized, the usual algorithm of endoscopic closure of CSF leaks should be employed, which are discussed in the chapter on skull base techniques. Nasal septal perforation occurs in 1.6% to 6.7% of septoplasties (8). A septal perforation complication

is prevented using careful mucosal handling, limiting electrocautery, preventing opposing mucosal tears, and avoiding quilting sutures that are excessively tight and could cause flap ischemia. A perforation may be managed with surgical closure with mucosal flaps and autologous or artificial grafts or a septal button. Saddle nose deformity may occur due to a weakened dorsal strut or displaced caudal septum postoperatively. Management of this deformity is discussed in Chapter 181. Anosmia may occur in up to 3% of patients and usually improves over time. Patients may also develop palate denervation if the long sphenopalatine or greater palatine nerves are injured while removing the maxillary crest or posterior bony septum, respectively. Dental anesthesia may also occur with injury to the nasopalatine nerve (8).

TURBINATE REDUCTION



Inferior turbinate hypertrophy is a fairly common etiology of nasal obstruction. Surgery of the inferior turbinates has been reported as the eighth most common procedure performed by otolaryngologists. The inferior turbinates are composed of conchal bone covered by lamina propria (including erectile tissue) and ciliated, pseudostratified, columnar epithelium. The autonomic nervous system controls the level of congestion of the inferior turbinates. The nasal cycle is a cyclic alteration of inferior turbinate vasculature, occurring every 2 to 7 hours. The anterior head of the inferior turbinate forms the posterior aspect of the internal nasal valve, and therefore turbinate congestion can severely impact nasal patency.

Inferior turbinate hypertrophy is typically caused by rhinitis of many etiologies, including allergic, infective, vasomotor, hormonal, or induced by medications. The vast majority of patients with inferior turbinate hypertrophy respond appropriately to medical management, such as topical or systemic corticosteroids, antihistamines, and decongestants. Unfortunately, long-term hypertrophy may become irreversible, thus surgical intervention is warranted (9).

In addition to mechanical obstruction of the nasal passages, the inferior turbinates may also play a role in functional obstruction. The sensation of appropriate nasal airflow is dependent upon the proper nasal airway resistance. Both excessively high and low resistances will lead to a subjective complaint of nasal obstruction. Therefore, patients with injured mucosa or complete absence of inferior turbinates may present with subjective nasal obstruction despite a widely patent nasal airway on examination.

Operative Procedure

Over the course of the years, numerous techniques have been developed to address the hypertrophic inferior turbinate, including partial or total inferior turbinectomy, outfracture, submucous resection, laser, electrocautery, cryosurgery, and radiofrequency ablation (10). Partial or total inferior turbinectomy was widely practiced in the early 1900s; however, concerns of postoperative bleeding, crusting, dryness, atrophic rhinitis, and empty nose syndrome made this technique fall out of favor. Inferior turbinate outfracture is a technique with very minimal morbidity, involving the use of a blunt elevator to fracture the conchal inferior turbinate bone laterally (Fig. 42.6). This procedure tends to be performed in conjunction with other procedures to address the hypertrophic inferior turbinate. Electrocautery of the inferior turbinate can be performed under local anesthesia in the office or under general anesthesia when combined with other procedures in the operating room. This procedure includes surface monopolar electrocautery, bipolar electrocautery, or submucous diathermy. Surface electrocautery has a tendency to injure the mucosa of the inferior turbinate with resultant nasal crusting and dryness. Submucous diathermy involves inserting an insulated needle electrode into the head of the inferior turbinate and extending submucosally to the posterior aspect of the turbinate. The diathermy is then activated for 5 to 10 seconds while the needle is withdrawn from the turbinate. Although immediate benefit is apparent, multiple studies have demonstrated long-term improvement is variable. Radiofrequency turbinate reduction is another popular technique to address inferior turbinate hypertrophy. In this procedure, the electrode probe is inserted submucosally into the inferior turbinate, similar to the diathermy technique. The radiofrequency pulses induce ionic agitation at the cellular level, inducing thermal injury to the deep mucosa, leading to scar contraction and a reduced inferior turbinate. In contrast to submucous diathermy, the radiofrequency technique creates much lower tissue temperatures and therefore thermal injury only extends 2 to 4 mm around the electrode, inducing a more controlled deep mucosal injury and preserving mucosal epithelium and function. Carbon dioxide laser turbinate reduction has the advantages of minimal blood loss and postoperative discomfort. The laser does, however, cause eschar formation on the surface of the turbinate, which may slough and lead to postoperative hemorrhage. Additional

1. Area of out fractured bone

Figure 42.6 Inferior turbinate outfracture.

disadvantages of the laser technique include the expense of the equipment and requirement of additional training and expertise. Cryosurgery involves placing a cryoprobe on the medial and lateral surfaces of the inferior turbinate for 60 seconds. This treatment seems to be most effective in patients with vasomotor rhinitis and multiple treatments may be required to control symptoms.

Submucous resection of the inferior turbinate involves the removal of the underlying erectile tissue and conchal bone. This procedure was first described by Spielberg in 1924. Traditionally, an incision is made in a posterior to anterior fashion along the inferior border of the anterior two-thirds of the inferior turbinate. Mucoperiosteal flaps are then raised to expose the inferior turbinate bone. The bone is then resected using turbinate scissors, Jansen-Middleson rongeur, or Takahashi forceps (Fig. 42.7). The mucoperiosteal flaps are then laid back into anatomic position and excessive mucosa is trimmed. The nasal cavity is then either packed with antibiotic-impregnated gauze or plicating horizontal mattress sutures are used to ensure proper healing. The microdebrider-assisted technique is an alternative method using powered instrumentation to remove the erectile tissue in the inferior turbinate. An incision is made in the anterior head of the inferior turbinate and a submucosal pocket is created. The microdebrider is then inserted into the pocket to remove the submucosal tissue (Fig. 42.8). Alternatively, a specialized microdebrider blade with a sharp tip for elevation and a 3-mm blade for turbinate reduction can be used. The microdebrider blade is then positioned laterally to remove the erectile tissue while preserving an intact overlying mucosal pocket. Suction electrocautery can be used to achieve hemostasis if needed. The reduction in the inferior turbinate is immediately appreciated and the procedure is completed (9,11).

Numerous studies have been performed comparing the various inferior turbinate reduction techniques. Huang et al.

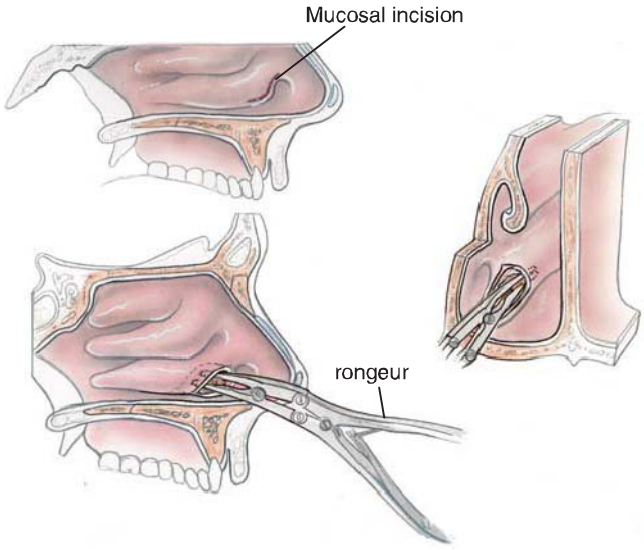


Figure 42.7 Submucosal resection of the inferior turbinate.

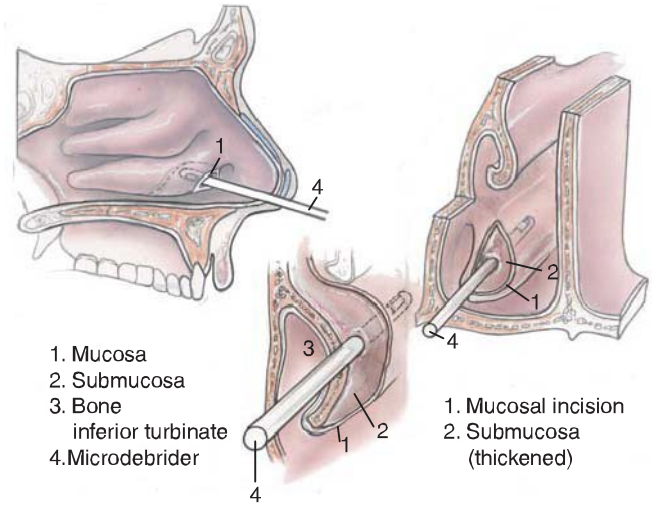

Figure 42.8 Microdebrider-assisted inferior turbinate reduction.

compared the microdebrider-assisted submucous resection technique with radiofrequency turbinate reduction in 120 patients and noted improved outcomes in the microdebrider group 3 years postoperatively (12). Wormald et al. studied 19 patients who underwent cauterization on one inferior turbinate and microdebrider-assisted submucous resection on the other. Symptom scoring, endoscopic scoring, as well as acoustic rhinometry were performed periodically for 5 years postoperatively. The microdebrider-assisted technique was superior to inferior turbinate cauterization in all endpoints studied. Additionally, cauterization was associated with recurrence of inferior turbinate hypertrophy, whereas microdebrider-assisted submucosal resection had stable long-term results (13).

Complications

Complications after inferior turbinate reduction are best avoided by appropriate intraoperative technique. The surgeon should strive to maintain as much intact mucosa as possible during any inferior turbinate procedure in order to preserve mucociliary function and to prevent nasal crusting, synechia formation, and hemorrhage. Manipulations at the posterior-most aspect of the turbinate should be avoided to prevent injury to branches of the sphenopalatine artery, resulting in immediate or delayed bleeding.

Rhinitis sicca and empty nose syndrome may develop after turbinate surgery. Classically, these entities occur with partial or total turbinectomy; however, they may also occur with excessive injury to the turbinate mucosa. The inferior turbinate is much more commonly involved than the middle turbinate. Patients with empty nose syndrome present with paradoxic nasal obstruction despite a widely patent nasal airway on examination. Patients report a feeling of nasal stuffiness in addition to the lack of nasal airflow sensation, which may lead to subjective complaints of difficulty breathing, shortness of breath, or even suffocation. Empty nose syndrome occurs in a small

percentage of patients who undergo turbinate procedures, but the clinician should be aware of this entity and strive to maintain the integrity of turbinate mucosa to avoid this complication. Atrophic rhinitis is a distinctly different condition; atrophic rhinitis is a chronic, degenerative condition characterized by inflammation and atrophy of the nasal mucosa. Patients present with significant crusting, foul odor, and nasal obstruction. *Klebsiella ozaenae* is often the culpable bacteria. Anatomically, empty nose syndrome and atrophic rhinitis patients may look similar, and submucosal implantation may benefit both conditions, although they have different origins (14).

NASAL VALVE OBSTRUCTION

The internal nasal valve is the narrowest portion of the nasal airway and therefore may contribute to obstruction. It is the site of maximal nasal airway resistance and it is hypothesized that its function is to assure nasal airflow does not exceed the ability of the nose to humidify and warm inspired air. The valve has a tendency to collapse at high airflow rates due to Bernoulli forces. This valve consists of the cartilaginous septum medially, the floor of the nose inferiorly, the caudal aspect of the upper lateral cartilage superiorly, the bony pyriform aperture laterally, and the head of the inferior turbinate posteriorly (Fig. 42.9). Deformities of the internal nasal valve include inferiomedially displaced upper lateral cartilage, septal deviation, inferior turbinate hypertrophy, and pyriform aperture stenosis. The external nasal valve is formed by the septum, the medial and lateral crura of the lower lateral cartilage, and the premaxilla (Fig. 42.9). Deformities

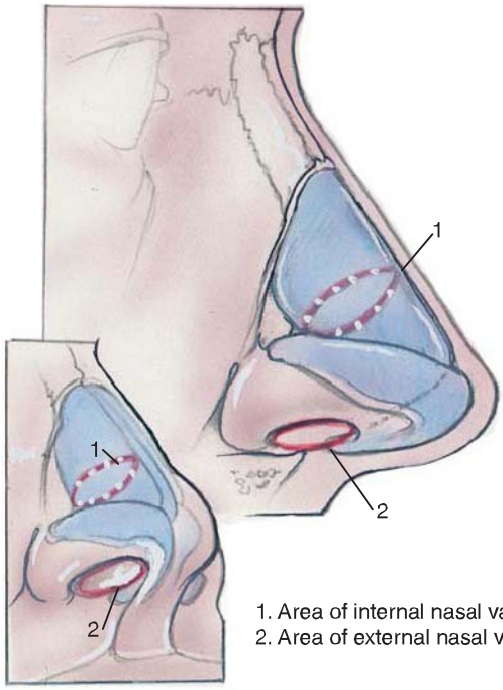

Figure 42.9 External and internal nasal valves.

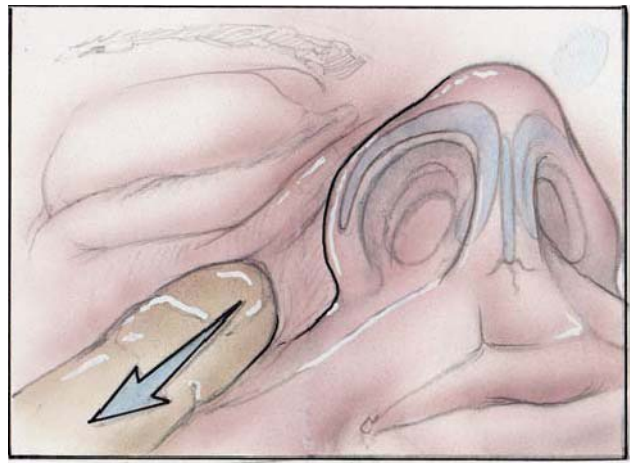

Figure 42.10 The Cottle maneuver.

of the external nasal valve may occur as a result of destabilization of the nasal septum and lower lateral cartilage, leading to upper lateral cartilage collapse. This may occur postoperatively, in particular after reduction rhinoplasty (15). Additionally, improvement of nasal congestion with a Cottle maneuver (Fig. 42.10), directs the otolaryngologist to consider nasal valve surgery to correct the obstruction.

Operative Procedures

There are numerous surgical treatments available to address the internal nasal valve. The otolaryngologist must choose the appropriate combination of procedures to adequately alleviate symptoms of nasal obstruction. Nasal septal deviation and inferior turbinate hypertrophy can contribute to obstruction in the nasal valve region and must be addressed at the time of surgery. Operative techniques specifically targeting the internal nasal valve can be performed with an open or an endonasal approach, depending on the surgeon's preference.

The most common surgical technique is application of spreader grafts, which was first described by Sheen in 1984. The 1 to 2 mm thick rectangular shaped grafts are harvested from the quadrangular cartilage and placed in a submucosal pocket between the septum and the upper lateral cartilage (Fig. 42.11). The grafts span the entire distance of the upper lateral cartilage to the nasal bone and therefore increase the angle between the septum and upper lateral cartilage resulting in an increase in the CSA of the internal nasal valve (15,16).

Numerous other types of cartilaginous grafts have also been described to address the nasal valve. In 1998, Guyuron et al. described splay grafts, in which conchal cartilage is placed concave side down over the dorsal septum and underneath the caudal aspect of the upper lateral cartilages. The graft uses the nasal dorsum to splay the upper lateral cartilages apart and widen the nasal airway. Butterfly grafts are a modification of this technique, in

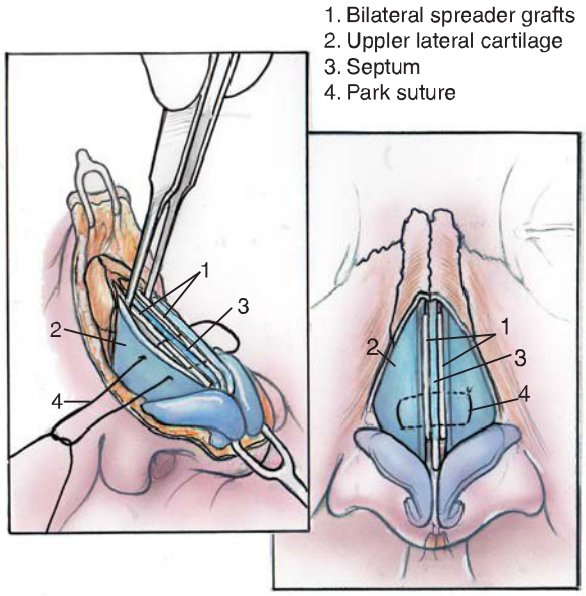

Figure 42.11 Placement of spreader grafts and Park suture.

which a conchal or septal cartilage graft is placed between the upper lateral and lower lateral cartilages, with its caudal border under the cephalic aspect of the lower lateral cartilage. Lastly, alar batten grafts have been described to support a weakened or absent lateral crus of the lower lateral cartilage, strengthening the external nasal valve. These grafts are harvested from the concha or septum and placed in a submucosal pocket caudal to the lower lateral cartilage and extending laterally over the bony pyriform aperture (Fig. 42.12).

Flaring or "Park sutures" have also been described to alleviate internal nasal valve obstruction. This technique involves a horizontal mattress suture placed at the lower border of the upper lateral cartilage, spanning across the nasal dorsum, and secured to the lower border of the contralateral upper lateral cartilage. As the suture is tightened, the upper lateral cartilages begin to flair, widening the internal nasal valve (Fig. 42.11). Paniello in 1996 described the use of a suspension suture to address the internal nasal valve. In this technique, a suture is placed through the periosteum of the inferior orbital rim through a lower eyelid transconjunctival approach and secured to the upper lateral cartilage, suspending the cartilage superiolaterally and widening the nasal valve (2,16). Although this technique is effective in the immediate postoperative period, the long-term efficacy of this procedure has not been reported.

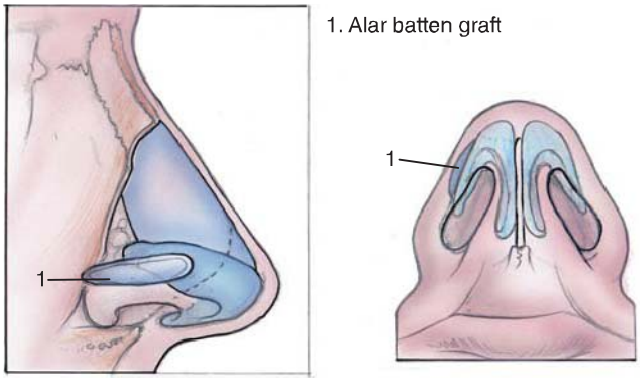

Figure 42.12 Placement of a batten graft.

CONCLUSION

Nasal obstruction is a common presenting complaint and has numerous etiologies. A thorough history and physical examination must be obtained in order to determine the most appropriate treatment regimen. Patients should be optimized with medical therapies prior to considering surgical intervention. A variety of techniques are available to address a deviated nasal septum, hypertrophic inferior turbinates, or nasal valve obstruction. The otolaryngologist should be aware of these various procedures in order to choose the most appropriate combination for each patient.

HIGHLIGHTS

- Nasal obstruction is common and caused by numerous etiologies, some reversible with medical therapy and some requiring surgical correction.
- Patients should be optimized with medical therapies even when a surgical intervention is planned.
- Causes of nasal obstruction amenable to surgical correction include septal deviation, turbinate hypertrophy, nasal valve collapse, nasal polyps, choanal atresia, and sino-nasal tumors.
- Caudal septal deflections can be challenging to correct, and care must be taken to provide a caudal strut to prevent postoperative nasal saddling.
- The most common complication of septoplasty is a septal perforation; however, other complications include nasal saddling, anosmia, septal hematoma, failure to correct deflection, and rarely CSF leak.
- A combination of techniques may be used to address the hypertrophic inferior turbinate with successful outcomes.
- Overly aggressive inferior turbinate reduction or resection may lead to rhinitis sicca or empty nose syndrome postoperatively.
- The internal and external nasal valve is complex and numerous structural abnormalities, including destabilization of the nasal septum and lower lateral cartilage, contribute to obstruction in this region.

43 Endoscopic Orbital and Lacrimal Surgery

Erik Kent Weitzel *Raymond I. Cho*

With the advent of endoscopic approaches to the sinuses, creative surgeons recognized additional potential for these techniques and quickly developed approaches to the medial and inferior orbit. The benefits were obvious when targeting the orbital apex that is exposed safely and completely with endoscopic techniques. Over time, the techniques have expanded to a wide range of procedures including dacryocystorhinostomy (DCR), optic nerve decompression, and anterior ethmoidal artery (AEA) ligation.

PERTINENT ORBITAL ANATOMY

Bony Anatomy

The orbit is defined as the bony confines circumferentially surrounding the eye and the extraocular musculature. The bony anatomy of the orbit involves a complex contribution of seven different bones of the skull. The medial orbital bone progresses anterior to posterior from the robust frontal process of the maxilla, to a thin lacrimal bone, then to an extremely thin ethmoid bone contribution also known as the lamina papyracea, and finally to the lesser wing of the sphenoid that houses the optic foramen. It is important when performing endoscopic DCR to understand that the lacrimal fossa is formed by fairly equal contributions of two bones joined vertically (see Fig. 43.1): anteriorly, the thicker frontal process of the maxilla and posteriorly, the very thin lacrimal bone. The orbital floor slopes superiorly as it courses from anterior to posterior and includes the orbital surface of the maxillary bone, zygomatic bone (anterolateral), and the orbital process of the palatine bone. The lateral wall consists of the orbital surface of the zygomatic bone anteriorly and the greater wing of the sphenoid posteriorly. The roof consists of the orbital surface of the frontal bone anteriorly and the lesser wing of the sphenoid posteriorly.

Vascular Anatomy

The endoscopic orbital surgeon must be an expert on the vascular anatomy of the orbit, particularly the ethmoidal arteries. Virtually, the entire arterial supply of the orbit arises from the ophthalmic artery, the first branch of the internal carotid artery, which enters the orbit through the optic foramen and gives rise to the central retinal, ethmoidal, lacrimal, zygomatic, supraorbital, and supratrochlear arteries. The AEA enters the anterior ethmoidal foramen through the frontoethmoidal suture at or just under the level of the skull base (fovea ethmoidalis) (Fig. 43.2). Because of its consistent relationship to the skull base, the AEA is safely used as an upper limit of entry into the anterior ethmoidal sinuses when entering the ethmoid sinuses through an orbital approach to prevent cerebrospinal fluid (CSF) leak (also known as external ethmoidectomy). The AEA bridges across the anterior ethmoid sinus between the second and third ethmoidal lamellae (1) along a posterolateral to anteromedial trajectory and back into the intracranial space through the lateral lamellae of the cribriform plate. There is often a natural dehiscence of the orbital bone around the anterior ethmoidal foramen that may be evident after anterior ethmoidal dissection when pushing on the eye. The posterior ethmoidal foramen lies 12 mm posterior to the anterior ethmoidal foramen and houses the posterior ethmoidal artery (PEA). Unlike the AEA, the PEA will not lie in a mesentery and is positioned at the junction of the anterior face of the sphenoid's intersection with the skull base.

The infraorbital artery, a branch of the maxillary artery, does not normally enter the orbital space, but deserves specific mention because of the potential for the endoscopic orbital surgeon to encounter it during medial orbital decompression. Traveling with the infraorbital nerve and vein, it enters the infraorbital groove/canal from the pterygopalatine fossa, sending a perforating branch into the

orbit through the floor before exiting the maxillary bone in the medial midface.

An intimate knowledge of the vascular anatomy of the orbit is essential for the endoscopic orbital surgeon to avoid the potentially devastating consequences of orbital hemorrhage. Maintaining patency of the central retinal artery and ophthalmic veins are critical for vision, and temporary interruptions of the blood supply can lead to permanent visual loss in less than 2 hours. Orbital compartment syndrome frequently develops as a result of retrobulbar hemorrhage or volume-occupying orbital lesions, and the orbit must be decompressed when the orbital pressure nears the occlusion pressure of the central retinal artery. Signs and symptoms of impending visual loss include blurred vision, loss of color vision, afferent pupillary defect, severe proptosis, or ophthalmoplegia. Monitoring intraocular pressures during such events with tenotomy is critical to indicate vascular perfusion to the retina. Intraocular pressures are normally between 10 and 21 mm Hg with a mean of 16 mm Hg. Pressures exceeding 30 to 40 mm Hg necessitate emergency surgical intervention, including lateral canthotomy with inferior and/or superior cantholysis, and orbital decompression if necessary. Studies have shown that lateral canthotomy and inferior cantholysis can effectively reduce intraocular pressures by 30 mm Hg (2). Involvement of an ophthalmologist in the management of orbital compartment syndrome is mandatory.

Neuromuscular Anatomy

Relevant neuromuscular anatomy includes the optic nerve and orbital apex contents. The orbital apex is variably defined, but typically described as the region of the posterior orbit starting at the annulus of Zinn where the rectus muscles originate and extending posteriorly to the optic foramen. Anatomical organization of the posterior orbit is best discussed in relation to the foramina. The superomedially located optic foramen transmits the optic nerve and ophthalmic artery and is located 6 mm posterior to the posterior ethmoidal foramen. The superior orbital fissure (SOF) transmits structures from the middle cranial fossa and is split in two by the origin of lateral rectus located in the annulus of Zinn (Fig. 43.3). The relationship of structures transmitted through the SOF relative to the origin of the lateral rectus defines them as either intra- or extraconal. The superior extraconal neurovascular structures include the lacrimal (V1 branch), frontal (V1 branch), trochlear (IV) nerves, and superior ophthalmic vein. Intraconal nerves include the superior and inferior divisions of the oculomotor (III), nasociliary (V1), and abducens (VI) nerves (3). The inferior orbital fissure provides a passageway into the pterygopalatine fossa and transmits the maxillary nerve (V2), infraorbital artery, and inferior ophthalmic vein (4).

No discussion of the orbit is complete without a discussion of cranial nerve II. The optic nerve is segmented into four parts including the intracranial, intracanalicular, intraorbital, and intraocular segments. From the chiasm, the intracranial component courses approximately 10 mm before entering the optic foramen. The next 8 mm of the optic nerve, called the intracanalicular segment, courses through the optic canal and is the only portion of the nerve confined within bone. The nerve then emerges from the optic canal and extends 30 mm to the globe as the intraorbital segment. The last portion of the nerve is the very small intraocular segment that lacks the three meningeal sheaths and is not myelinated (5).

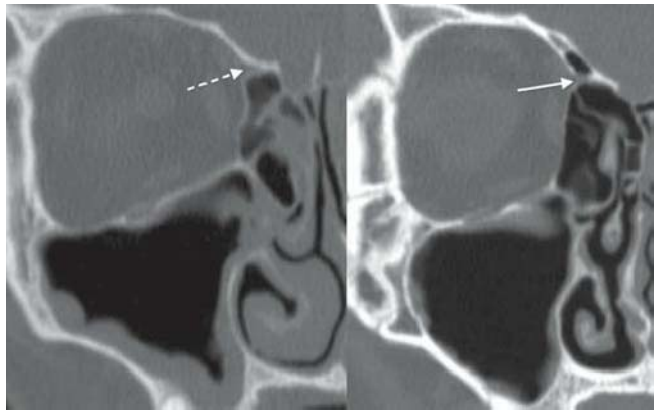

Figure 43.2 Coronal bone-window CTs of the right orbit in two different patients showing the AEA in two configurations. *Dotted arrow* shows an AEA attached to the skull base and not at risk for damage during clearance of the ethmoid skull base. The solid *arrow* shows a mesenteric AEA that is at risk for damage during sinus surgery.

Lacrimal Anatomy

The lacrimal system lies just anterior to the medial insertion of the orbital septum and therefore is by definition extraorbital although typically discussed in conjunction with orbital topics (6). The overall flow of tears derives from the combined output of the two lobes of the lacrimal gland (orbital and palpebral lobes), the major reflex lubricators of the eye, and small conjunctival glands responsible for basal secretion. After moisturizing the eye, tears enter the superior or inferior lacrimal puncta, course through the superior or inferior canaliculi into the common canaliculus, and emerge into the lacrimal sac through the valve of Rosenmuller. Ten percent of patients will not have a common canaliculus so that the inferior and superior canaliculi penetrate the sac separately. Approximately one-third of the lacrimal sac lies above the common canaliculus (6). This superior lacrimal sac region, known as the fundus, extends above the axilla of the middle turbinate, which becomes important when attempting to marsupialize the entirety of the lacrimal sac. Inferiorly, the sac transitions into the lacrimal duct before emerging under the inferior turbinate through Hasner valve. The lacrimal system is driven by the pump action of blinking, thereby forcing tears through the horizontally oriented canalicular anatomy (Fig. 43.4).

ADULT DACRYOCYSTORHINOSTOMY

Background

The most common patients considered for DCR are females in their early 60s complaining of continuous tearing of a single eye (7). The causes of epiphora are diverse but predictable relative to the patient's age. Children typically will have a congenitally imperforate Hasner valve effectively treated with short-term lacrimal intubation. Young adults' epiphora is most likely caused by either trauma related anatomical disturbances or herpetic inflammation with stenosis of the canalicular system. Epiphora in middle-aged women is generally caused by a dacryolith formed in the lacrimal sac. Finally, the etiology in elderly women is usually from idiopathic stenosis of the distal lacrimal duct. The two etiologies typical of middle-aged and elderly women are the only ones amenable to DCR. Incomplete obstructions of the lacrimal system will differ from typical

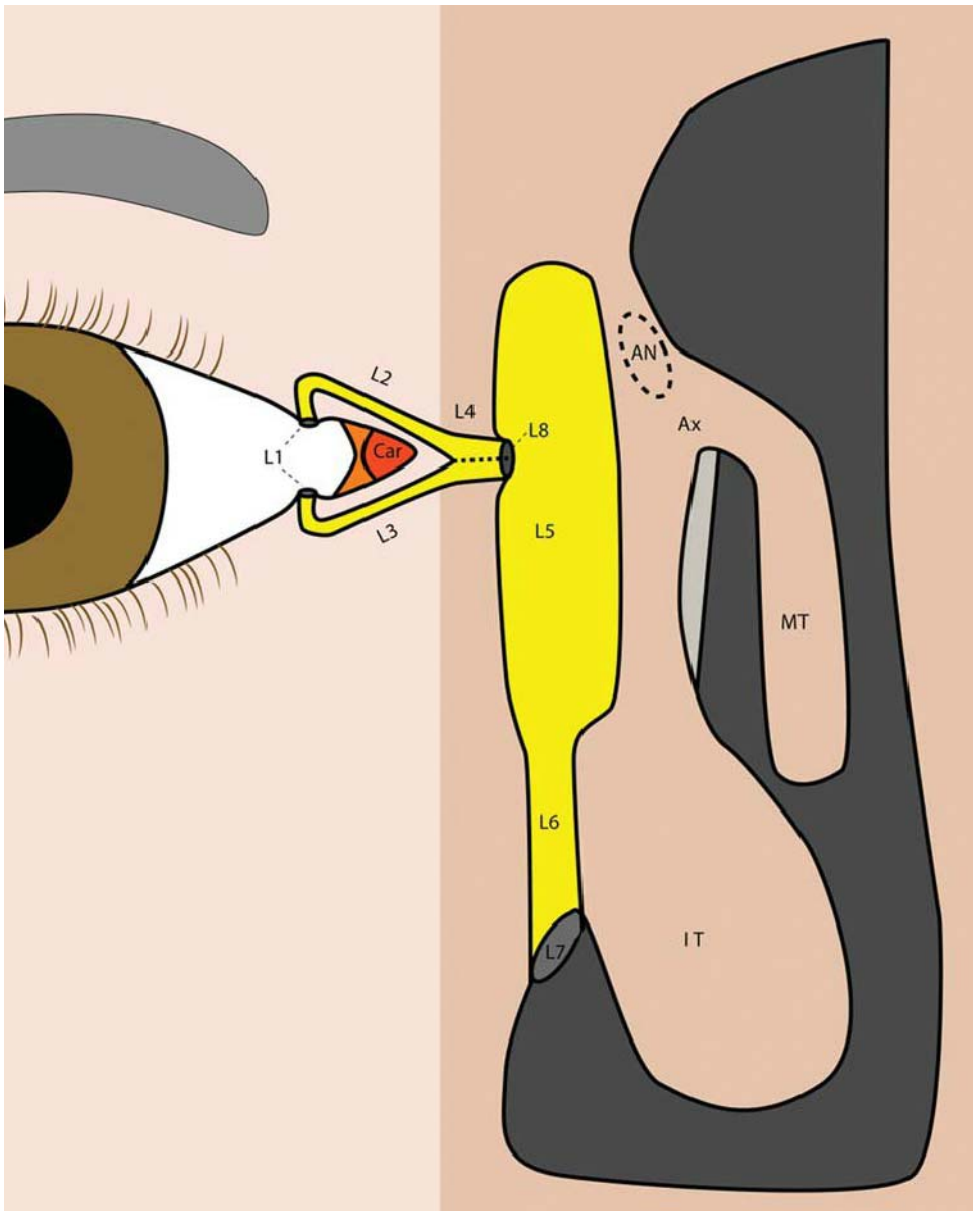

Figure 43.4 Right lacrimal system. Lacrimal puncta in the center of the mounded papilla (*L1*); Superior (*L2*) and Inferior (*L3*) canaliculi merge into the common canaliculus (*L4*). *Dotted line* reminds us that 10% of patients do not have a common canaliculus and separately enter lacrimal sac (*L5*) through the common internal punctum (*L8*) also called the valve of Rosenmuller. A substantial amount of the sac extends above the axilla (*Ax*) of the middle turbinate (*MT*) and often requires extensive drilling through the frontal process of the maxilla and entry into the agger nasi (*AN*) cell to open fully. Lacrimal duct (*L6*) drains through Hasner valve (*L7*) under the inferior turbinate (*IT*) to enter the inferior meatus.

presentations as they tend to only have epiphora in cold or windy weather, but fail to have tearing when inside, and may not develop the infections that are common with complete obstructions.

The purpose of the lacrimal system is to protect and hydrate the cornea through the continuous production, movement, and drainage of tears. The tear film is a delicately balanced multilayered conglomeration of three different liquid components. The largest contribution comes from the central aqueous layer largely produced by the two lobes of the lacrimal gland with minor contributions from the glands of Wolfring and Krause found within the eyelids. The deep layer of the tear film consists of mucus produced by conjunctival goblet cells that cause the aqueous layer to adhere to the cornea. The superficial layer of tear film is a very thin layer of oil produced by the meibomian glands that prevents evaporation of the aqueous layer.

Evaluation

In true epiphora, tears run down the face, which is to be distinguished from a "watery eye" in which tears do not

drain onto the skin. This distinction is important because epiphora is usually caused by obstructions within the canalicular system or nasolacrimal duct and is treated with surgery, while disorders that cause a watery eye are generally treated medically. While watery eyes also drain through the lacrimal system, the cause is usually an excessive accumulation of tears on the surface of the eye due to heterogeneous tear distribution from ineffective blinking or deficits in tear film layering, which leads to ocular irritation and reflex tearing.

A comprehensive examination of epiphora begins with careful study of the lids. The position of the punctum should approximate the globe. Ectropion or entropion will lead to abnormal punctal position and prevent normal drainage of tears. The eyelashes should also be inspected to make sure they are not rotated and causing ocular irritation. Evaluation of lacrimal pump problems includes assessment of lid deformities, incomplete blink due to facial nerve weakness, or lid laxity. Lid laxity is tested with the two-part snap test that involves gently pulling the lid away from the eye and releasing it. A normal lid cannot be pulled 6 mm away from the conjunctiva and quickly snaps back into normal position.

The lacrimal system is studied by means of the dye disappearance test, probing of the canaliculi, and irrigation. The examination is begun by anesthetizing the eye topically, followed by placement of a large drop of 2% fluorescein in both eyes. In a normal eye, the fluorescein should clear from the eyes within 5 minutes. Recovery of dye from the nares with a cotton-tipped applicator (CTA) or nose-blowing (the primary dye or Jones 1 test) also indicates functional patency of the lacrimal drainage system. Any sign of dacryocystitis on exam suggests obstruction.

If the above tests reveal the presence of obstruction, further testing can identify the location of the obstruction. Lacrimal probing is performed with a 0 or 00 Bowman probe through the canaliculi with care not to create a false passage during probing. A normal exam threads the probe along the canaliculus of interest into the common canaliculus, through the common internal punctum (valve of Rosenmuller), and "hard-stops" when it impacts the mucosa-covered bone of the medial lacrimal sac. If the probe cannot pass soft tissue in the common canaliculus or in the sac, the probe is said to have had a "soft-stop" implying proximal lacrimal system pathology. Finally, lacrimal irrigation is performed with a lacrimal irrigation cannula through the lower or upper canaliculus. It should be easy to irrigate and cause flow into the nose that the patient can taste. Reflux around the needle or out of the opposite canaliculus is abnormal. Probing and irrigation performed after the Jones 1 test is known as the Jones 2 test, and can help to localize the level of lacrimal system obstruction. Reflux of clear fluid from the same punctum being irrigated indicates obstruction proximal to the common canaliculus; reflux of clear fluid from the opposite punctum indicates obstruction of the common canaliculus or common internal punctum; and reflux of fluorescein-stained fluid through the opposite punctum indicates nasolacrimal duct obstruction. A final element of the exam includes a thorough nasal exam to exclude obstructing intranasal pathology (8).

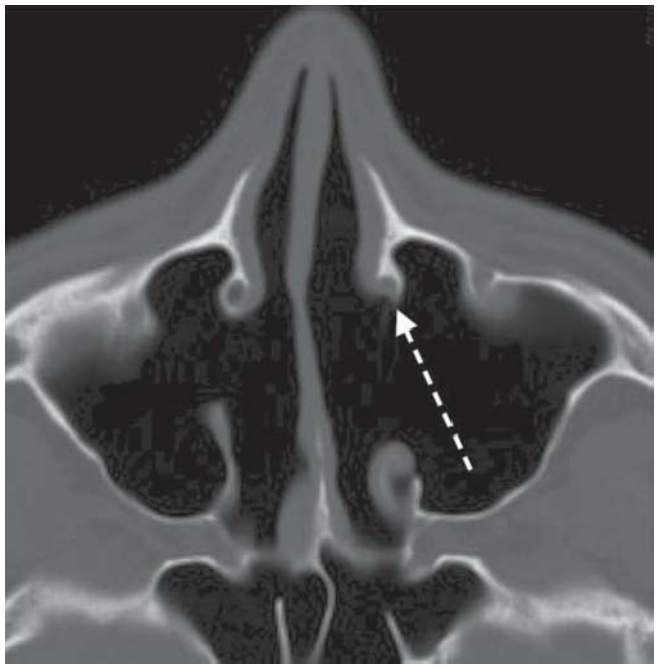

Figure 43.5 Axial bone-window CT of lacrimal duct trauma and stenosis caused by excessive back-biting during maxillary antrostomy. The posterior wall of the nasolacrimal duct is absent (*arrow*). Endoscopic intranasal exam was able to identify the pathology during the initial patient evaluation leading to rapid effective treatment with DCR.

An abnormality detected on this exam suggests lacrimal obstruction, and coupled with appropriate symptoms, is justification for DCR. However, sometimes patients complain of epiphora, but the exam is not convincing for obstructive pathology. In these cases, lacrimal scintillography is indicated to identify those cases with partial obstruction that can still benefit from DCR. Dacryocystogram has also been described as a useful study for identification of complete anatomic blockages; however, this study may be considered redundant to a high-quality exam (Fig. 43.5).

Technique Options

Lacrimal duct and sac obstructions are commonly treated by three procedures including external, endoscopic, and laser-assisted DCR. Outcomes with endoscopic procedures are highly dependent on how the sac is managed, thus any discussion on endoscopic DCR must specify extent of sac marsupialization. The two most commonly discussed variations on endoscopic technique involve either complete preservation and marsupialization of the medial sac or medial lacrimal sac wall excision. Unsuccessful options to be avoided include placement of a grommet through the medial sac wall or a vertical sac slit without

TABLE 43.1 EXTENSIVE REVIEW OF THE LITERATURE BY LEONG ET AL. (7) SUMMARIZED TYPICAL OUTCOMES OF POPULAR DCR TECHNIQUES

Procedure	Immediate Success Rate (%)	Long Term Success Rate
Endoscopic (11)	84–94	92% at 6 y
External (12)	65–100	94% at 4 y
Endonasal Laser-Assisted (13)	47–100	38% at 5 y

marsupialization, both associated with over 65% failure rates (9). Less common techniques include transcanalicular laser-assisted, balloon dacryoplasty, and conjunctivodacryocystorhinostomy (CDCR).

Procedure outcomes vary widely, with typical success rates for the most commonly reported procedures summarized in Table 43.1. Success rates are similar for endonasal and external DCR (10) and decisions regarding choice of procedure are highly dependent on surgeon experience. Laser-assisted DCR suffers from worse long-term results than the other two popular techniques. For atrophic sacs, an alternative technique maintains permanent silastic tubes through an opened sac. If the patient can tolerate the tubes, success rates approximate sac marsupialization (9). However, most patients will complain of foreign body sensation that requires frequent stent adjustment swaying surgeons toward a nonstented option in a majority of these patients.

Adjunctive therapies widely used at the conclusion of DCR including the use of antimetabolite agents and postoperative silicone tubing of the lacrimal system may not be beneficial. Research now suggests that antimetabolites including Mitomycin C or 5-Flourouracil most likely do not improve results (7); however, a few controversial studies have reported better outcomes (14,15). Stenting the proximal lacrimal system with silicone tubing for 1 to 6 months has been a standard postoperative measure to encourage the system to heal in a patent configuration. However, recent reports suggest that tubing may be considered optional with little added benefit to outcomes (16,17).

Endoscopic Technique (18,19)

Endoscopic "access" septoplasty is performed in a majority of cases prior to beginning DCR. This limited septoplasty selectively addresses the anterior-superior septum allowing full exposure to the axilla of the middle turbinate. Additional preparatory work includes utilizing a 30-degree scope for the procedure angled in an upward/lateral direction, injection of the middle turbinate axilla with 1:100,000 epinephrine, and placement of 1:1,000 epinephrine-coated pledgets in the anterior nasal cavity to create vasoconstriction for hemostasis (Fig. 43.6).

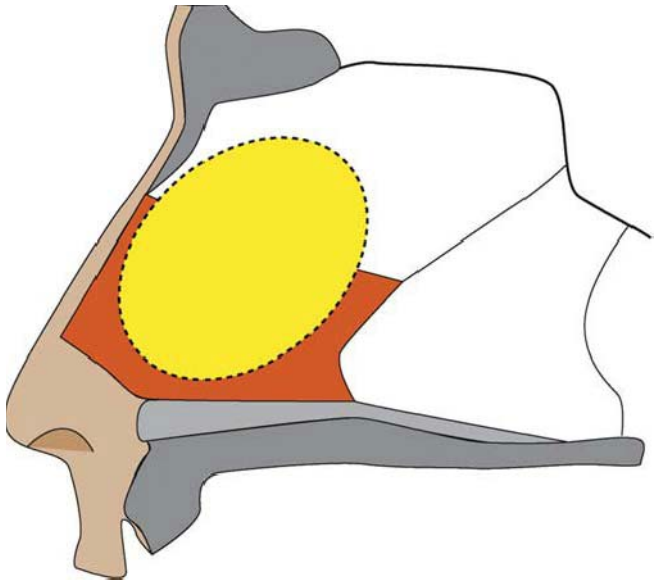

Figure 43.6 Dotted line represents the section of septum (bony and cartilaginous) removed in an "access septoplasty," which optimizes access to the axilla of the middle turbinate. Note that this limited septoplasty avoids the inferior portions of the septum, which are time consuming to remove.

The DCR flap is started posterosuperiorly at a point 3 mm posterior to and 8 to 10 mm above the axilla. The incision is developed 10 mm anterior to the axilla and then dropped inferiorly down to the level of the insertion of the inferior turbinate. A final horizontal incision is created at the level of the insertion of the inferior turbinate from the uncinate to the base of the existing incision. A sharp suction freer is used to elevate this flap over the frontal process of the maxilla, off of the lacrimal bone, and on to the uncinate where it will remain posteriorly pedicled throughout the case. It is also important to elevate the flap off of the axilla. The mucosal flap is protected during the case by rolling it medial to the middle turbinate. Hemostasis is maintained by periodically placing pledgets with 1:1,000 epinephrine (Fig. 43.7).

A round knife or Woodson elevator is used to flake off the very thin lacrimal bone of the posterior lacrimal fossa. A finger pressed on the ipsilateral medial canthus will help identify the lacrimal sac. A forward biting Hajek-Koeffler punch or a forward biting 2 or 3 mm Kerrison is used to remove the anterior half of the lacrimal fossa made of the extremely thick frontal process of the maxilla. The rongeur is carefully positioned between the sac and bone and can remove the majority of this bone. Finally, a DCR diamond drill bit is used to remove any bone that was ergonomically impossible to remove with the rongeur. Drilling is also carried out circumferentially around the sac saucerizing this bone to create a crater in which the lacrimal sac is prominently exposed. Often, the agger nasi cell is entered during this process due to the superior extent of the natural

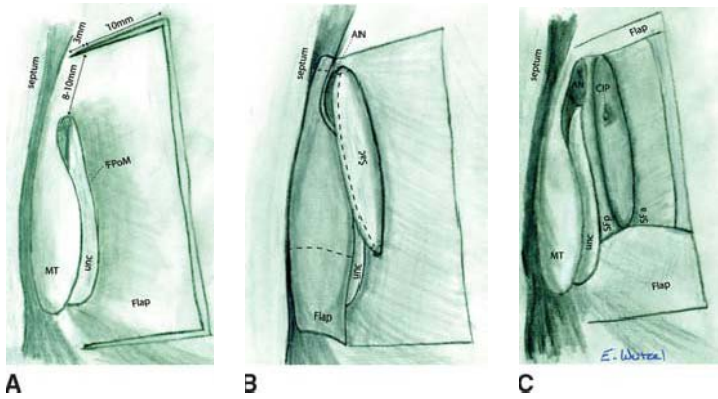

Figure 43.7 Left DCR. Diagram **(A)** shows the dimensions of a typical DCR flap relative to the frontal process of the maxilla (FPOM), uncinate (unc), and middle turbinate (MT). In **(B)**, the flap has been elevated and rolled medial to the middle turbinate. The bone over the lacrimal sac has been removed and saucerized producing a "proud" sac that prominently emerges from the surrounding bone. Bone removal superiorly usually opens the agger nasi (AN) cell. Dotted lines represent incisions to be made on the DCR flap (for removal of the central portion) and the lacrimal sac (for marsupialization). In **(C)**, the DCR is complete (without intubation tubes) showing the marsupialized anterior (SFa) and posterior (SFp) lacrimal sac flaps covering exposed bone and primarily approximating surrounding mucosa.

position of the high lacrimal sac. Once entered, adequate additional bone and mucosa should be removed so that this cell does not obstruct during the healing process. It is imperative during the use of the rongeur or drill that the delicate lacrimal sac is not damaged.

Lacrimal puncta are dilated if necessary prior to insertion of Bowman lacrimal probes. The probe is carefully routed either superiorly or inferiorly (whichever is easier) along the canalicular system to emerge into the sac. Intranasal inspection will reveal a pinpoint medial tenting of the sac if the probe has passed the common internal punctum. If the probe gets caught within the canalicular system, the sac will have a broad ballooned movement and should not be incised. Once the lacrimal probe is holding only the medial wall on tension, an angled knife blade (Beaver blade no. 66) is used to create a vertical incision to the top and bottom of the sac. A ball probe can be inserted into the sac at this point to check the full vertical height to ascertain that the entire medial sac has been cleared of bone. Belucci scissors are used to release the posterior flap at its superior and inferior limits whereas a highly recurved sickle knife, a no. 12 blade, or a thin backbiter can be used to release the anterior flap in a similar fashion. If the surrounding bone has been properly saucerized, the medial sac mucosa will naturally fall and lay open without curling up. The common internal punctum should be visible in the center of the sac. The lateral nasal wall flap lifted at the beginning of the case is now trimmed of mucosa to accommodate the now opened sac. This usually results in leaving only a small band of mucosa superiorly and inferiorly to cover exposed bone.

For procedures that require temporary or permanent stenting with silicone lacrimal tubes, a wide variety are available that can accomplish this task. The tubes are inserted through both the superior and inferior canalicular pathways to emerge through the common canaliculus. Individually, they are withdrawn from the nose. While a cotton swab is placed in the medial canthus to reduce tension on the lacrimal puncta, a 1 cm piece of gelfoam is slid up the tubes to hold the flaps in good position. A short segment of a 14°F catheter is slid up the tubes as well to hold the gelfoam in place. Finally, a medium clip secures the tubes together just behind the catheter segment (disposable clip appliers create too much force and will cut the tubes). The tubes are trimmed to keep the intranasal portion of the tube from bothering the patient.

Patients are sent home on oral antibiotics for 10 days, antibiotic eye drops, and pain medications. Patients follow up at 6 weeks for tube removal, which is accomplished by cutting the tubes at the medial canthus while retracting the looping tube segment between the lacrimal puncta with a right-angled ear hook. The tubes are then grasped and removed through the nose. Fluorescein dye placed in the ipsilateral eye should show excellent nasal penetration through the marsupialized sac.

Complications

Perioperative

Endoscopic DCR has a highly variable reported rate of complication. Wormald's seminal description of the technique reported one delayed epistaxis in 44 patients (18). However, an extensive literature review showed much higher reports of complication with endoscopic DCR than external or laser-assisted techniques (7). The most common intraoperative complication is reported as wound hemorrhage followed by orbital fat exposure (7). However, fat exposure should be an uncommon complication as it can only occur when the dissection is taken posterior to the uncinate, which is an easily identifiable posterior landmark (18). Postoperative complications of endoscopic DCR are most frequently periorbital hematoma followed by synechiae.

Surgical Failures

Silicone stents placed under too much tension may cause "cheese wiring" of the lacrimal puncta and lead to iatrogenic epiphora due to misaligned puncta relative to the conjunctiva. This has been reported in up to 0.1% of cases and is easily prevented by placement of the cotton swab end of a CTA in the medial canthus and looping the lacrimal tubes around it while it is secured intranasally.

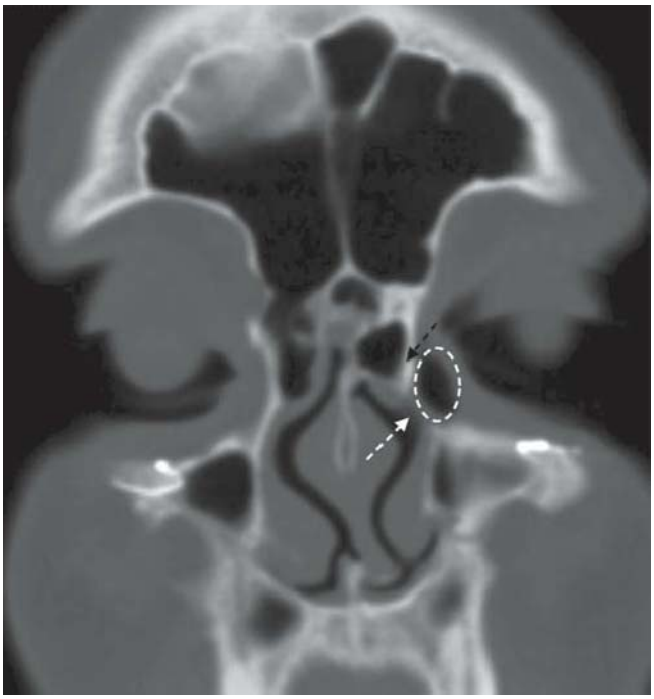

Figure 43.8 Failed left DCR. Coronal bone-window CT shows that the lacrimal sac (white dotted oval) has inadequate bone excision, creating a small inferomedial fistula (*white arrow*). The *black arrow* highlights a large segment of bone making up the lateral wall of the agger nasi cell that when removed at revision surgery cured the patient's symptoms.

A properly placed tube will place no tension on the puncta but not drift on to the cornea. Another common reason for surgical failure and need for revision is inadequate bony removal. As seen in Fig. 43.8, the previous surgeon has removed only a small portion of the bone inferomedial to the sac. This results in a chronic fluid meniscus due to a so-called sump-syndrome and lacrimal pump failure due to increased system resistance. Good outcomes in DCR mandate complete bone removal medial to the lacrimal sac and saucerization of the surrounding bone to allow the lacrimal sac flaps to lay open when marsupialized.

Revisions

Revision DCR is unchanged from the primary technique. However, attention must be paid to the sac available for marsupialization. Prior surgeons may have inadequately opened the existing sac leading to the symptomatic failure, where the ample remaining mucosa makes the revision quite simple. Outcomes in this circumstance are expected to be similar to primary DCR. If however, the available sac is highly scarred or small, outcomes will be compromised. Free mucosal grafts circumferentially covering damaged mucosa around the common internal punctum have been described to encourage primary wound healing. These can be placed as a free graft strung along the silicone tubes into the nose at the completion of surgery and placed under the gelfoam, which will hold it in place (20). Overall outcomes of revision endoscopic DCR tend to still be quite good regardless of sac configuration with 89% success rates reported (19,21).

Conjunctivodacryocystorhinostomy

Epiphora due to obstruction or loss of the canalicular system can be particularly challenging to treat. Causes include trauma, tumors, surgery, chronic inflammation, herpetic disease, topical medications, and chemotherapeutic agents (e.g., Docetaxol). Depending on the level and severity of obstruction, punctal/canalicular probing, dilation, trephination, reconstruction, or intubation have widely variable but often disappointing results. CDCR is considered by most surgeons a last resort, but in many cases can effectively reestablish lacrimal outflow.

The CDCR procedure bypasses the entire normal lacrimal outflow system by creating a direct communication between the medial tear lake and the nose using a Pyrex (Jones) tube (Gunther-Weiss Scientific Glassblowing, Portland, OR). It can be performed following failed external or internal DCR, or in conjunction with a primary DCR. Although the Jones tube can be placed without creating a formal DCR ostium (as described below), many surgeons feel that the presence of an ostium improves the chances for long-term success. After infiltrating the caruncle of the affected eye and the ipsilateral nasal mucosa with 2% lidocaine with 1:100,000 epinephrine, the caruncle is partially or completely excised to create room for the flange of the Jones tube. A Henderson guide needle is then placed through the medial fornix and directed in an inferomedial direction into the nose under endoscopic visualization, or under direct visualization if a primary external DCR is also being performed. Ideally, the needle should enter the nose anterior to the middle turbinate. Once the proper guide needle position has been established, a Henderson trephine is passed over the needle to widen the tract. The trephine itself can be placed into an optimal position in the nose, with the tip sufficiently past the lateral nasal wall but well clear of the septum, and measured at this point to determine the length of the Jones tube. Additional endonasal procedures such as septoplasty or partial turbinectomy may be indicated to ensure that the distal end of the Jones tube does not become obstructed. The trephine is withdrawn and the appropriately selected Jones tube is passed over the guide wire into the nose. Various design modifications of the Jones tube are available, such as frosting, Medpor coating, angling, multiple flanges, and suture holes, all with the intent of decreasing the risk of postoperative tube migration. With the Jones tube in position, a drop of irrigation solution is placed within the medial fornix, which should be observed to quickly disappear through the Jones tube.

Postoperatively, the patient is instructed to daily place tears within the medial fornix and sniff. While a functioning Jones tube can work extremely well, the long-term

propensity for occlusion or migration can make postoperative management a chore for many individual patients and their surgeons.

ORBITAL DECOMPRESSION (22)

Background

Orbital decompression had been performed for over a century prior to the description in the 1950s by Walsh and Ogura (23) of a new technique that approached the medial wall and floor of the orbit through a Caldwell-Luc. The next major advancement occurred in the 1990s with introduction of endoscopic techniques when Kennedy (24) and Michel (25) independently described medial wall decompression. The improved exposure of the medial orbital apex with the endoscopic approach quickly made this the more popular approach for otolaryngologists.

Indications

Endoscopic orbital decompression is utilized to diminish pressure within the orbit and cause globe recession for Graves orbitopathy, retro-orbital hemorrhage, and orbital cellulitis/abscess. Specific indications include compressive optic neuropathy, exposure keratitis, or aesthetic concerns.

Dysthyroid orbitopathy resulting from Graves' disease-related inflammation of orbital contents is the most common reason to utilize orbital decompression. The orbital inflammation with Graves disease is due to a combination of T-cell infiltration and deposition of glycosaminoglycans in both the orbital fat and the extraocular muscles. The clinical presentation of dysthyroid orbitopathy is highly variable, with some patients manifesting primarily orbital fat expansion, while others suffer predominantly from extraocular muscle enlargement. The tendency is for the former to exhibit proptosis and exposure keratopathy, and the latter group strabismus and compressive optic neuropathy.

Dysthyroid orbitopathy develops in an acute stage with active inflammation over 18 months and then stabilizes through fibrosis into a chronic stage. It is preferable to perform surgery after the disease process has stabilized. Acute-stage manifestations can be treated medically with intravenous (IV), oral, injected steroids, orbital radiation, or immunomodulatory agents until the active orbitopathy stage resolves. However, vision-threatening complications that are unresponsive to medical therapy may necessitate surgery during the active phase. Surgical treatment of dysthyroid orbitopathy has been classically performed in a staged fashion, with orbital decompression performed first, followed by strabismus surgery, upper and/or lower lid recession, and blepharoplasty. The choice of decompression should be based upon the degree of proptosis and/or exposure keratopathy, and the presence of compressive optic neuropathy (Fig. 43.9).

Figure 43.9 8mm of proptosis reduction (before [**A**] and after [**B**]) was achieved with bilateral lateral orbital decompression and upper and lower lid recessions. This patient's results show the dramatic aesthetic improvement that can be achieved with this procedure.

Retrobulbar or orbital hemorrhage is generally a traumatic or iatrogenic complication that can result in vision-threatening orbital compartment syndrome. Orbital decompression can be utilized if initial lateral canthotomy and cantholysis do not effectively decrease intraorbital pressures. If enophthalmos develops, delayed floor or medial wall reconstruction can be performed after hematoma resolution.

Orbital cellulitis can require decompression if medical management doesn't adequately control orbital pressures. Since orbital cellulitis typically results as a complication of acute sinusitis, total sphenoethmoidectomy performed prior to endoscopic decompression will generally resolve the underlying disease process as well. Due to active inflammation, these cases tend to have extremely poor surgical fields heightening their difficulty. Periorbital abscesses unresponsive to medical management benefit from localized orbital decompression to drain the purulence (Fig. 10). This procedure is made fairly simple with the use of image guidance, a malleable suction freer, and a neuropatty to dissect between the periorbita and orbit (Fig. 43.11).

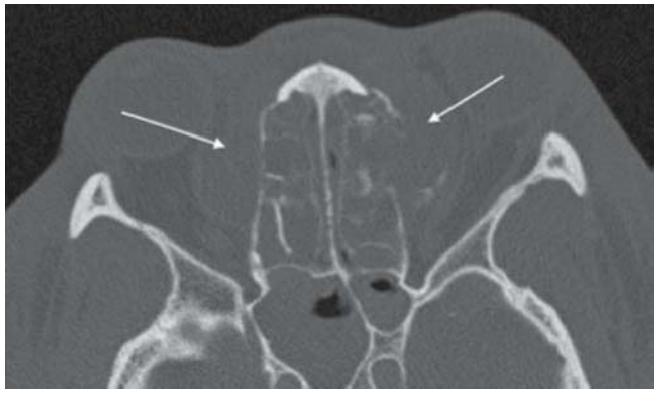

Figure 43.10 Axial bone-window CT showing bilateral retrobulbar hematomas (*arrows*) caused by blunt trauma. Note the associated lamina papyracea fractures and bilateral proptosis.

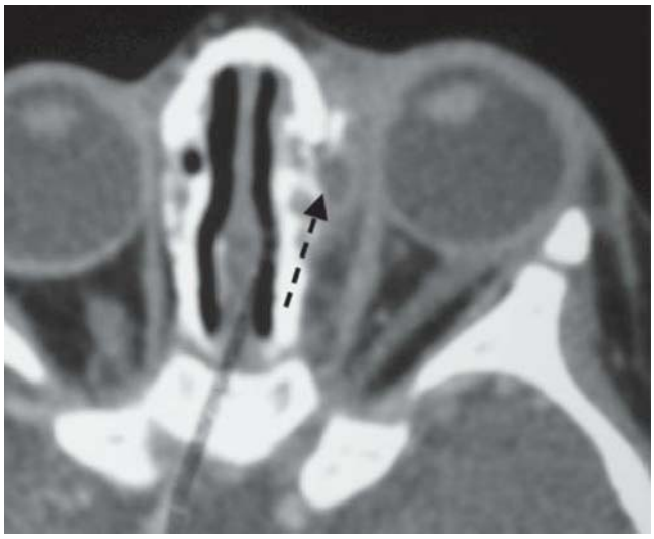

Figure 43.11 Axial contrast-enhanced CT of a child with left ethmoid sinusitis resulting in periorbital cellulitis and orbital subperiosteal abscess (*arrow*).

TYPES OF DECOMPRESSIONS

Medial

The true medial wall of the orbit consists of the lamina papyracea, a paper-thin portion of the ethmoid bone. Removal of this bone is accomplished either through a transnasal endoscopic approach, transcaruncular, medial lid crease, or Lynch incision. Some rhinologists consider isolated removal of the lamina papyracea inadequate and additionally remove the orbital floor medial to the infraorbital nerve. Although this is commonly termed "medial wall decompression" in our literature, the removal of the floor component technically makes this a hybrid procedure. Confusion around these descriptions makes it imperative that rhinology and oculoplastic teams preoperatively discuss common surgical expectations. Both procedures require a total ethmoidectomy and wide maxillary antrostomy to prevent postoperative obstructive sinusitis and allow greatest possible medial decompression into the nose (Fig. 43.12). Modifications of this technique exist that selectively decompresses the posterior orbit for isolated optic neuropathy (26).

Lateral

Lateral orbital decompression includes removal of the greater wing of the sphenoid bone via either a lateral canthotomy, lateral lid crease, or extended lateral canthal incision. Lateral decompression can be used either alone or in conjunction with a medial decompression to provide a "balanced" decompression. Studies suggest a lower rate of diplopia with this procedure while achieving similar or even greater amounts of recession compared to medial floor/medial wall removal (27–29). The lower rates of postoperative new-onset diplopia are thought to be due to preservation of natural vectors of globe movement by allowing the orbital contents to spill over the orbital confines in a balanced medial and lateral fashion (Fig. 43.13). Although medial decompression has traditionally been advocated as the surgery of choice for thyroid-related compressive optic neuropathy, lateral decompression has also been shown to be efficacious for this condition (30).

Floor (Posterior/Anterior)

The orbital floor is accessible through endoscopic, transantral, and translid approaches and historically was the workhorse of decompression until supplanted by medial and

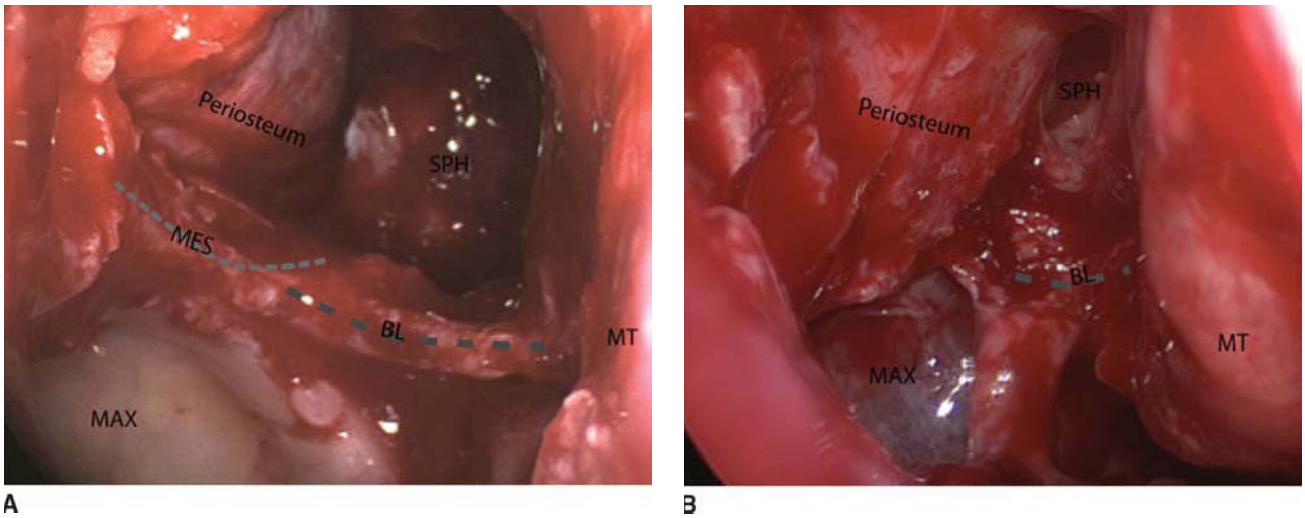

Figure 43.12 Right endoscopic view after **(A)** isolated medial wall and **(B)** medial/floor decompression. Note the increased exposure of the orbital periosteum in **(B)** due to removal of the maxilloethmoid suture (MES) and orbital floor lateral to V2. View includes maxillary (MAX) and sphenoid (SPH) sinuses as well as the middle turbinate (MT) and the base of the basal lamella (BL).

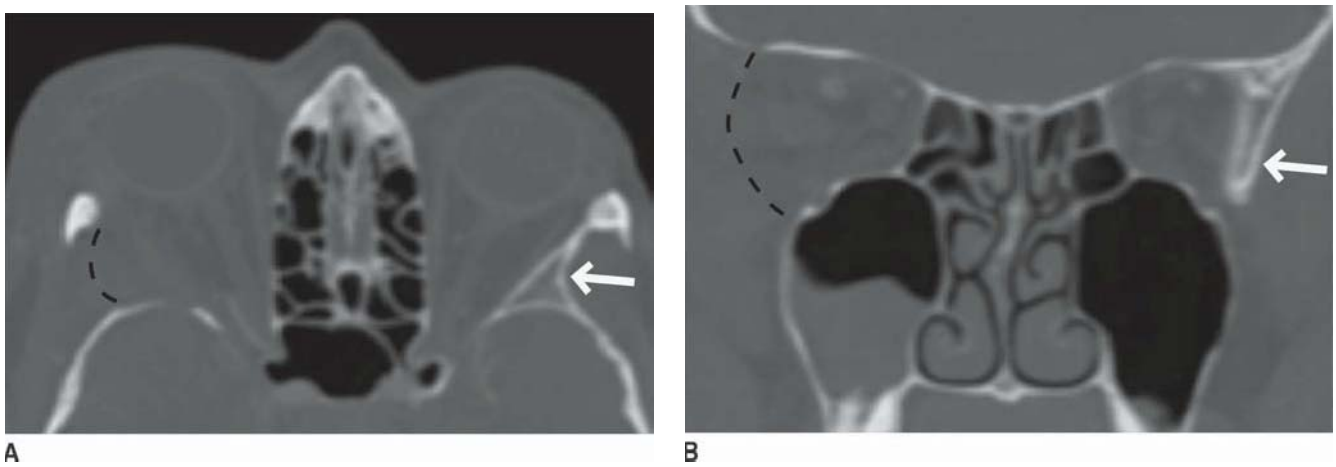

Figure 43.13 Postoperative axial **(A)** and coronal **(B)** bone-window CT of a right lateral wall decompression. The *white arrow* marks the intact bone whereas the black dotted lines show the edge of the orbital contents that have herniated through the decompression defect.

lateral options. Currently, it is rarely utilized as a standalone procedure due to its propensity to cause hypoglobus and enophthalmos. The portion of the orbital floor that typically is removed is that component medial to the infraorbital groove. In extreme cases, highly aggressive floor removal also can include the segment lateral to the infraorbital nerve, but this inevitably places the function of the nerve at risk. The medial floor component should additionally be distinguished into a posterior and anterior segment. Posterior segment removal is performed specifically for treatment of optic neuropathy from apex congestion and increases the radial arc of bone removed from 66 degrees with isolated lamina papyracea removal to 117 degrees when adding the floor component (unpublished data). This increased bone removal has been shown to be advantageous for optic nerve decompression in Graves disease (26). The anterior floor segment is removed to create globe recession for the purpose of addressing proptosis (Fig. 43.14).

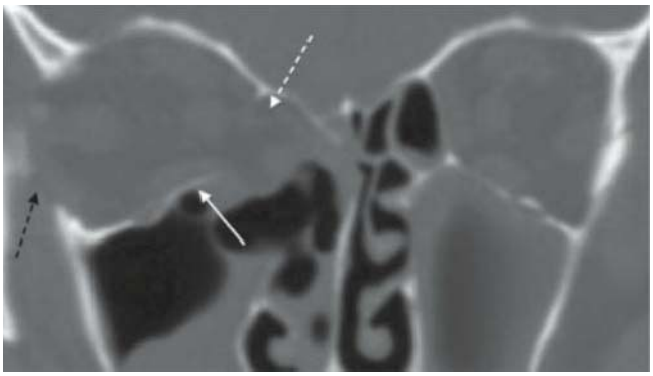

Figure 43.14 Postoperative coronal bone-window CT shows balanced orbital decompression. The lateral wall (*black dotted arrow*) and medial wall (*white dotted arrow*) decompressions have resulted in significant herniation of orbital contents. The orbital floor has been preserved in this example (*white solid arrow*).

Superior

Decompression of the orbital roof is only performed in the most recalcitrant cases requiring additional decompression after three-wall decompression has failed. Superior orbital decompression is performed through a frontal craniotomy with elevation of the frontal lobe in conjunction with a neurosurgical team. Severe complications have been reported including intracranial hemorrhage, frontal lobe trauma, meningitis, and pulsatile proptosis (28,31–33).

Fat

Through transconjunctival or other orbitotomy approaches, selective fat removal of the anterior orbit can be accomplished to achieve additional decompression in order to "fine-tune" a result.

Orbital Approaches for Endoscopic Access

Endoscopic Transnasal

Typical preparations for functional endoscopic sinus surgery (FESS) can be utilized for this approach; however, an ophthalmologic prep solution (5% Betadine paint) is required for the face to protect the cornea. Lacrilube or other hydration of the cornea must additionally be accomplished throughout the case. An "approach septoplasty" is helpful in all orbital surgery. As described by Wormald (40), this targeted submucosal resection removes the high cartilaginous and bony septum to improve access to the axilla of the middle turbinate. Access septoplasty is performed in over 70% of DCR cases (19) as it creates potential space in the anterior nasal cavity to accommodate additional space for endoscope movement, which is advantageous for anterior orbital inspection.

Maxillary Trephination

A canine fossa trephination (CFT) provides an alternative vector for approaching the anterior orbital floor. The procedure has been described in detail (40), but concern for Caldwell-Luc type chronic postoperative complications shrouds the wide acceptance of this procedure. To address this concern, Singhal et al. studied the procedure noting that 40% of patients undergoing CFT develop postoperative symptoms including facial tingling/numbness/pain, cheek pain/swelling, teeth numbness, and gingival problems. The immediate severity of these complaints can be quite high, but resolve quickly and do not require treatment. By 3 months after surgery, only 5% of patients have ongoing minimal symptoms, which in this large series included two patients with very mild paresthesias (41).

Transcaruncular

This minimally invasive approach avoids skin incisions while allowing extensive medial orbital exposure. It was originally described as a direct approach for repairing medial orbital fractures (42). The approach is worthy of mention as it has been utilized with increasing frequency in conjunction with endoscopic rhinologic approaches to the posterior-medial orbit while avoiding ethmoid dissection. This can be especially useful as a hidden approach to the anterior ethmoid neurovascular foramen. Additionally, the approach is extremely useful for repairs of orbital defects prior to drilling near the orbit (Fig. 43.15), thereby minimizing the risk of winding orbital tissue around a drill.

The caruncle is an ectodermal structure that lies just lateral to the medial commissure and contains adnexal skin structures covered by nonkeratinized stratified squamous epithelium. The approach can be made as a vertical incision, either directly through the caruncle or between the caruncle and adjacent plica semilunaris. Blunt dissection is carried posteromedially to the posterior lacrimal crest. Sharp incision then opens the periorbita allowing lateral retraction of intact periorbita. It is common for the periorbita to be weak and fat to herniate into the field during this procedure, necessitating the use of numerous malleable retractors. Measurement of 24 mm from posterior lacrimal crest to the anterior ethmoid artery is useful for verification of the correct foramen.

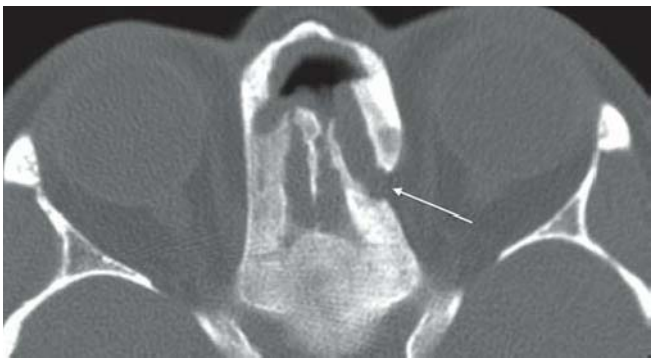

Figure 43.15 Axial bone-window CT from a patient who required extensive drilling on the skull base for fibrous dysplasia. There is a large left orbital dehiscence (*arrow*). Temporary placement of a medial orbital wall implant during surgery will protect the orbital contents from such injury.

Endoscopic Orbital Decompression

A wide maxillary antrostomy and total sphenoethmoidectomy with a complete frontal dissection precedes the start of the procedure (Fig. 43.16). It is helpful to widen the sphenoid ostium to have excellent visualization of the thickened lateral prominence also known as the optic tubercle. This bone corresponds to the medial attachment of the annulus of Zinn. The maxillary ostium should have the widest possible diameter to prevent postdecompressed herniated orbital fat from obstructing the neo-ostium. A middle turbinectomy is reported to be beneficial (22) to accommodate additional herniated fat from medial decompression. The procedure is begun by removing the lamina papyracea in its entirety with a Freer elevator. A 1 cm portion of lamina is left at the base of the frontal ostium to prevent herniating fat from creating postobstructive frontal sinusitis. The range of decompression that can be accomplished endoscopically varies from medial wall decompression to removal of the medial wall and medial orbital floor (to the infraorbital groove). If working with an ophthalmologist, it is imperative to have similar preoperative expectations of what bone is to be removed as "balanced" decompression may be interpreted as strictly ethmoid bone removal (no floor component). Once the bone is removed, periorbita will be exposed holding back orbital fat from obscuring endoscopic view. Due to the tendency of herniating fat to obscure endoscopic visualization, periorbita must be incised from a posterior to anterior direction. A 1-cm strip of periorbital "sling" left over the medial rectus is reported to minimize postoperative diplopia (22,39). The ipsilateral eye is then repeatedly compressed to encourage additional medial herniation of fat. The process can be encouraged by use of a ball probe to break up small fascial bands holding the fat together. Care must be taken to not damage the medial rectus during this process if employed. Consensus differs on the order of wall removal in balanced decompression and likely is irrelevant since both are removed safely as isolated procedures.

Perioperative care includes antibiotics, steroid taper, and low-pressure irrigations. No packing should be used after these cases for fear of artificially increasing intraorbital pressures with either the packing itself or development of a loculated hematoma lateral to the packing (22).

Surgical Risks

The main surgical risk from orbital decompression as documented by numerous publications is new onset diplopia. The incidence of this appears to vary dramatically

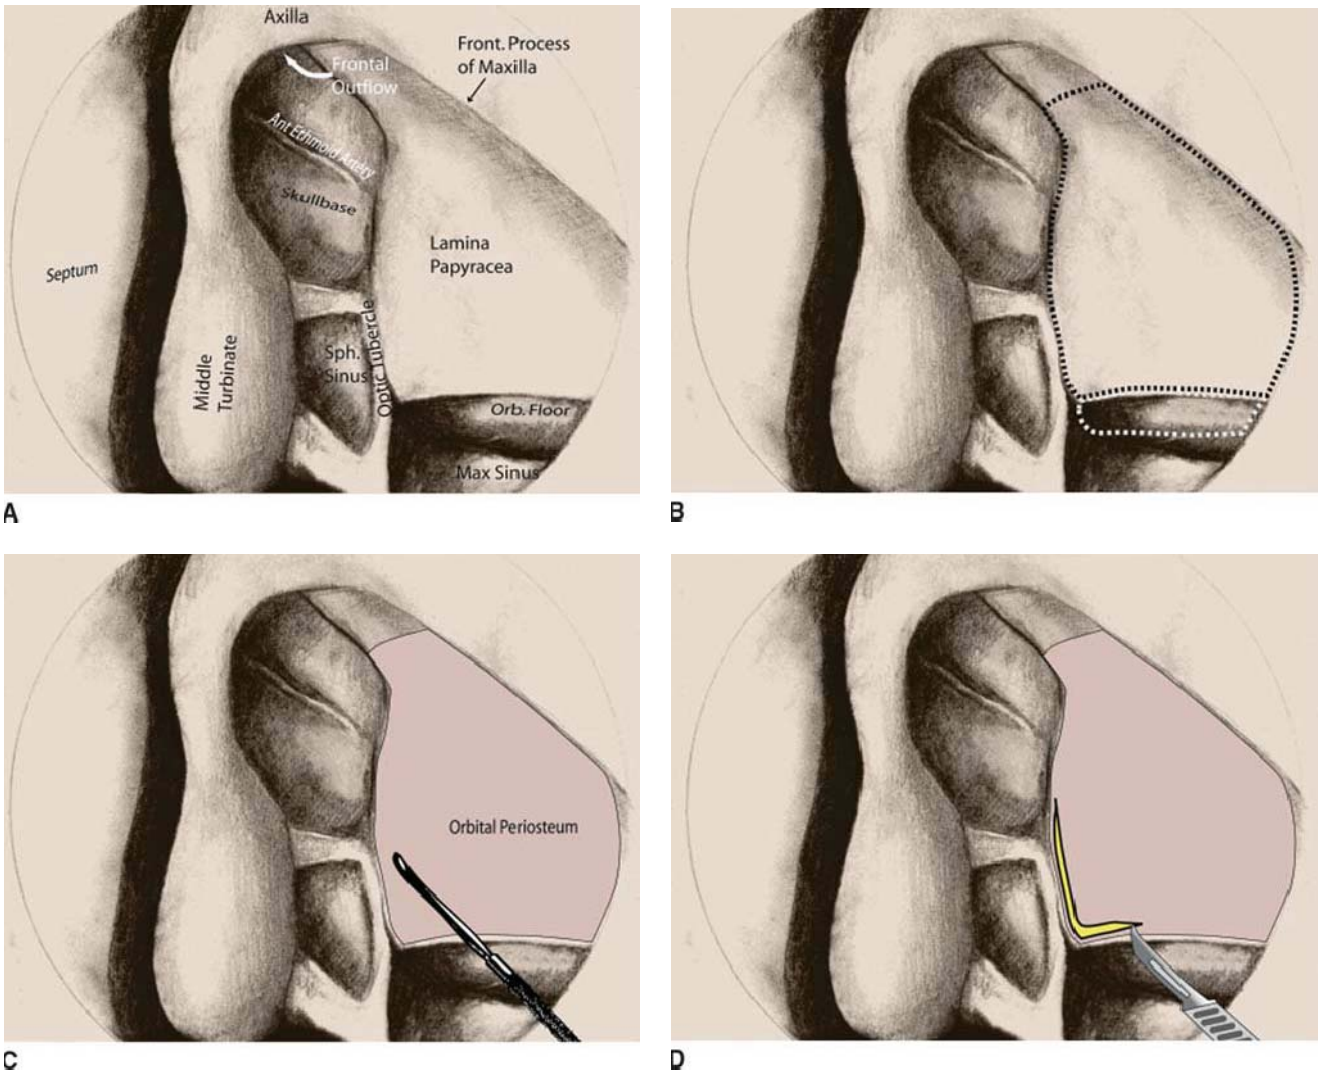

Figure 43.16 Left middle meatus diagram after full house FESS. All major structures are annotated in **(A)**. In **(B)**, *black dotted lines* denote the bone to be removed for a strict medial wall decompression, sparing 1 cm of bone to protect the frontal outflow tract from obstruction. The white dotted line is the floor component that can be removed medial to V2. In **(C)**, orbital periosteum has been exposed in preparation for a medial wall decompression. Using a 12 blade, the periosteum is being incised and removed from posterior to anterior in **(D)**. The medial rectus is hidden just below a shallow layer of fat, so extreme care is required for this maneuver. Artist acknowledgment: Andria M. Caruso, MD.

depending on technique (Table 43.2). Many patients have diplopia as a result of Graves orbitopathy, and there is an additional risk that this diplopia will not be improved by the surgery. Patients with diplopia will frequently require further strabismus surgery for this problematic complication (22). Less than 5% of patients will experience deterioration in vision from orbital decompression. Additional risks include postoperative epistaxis, which should be managed with bipolar suction, and new onset frontal or maxillary ostial obstruction from herniated fat. Maxillary obstruction requires further ostial enlargement with either maxillary antrostomy or mega-antrostomy. Frontal obstruction (Fig. 43.17) generally requires frontal drill-out after temporary medial orbital implant placement to protect the orbital contents during surgery.

TABLE 43.2 LITERATURE COMPILATION OF COMMON OUTCOME MEASURES ASSOCIATED WITH ORBITAL DECOMPRESSION

Walls Removed	Recession (mm)	New Postop Diplopia
Lateral (30,34)	3.5–6.3	8%
Medial (30,35)	2.6–4.9	38%
Medial + Floor (36,37)	5	100%
Balanced, No Floor (36,38)	0–10	10–40%
Balanced + Floor (28,36)	3–10	0–29%
Balanced + Floor w/ Sling (39)	5.1	0%
Four Wall Removal (32)	10–17	N/A

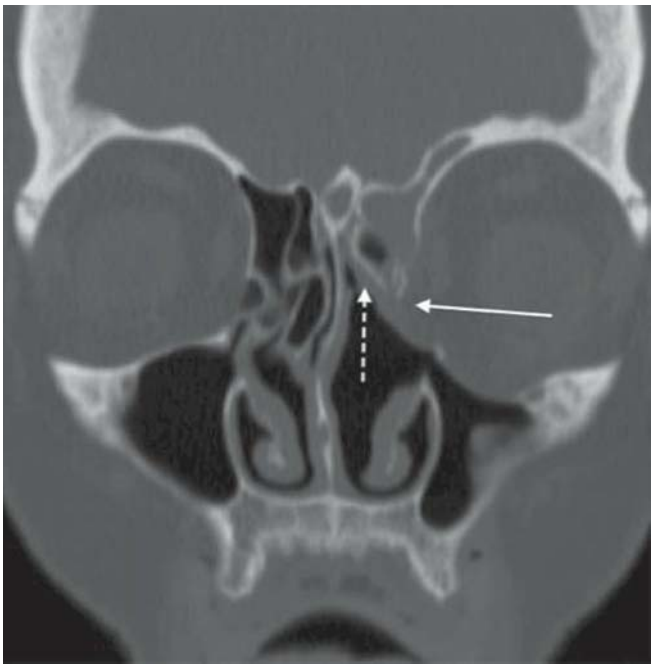

Figure 43.17 Coronal bone-window CT from a patient with Graves disease who has undergone left orbital decompression. Because the previous surgery did not include an adequate frontal dissection (*dashed arrow*) prior to the medial decompression, the herniated orbital fat (*solid arrow*) is now obstructing the frontal sinus.

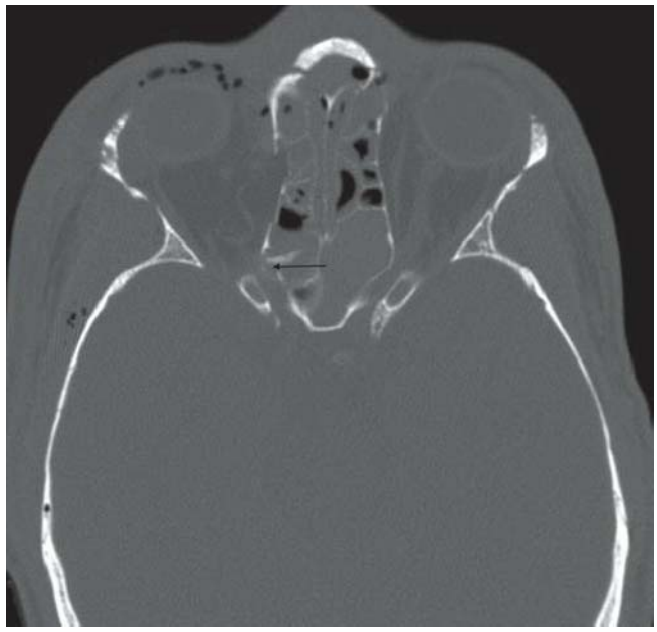

Figure 43.18 Caption: Axial bone-window CT of a patient who sustained blunt trauma to the right globe with a piñata stick. The trauma force was transmitted posteriorly, resulting in fracture of the optic canal (*arrow*). Visual acuity loss recalcitrant to high-dose steroids prompted optic nerve decompression.

OPTIC NERVE DECOMPRESSION

Background

Unlike the previous topics of discussion, optic nerve decompression is far more controversial. Due to the rarity of the need for such a procedure and the dire circumstances under which it is performed, there is limited and conflicting data to ascertain its value. The procedure is most often utilized under the diagnosis of traumatic optic neuropathy (TON) for which it has the most controversial indications. Specifically, a meta-analysis of low-quality evidence (43) gave opposite recommendations to the 1999 Optic Nerve Trauma Study (44) regarding the value of this procedure.

Accepted indications include the need to reduce excessive pressure on the edematous optic nerve from trauma (Fig. 43.18), pseudotumor cerebri, fibrous dysplasia, and compressive tumors. Endoscopic approaches appear to offer a more limited risk profile relative to intracranial decompressions due to reduced risk of CSF leak and elimination of the need to cut the falciform ligament and anterior clinoid process while achieving similar bony decompression throughout the optic canal (5). A temporizing measure that can be effective in acute traumatic settings where temporary nerve edema is causing compressive optic neuropathy is administration of high-dose methylprednisolone (30 mg/kg bolus) followed by a continuous infusion of 5.4 mg/kg/h given for 48 hours (22).

Patients may present with vague visual symptoms noting loss of color perception or peripheral vision prior to changes in visual acuity. Involvement of an ophthalmologist is mandatory for all cases of suspected optic neuropathy for definitive diagnosis (22). Measurement of ocular pressures, a high-quality ophthalmologic exam, and an orbital computed tomography (CT) are prerequisites to surgical therapy (22).

The position of the ophthalmic artery relative to the optic nerve is highly relevant to safe endoscopic surgery of the optic canal. Disruption of this artery will cause irreversible blindness. In the intracranial segment of CNII, the ophthalmic artery typically runs inferomedial to the nerve. However, in the optic canal, the ophthalmic artery will typically switch to an inferior position. This means that decompression with nerve sheath incision can be performed safely from a medial approach; however, the relationship of the artery to the nerve is highly variable along its length becoming more vulnerable as the surgery proceeds toward the intracranial segment (5).

Technique

A complete sphenoethmoidectomy provides adequate exposure for this procedure. The anterior face of the sphenoid should be removed as extensively as possible in a lateral direction over to the thickened bony ridge marking the posterior aspect of the orbit known as the optic tubercle (40). Using a diamond drill bit and irrigation, this bone and the bone along the optic canal is thinned

to egg-shell thickness. Care is taken to avoid damage to the internal carotid artery, which is most at risk inferior to the nerve at the opticocarotid recess. An elevator is used to remove bone starting on the posterior orbit about 1 cm anterior to the optic tubercle and working posteriorly until the entire medial portion of the optic canal is dehiscent.

At the conclusion of the procedure, a medial, longitudinally oriented nerve sheath incision may be performed. Again, quality evidence to support this incision is lacking with proponents suggesting improvement in visual outcomes due to release of compartment syndrome pressure on venous drainage and detractors citing increased risk of CSF leak with potential damage to nerve fascicles, pial vasculature, or the ophthalmic artery (45).

HIGHLIGHTS

- DCR by either the endoscopic or external approach with complete sac marsupialization is a highly successful treatment for epiphora due to obstructions of the lacrimal sac or duct.
- The lacrimal sac is located within the lacrimal fossa (anteriorly thick frontal process of the maxilla and thin posteriorly lacrimal bone) with a significant portion of the sac located above the axilla of the middle turbinate.
- New onset diplopia after orbital decompression is a common and troublesome complication that appears to be correlated to the technique of decompression.
- Complete ethmoidectomy and wide ostial enlargement of all sinuses with preservation of 1 cm of lamina papyracea around the frontal outflow tract minimizes risk of postobstructive sinusitis after orbital decompression.
- Optic nerve decompression is controversial in the setting of TON and should only be performed in consultation with an ophthalmologist.
- Endoscopic optic nerve decompression provides an ideal approach to the entire bony optic canal and minimizes risk of damage to the ophthalmic artery, which typically runs inferior to the nerve in the canal.

ACKNOWLEDGMENTS

The authors would like to thank the following individuals for their contributions to this chapter: Andria M. Caruso, MD for Figure 16 artwork, Lt Col Jose E. Barrera MD for editorial assistance, and Char Branstetter MD for caption editorial and assistance with Figure 18.

44 Complications of Sinus Surgery

James A. Stankiewicz *Kevin C. Welch*

Risk is inherent with any surgical procedure. Fortunately, most surgeries performed to relieve sinus disorders are uncomplicated and result in high patient satisfaction. Complications resulting from sinus surgery can be divided into two categories: (a) intraoperative complications and (b) postoperative complications. Intraoperative complications can be devastating and include both vascular and neurologic injury, not the least of which includes catastrophic bleeding, visual loss, and cerebrospinal fluid (CSF) leaks with ascending meningitis. Postoperative complications are typically less severe and can be considered functional complications leading to poor long-term surgical outcomes, patient dissatisfaction, or need for revision sinus surgery. Despite intense preparation and experience, complications resulting from sinus surgery do occur. With early recognition, many complications can be controlled early and reversed.

Sinus surgery should never be considered routine; the surgeon must be thoroughly prepared prior to the operation and constantly alert, anticipating complications as the procedure ensures. It is important to understand the nature of these complications to increase awareness and prevention. This chapter reviews the relevant anatomy; discusses the complications of specific sinus procedures; and evaluates specific complications, pathophysiologic mechanisms, and management.

RELEVANT ANATOMY OF THE ORBIT

Soft Tissue and Bony Anatomy

A thorough understanding of sinonasal anatomy is crucial to performing safe and successful sinus surgery. It cannot be understated; however, that knowledge of the regional anatomy is critical to avoiding the complications discussed in this chapter. Orbital complications resulting from sinus surgery are fortunately rare, and this stems from understanding the relationship of the orbit and its internal structures with the sinuses themselves. The orbit comprises seven bones: maxilla, zygoma, frontal, lacrimal, sphenoid, palatine, and ethmoid. The seven bones together form a conical-shaped structure that is approximately 4 cm wide by 5 cm long. The contents of the orbit are divided into the anterior and posterior compartments, which are divided anatomically by the orbital septum and the globe. The orbital septum is the reflection of the periorbita into the tarsal plates. Separating the anterior and posterior eye chambers, the septum is tough and holds the orbital contents in place. To its detriment, the orbital septum also holds orbital effusions such as hemorrhage and infection within the orbit, preventing the fluid from passing directly into the preseptal space and instead allowing potentially dangerous increases in orbital pressure. The anterior compartment of the orbit contains the lids, orbital soft tissue, and the lacrimal apparatus. The posterior orbital compartment, or retrobulbar space, is subdivided into the intraconal and extraconal spaces, which are separated by a fascial sling that envelops the extraocular muscles.

The intraconal space contains the vital orbital structures, including the optic nerve, portions of the ophthalmic artery, branches of the ophthalmic artery (central retinal artery, long and short ciliary arteries, lacrimal artery, portions of the anterior ethmoidal artery, and the posterior ethmoidal artery), the ophthalmic veins, and orbital fat. The blood supply to the retina, chiefly the choroid choriocapillaris (outer half) and the central retinal artery and branches, lies within the intraconal space as well. The blood supply is protected by various compensatory mechanisms so that retinal blood flow is maintained even if the entire system is under stress.

The extraconal space can be subdivided into superior, inferior, medial, and lateral compartments. The superior extraconal space contains the levator muscle, supratrochlear and supraorbital nerves, the trochlear nerve, and the supraorbital artery. The lateral extraconal space is not as relevant in sinus surgery; however, it contains the lacrimal gland, the lacrimal neurovascular structures, and fat. The inferior extraconal

space contains fat and the infraorbital nerve and vessels. The medial extraconal space is the most relevant space in sinus surgery and contains a plethora of vascular structures: distal portions of the posterior ethmoidal artery, the distal portion of the ophthalmic artery, and the anterior ethmoidal artery as well as fat. Of extreme importance is the relationship of the ophthalmic artery and the anterior ethmoidal artery. The ophthalmic artery courses anteriorly in the extraconal space just inferior to the superior oblique muscle before giving rise to the anterior ethmoidal artery near the anterior ethmoidal foramen along the medial orbital wall. Radiographically, this is best identified in the coronal plane along the convergence of the medial rectus muscle and the superior oblique muscle (Fig. 44.1). In approximately 10% of cases, this neurovascular bundle can be suspended from the anterior ethmoid skull base in a bony mesentery, often associated with a supraorbital ethmoid air cell (1). Considering the *limen nasi* as a fixed landmark, the artery is located approximately 55 degrees from the nasal floor and at 50 mm.

Superficial to the orbital fat in the extraconal space is the orbital periosteum, or periorbita. The periorbita is tough and fibrous but can be elevated easily except at the suture lines, where it passes through to fuse with the periosteum on the opposite side. Medial to the periorbita is the *lamina papyracea* of the ethmoid bone, which is paper thin and is easily susceptible to injury during sinus surgery. The *lamina papyracea* is the lateral-most extent of the ethmoid sinuses. Finding the *lamina papyracea* is essential to preventing orbital complications. The orbit and the paranasal sinuses are intimately related on three sides.

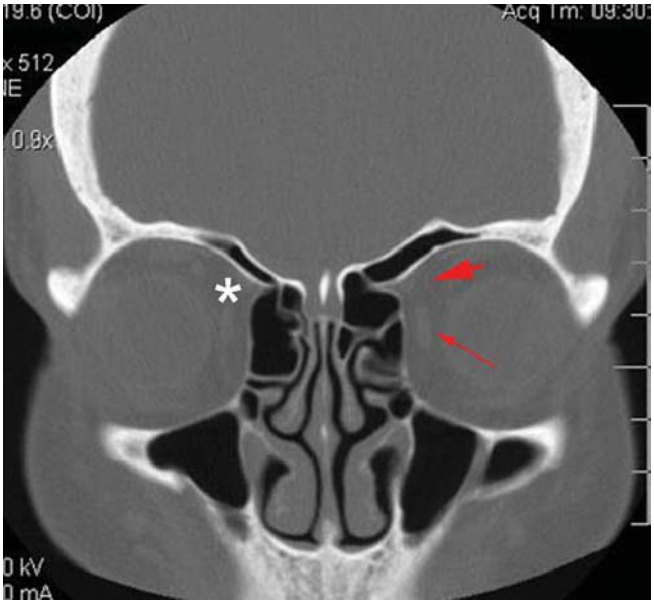

Figure 44.1 A coronal CT of the paranasal sinuses featuring the location of the anterior ethmoidal artery (*asterisk*) near the convergence of the medial rectus (*arrow*) and superior oblique (*arrowhead*) muscles. Note that in this patient, the anterior ethmoidal artery (*asterisk*) is located within a bony mesentery, suspended from the skull base.

Posteriorly, the orbit converges and permits passage of neurovascular structures through the superior orbital fissure, the inferior orbital fissure, and the optic canal. Through the optic canal traverses the optic nerve and ophthalmic artery, as well as various vasa nervosa that supply the optic nerve itself. Posteriorly, this optic canal narrows and can form an indentation in the sphenoid sinus at the junction of the cavernous carotid artery known as the opticocarotid recess (Fig. 44.2), which anatomically relates to the anterior clinoid process of the sphenoid bone. This region is notable for dehiscence of the carotid artery and optic nerve, which can occur in 4% to 22% (2–5) and 4% to 8% (3,5) of cases, respectively.

Practical Application of Orbital Anatomy

The lamina is curved and gives way superiorly to the supraorbital ethmoidal cells and inferiorly to the maxillary sinus. It is important to define the lamina surgically when working in the ethmoid and maxillary sinuses to avoid entrance into the orbit via compromise of the *lamina papyracea* and periorbita and injuring the vasculature or musculature. It is appropriate to stay near the superior part of the inferior turbinate when making a middle meatal antrostomy and to not open the true ostium any more anteriorly than the anterior end of the middle turbinate. Specifically, the true ostium of the maxillary sinus is situated along the inferior half of the maxillary line in 94% of specimens and *just* inferior to the mid-point of the maxillary line in 60% of cases (Fig. 44.3). The os is obliquely oriented and less than 5 mm posterior to the lacrimal duct. Dissecting anterior to the true ostium only encounters the blind bony pouch of the infundibulum and does not provide any additional functional improvement in maxillary sinus mucociliary clearance. Moreover, dissection more anteriorly than this places the lacrimal duct at risk of injury. After the antrostomy is made, the inferolateral aspect of the *lamina papyracea* can be identified superior to the ostia and if the opening is large enough, the floor of the orbit can be identified as well. Proceeding through the maxillary os in a lateral or superolateral direction will likely result in injury to the orbit; therefore, once the os is identified, entry in the maxillary sinus is performed in an inferolateral direction to safely avoid the *lamina papyracea*.

The structures of the orbit viewed through an endoscope appear different on the right and left sides (6). The actual right nasal and meatal structures lie visually straight back. On the left, the ethmoid sinuses are actually more medial in location, especially anteriorly and superiorly. Because of altered perception, a *right-handed* surgeon operating on the left side who takes the same straight-back approach as on the right, especially during an endoscopic procedure, contacts *lamina papyracea* and enters the orbit, particularly in the superior and lateral orbit area. It is important to stay in the medial aspect against the middle turbinate. See Table 44.1 for a tabulation of important orbital anatomy.

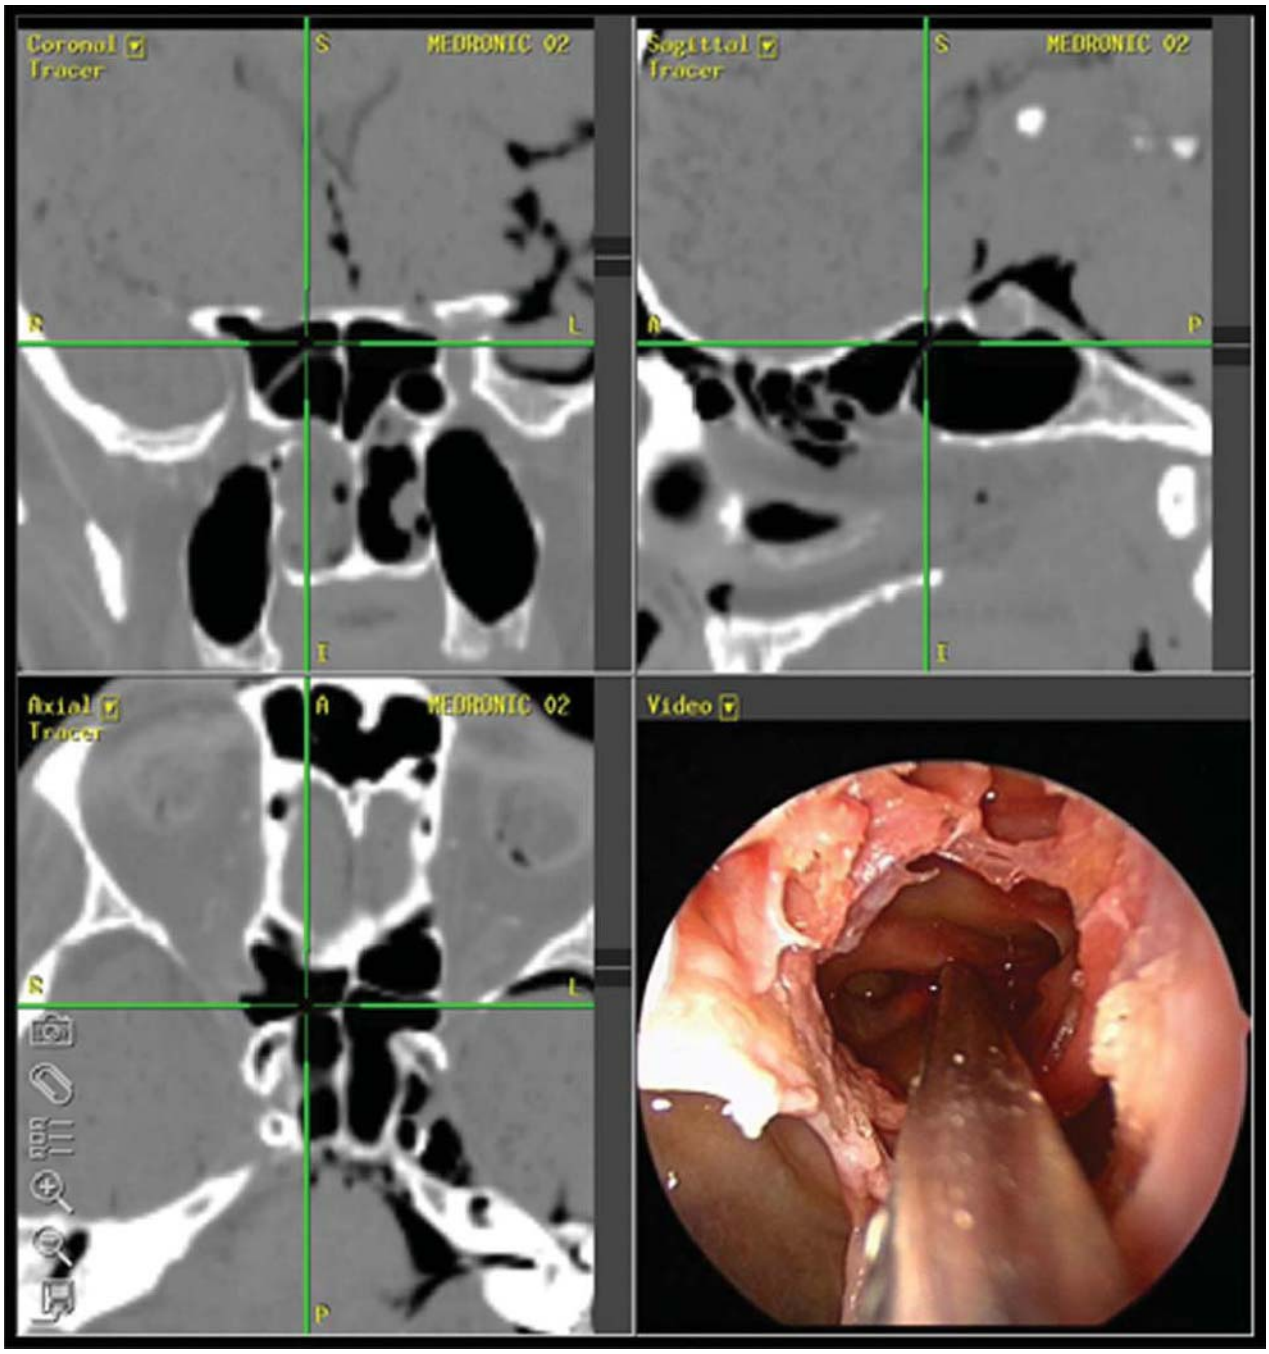

Figure 44.2 Triplanar images of an endoscopic dissection performed on a cadaver. The probe is pointing to the location of the opticocarotid recess where the carotid artery and the optic nerve are prominent within an Onodi (sphenoethmoid) cell.

RELEVANT ANATOMY OF THE ANTERIOR SKULL BASE

Bony Anatomy

The surgeon should be aware that the skull base slopes downward beginning at the frontal recess and terminating at the *planum sphenoidale* (Fig. 44.4). It is a mistake to assume that this slope is both smooth and two-dimensional. Anteriorly, the skull base is variable in structure as described by Keros (7), as the ethmoid roof (a.k.a. *fovea ethmoidalis*) is generally higher laterally than it is medially where the cribriform plate is identified. The anterior ethmoidal artery can pierce the cribriform plate and even be intracranial as it travels medially toward the septum. The bone at this point is 10 times thinner than in other areas of the cribriform plate and thus can be easily violated. Surgeons need to beware of a low skull base or cribriform plate, as found at computed tomography (CT).

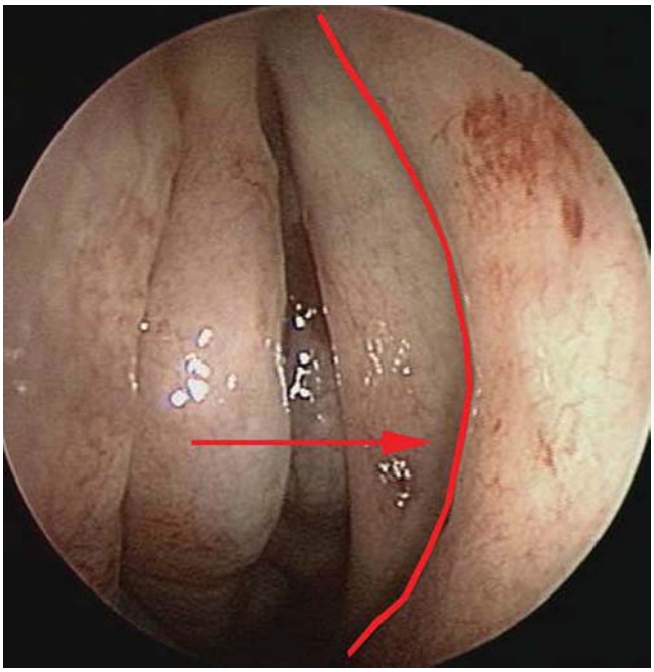

Figure 44.3 An endoscopic view of the middle meatus. The middle turbinate is medialized. A curvilinear line can be imagined at the junction of the uncinate process and the lacrimal bone. The maxillary sinus ostium (*arrow*) is located (in two-thirds of cases) at the junction of the inferior one-third and the superior two-thirds of this line.

TABLE 44.1 SUMMARY OF IMPORTANT ANATOMIC RELATIONS

- The *lamina papyracea* is superior to and just lateral to the natural ostium of the maxillary sinus.
- Ethmoid dissection is performed lateral to the middle turbinate, never medial or superior.
- The maxillary antrostomy is performed just superior to the inferior turbinate with the surgical instrument lying on top of the inferior turbinate.
- The maxillary antrostomy should not be more anterior than the anterior end of the middle turbinate. A backbiter is used to incise the uncinate process and create an "uncinate window." The natural ostium of the maxillary sinus is in the lower half of the infundibulum behind the uncinate process.
- The maxillary antrostomy is at the level of the inferior orbital rim.
- The frontal recess lies at 6–6.5 cm from the *limen nasi*.
- In adults, the anterior ethmoidal artery and base of the skull (posterosuperior *fovea ethmoidalis*) are 6 cm from the nasal opening or 5.5 cm from the *limen nasi*.
- In adults, the sphenoid sinus ostium is 7 cm from the nasal opening.
- In adults, the basal lamella of the middle turbinate is 6 cm from the nasal opening (posterior ethmoid bones lie behind this).
- The nasopharyngeal wall approximates the posterior sphenoid wall to within 1 cm.
- The surgeon should identify and cannulate the sphenoid ostium, if possible. The superior turbinate is the gateway to the sphenoid sinus since the ostium is just medial to the vertical midline of the superior turbinate. The ostium lies one-third of the way up the anterior wall from the choana just next to the septum.
- If the middle turbinate must be removed, the surgeon should remove only the inferior or anterior part of the turbinate and preserve the superior part as an anatomic landmark.

Two excellent articles relating to anatomic variations on CT scanning important to the sinus surgeon describe and enhance this anatomic discussion and are highly recommended (8,9). As the skull base transitions posteriorly to meet the *planum sphenoidale*, the ethmoid roof can be identified at the same level as the cribriform plate.

The sphenoid sinus is the key to identifying the skull base. The sphenoid sinus is bounded anteriorly and superiorly by the sphenoid crest, which articulates with the perpendicular plate of the ethmoid bone. Inferiorly and anteriorly, the sphenoid bone converges into the rostrum, which articulates with the vomer of the septum. Lateral to the sphenoid crest are the two sphenoid ostia, both of which measure approximately 2mm in dimension. Each ostium is located approximately 15-20mm above the choanal arch. The ostia are the anatomic keys to the skull base. These ostia can be obstructed by posterior ethmoidal disease making them difficult to directly visualize. However, a beaded probe or image-guidance probe placed onto the sphenoid ostium safely identifies the appropriate area for opening into the sphenoid sinus, which is anatomically inferior and medial. The sphenoid ostium can be approached in a position medial to the middle turbinate (transethmoid) or approached laterally in a plane between the superior turbinate and the septum, just superior to the choanal bridge (transnasal). The superior turbinate is a well-established landmark for the ostium of the sphenoid sinus since it is typically medial to the lower one-third to one-half of the superior turbinate. Viewed in an axial plane, the anterior wall of the sphenoid sinus approximates the posterior wall of the maxillary sinus. The only intervening anatomic structure is the pterygopalatine fossa, which is thin and permits the sphenopalatine artery and it branches to enter the sinonasal cavity. The anterior aspect of the sphenoid bone usually is extremely thin, but thickens both medially near the rostrum and sphenoid crest and laterally near the orbital apex. If resistance is felt, the bone should not be penetrated blindly, rather entered cautiously with a drill or other instrument after the anatomy is confirmed radiographically. The posterior ethmoidal cells can be opened in a medial direction through the posterior middle turbinate to allow visualization of the sphenoid ostium, which safely identifies the lateral aspect of the sphenoid and posterior ethmoidal cells that can be penetrated.

Anterior to the planum sphenoidale, the bone transitions into the cribriform plate, the lateral cribriform lamella, and the *fovea ethmoidalis* (ethmoid roof). This anatomy is best considered in the coronal plane despite its

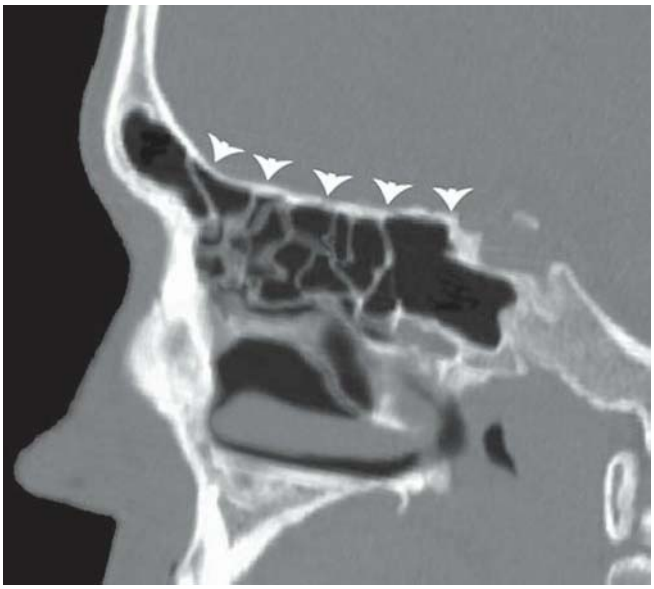

Figure 44.4 A sagittal reconstruction of the paranasal sinuses and anterior skull base. Note that the skull base (*arrowheads*) slopes in a downward fashion starting at the frontal recess and terminates at the *planum sphenoidale* (sphenoid roof). It is important to note this when operating within the posterior ethmoid sinuses.

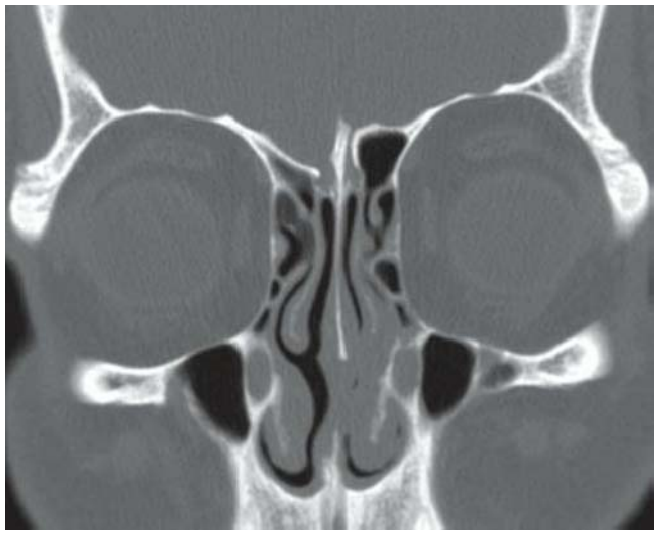

Figure 44.5 A coronal CT of the paranasal sinuses and anterior skull base. Keros categorized three types of skull base anatomy based on the length of the lateral lamella. However, the length of the lateral lamella may be different on each side. Therefore, the surgeon should always note any asymmetry in the skull base anatomy.

three-dimensional variance. The cribriform plate represents the lowest midline structure in the medial aspect of the nasal vault. The lateral mass of the ethmoid is suspended from the *fovea ethmoidalis* or ethmoid roof. Intervening between the ethmoid roof and cribriform plate is the lateral cribriform lamella, or simply lateral lamella. The length of the lateral lamella (and hence the depth of the cribriform plate) was noted by Keros (7) in several anatomic dissections. Keros classified the anterior skull base depth based upon the length of the lateral lamella: 1 to 3 mm (type I), 4 to 7 mm (type II), and 8 to 16 mm (type III). The skull base may also be asymmetric in design (Fig. 44.5). Some (10) have shown that type II anatomy is encountered most frequently and that patients with a lower skull base depth (i.e., type I) have a lower incidence of skull base injury.

Suspended from the articulation of the lateral lamella and the cribriform plate is the sagittal attachment of the middle turbinate; therefore, it is clear that the middle turbinate is an important landmark. In addition to directing the surgeon to the transition between the cribriform and the lateral lamella, the anterior most portion of the middle turbinate marks the anterior limit of maxillary dissection, marks the medial-superior extent of the lacrimal sac, and is important in identifying the frontal recess. The sagittal portion of the middle turbinate transitions posteriorly as the (third) basal lamella and is visualized in coronal and horizontal planes. The basal lamella identifies the transition between the anterior and posterior ethmoidal sinuses, and the lower half of the middle turbinate and its insertion into the choana help to identify the entrance into the sphenoid sinus. These characteristics, not to mention its host of olfactory neurons, make the middle turbinate a structure worth preserving. However, turbinates that are mechanically obstructive, such as concha bullosa or those with significant polypoid degeneration, may need partial or total removal (Table 44.1).

Measuring the anatomic structures is important to avoiding complications. The distance from the nasal spine or nasal opening to the frontal recess is 6 cm, to the base of skull is 7 cm, and to the anterior wall of the sphenoid is 7 cm in adults of normal size. The nasopharyngeal wall approximates the back wall of the sphenoid sinus, usually to within 1 cm. The choanal bridge (just above the choana and below anterior wall sphenoid) is 7 cm. The basal lamella of the middle turbinate is 6 cm. In children, these dimensions are variable, and the surgeon needs to exercise caution. However, one can always find the distance to the sphenoid bone and the base of the skull by measuring the distance to the choanal bridge just above the choana (Fig. 44.6).

Practical Application of Skull Base Anatomy

The relationship between the maxillary and ethmoid sinuses should be examined in the coronal and sagittal planes on CT imaging prior to the start of surgery. In particular, the ratio of the posterior ethmoid to maxillary sinus height should be assessed. In patients with a vertical height ratio of 1:1 (maxillary sinus height to posterior ethmoid height) are less likely to incur skull base injury. However, in patients with a 2:1 or greater than 2:1 maxillary sinus height to posterior ethmoid height (Fig. 44.7), the posterior ethmoid skull base is encountered rather quickly due to the sloping nature of the skull base in this region. Inadvertent injury to the skull base may occur once

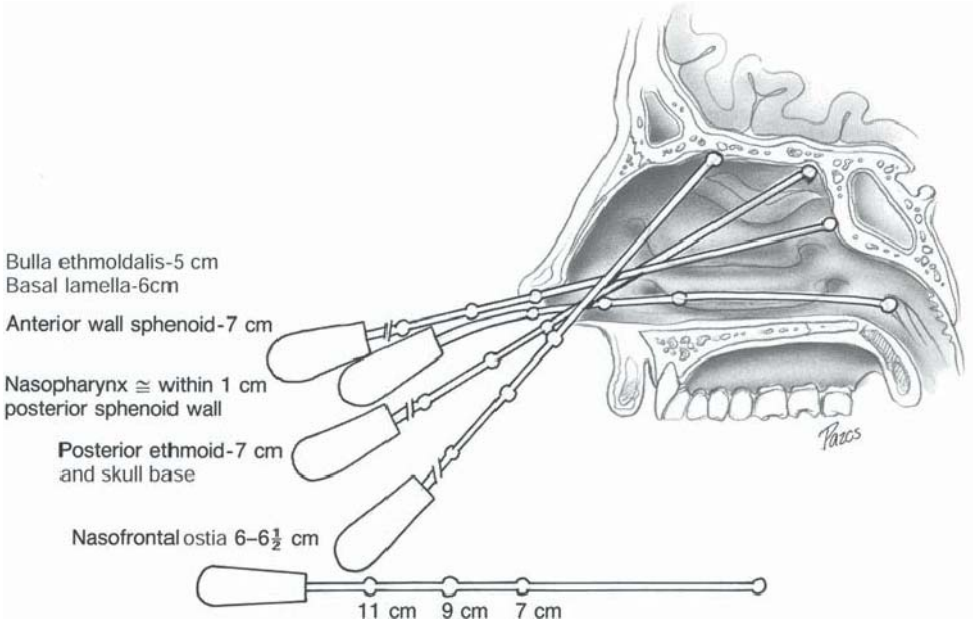

Figure 44.6 Beaded probe measurements to various areas of the nose from the nasal opening (nasal spine). (From Stankiewicz J. Complication of endoscopic sinus surgery. *Otolaryngol Clin North Am* 1989;22:749, with permission.)

proceeding through the basal lamella if the patient has a 2:1 or greater than 2:1 ratio. Therefore, the surgeon must consider this "angle of attack" when penetrating the basal lamella and entering the posterior ethmoid cavity. Entering the posterior ethmoids via the medial-inferior aspect of the coronal face of the basal lamella, along the roof of the maxillary sinus or floor of the ethmoid bulla, will provide a much safer avenue toward the sphenoid sinus and away from the skull base (Fig. 44.8).

COMPLICATIONS OF OPEN SURGICAL PROCEDURES

Specific complications of sinus surgery are numerous. Several can be catastrophic because of the proximity of the paranasal sinuses to the orbit and brain. All otolaryngologists should be familiar with work of Harris P. Mosher (11), who described the ethmoid labyrinth in great detail in his 1929 publication. Mosher described intranasal

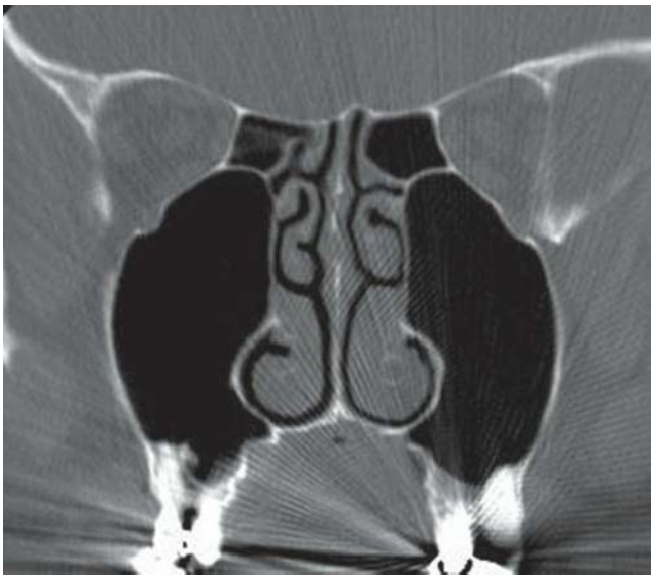

Figure 44.7 A coronal CT of the paranasal sinuses reveals significant asymmetry of the height of the maxillary sinus when compared to the height of the posterior ethmoid sinuses. A ratio (maxillary sinus height:ethmoid sinus height) ≥2:1, such as in this patient, places the posterior ethmoid skull base at high risk for injury when proceeding through the basal lamella.

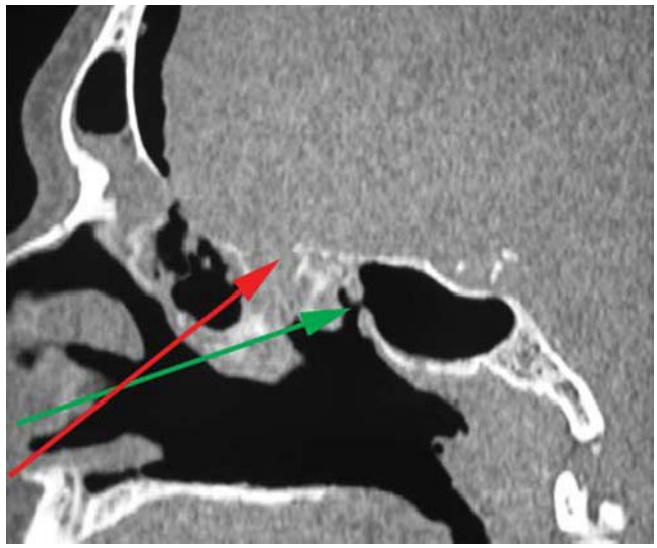

Figure 44.8 A sagittal reconstruction of the paranasal sinuses. This patient sustained an injury to the skull base that resulted in CSF rhinorrhea and pneumocephalus. This injury was due to high penetration of the basal lamella (*red arrow*). An angle of attack that penetrates the basal lamella at the roof of the maxillary sinus or base of the ethmoid bulla (*green arrow*) is safer when entering the posterior ethmoid sinuses.

TABLE 44.2 COMPLICATIONS SINUS SURGERY

Vascular injury
- Carotid artery
- Anterior communicating artery
- Carotid cavernous fistula
- Ethmoidal arteries (anterior and posterior)
- Sphenopalatine artery
- Septal branch of the sphenopalatine artery

Nerve injury
- Infraorbital hypesthesia
- Infraorbital pare sthesia
- Supraorbital and supratrochlear hypesthesia
- Supraorbital and supratrochlear paresthesia
- Inferior alveolar hypesthesia
- Inferior alveolar paresthesia

Facial disorders
- Facial edema
- Subcutaneous emphysema

Orbital disorders
- Blindness
- Diplopia
- Nasolacrimal duct injury
- Nasolacrimal sac injury
- Injury to Hasner valve
- Orbital hematoma
- Orbital emphysema
- Periorbital ecchymosis
- Lid edema
- Anisocoria

Brain and neurologic
- Cerebrospinal fistula
- Meningitis
- Frontal lobe injury
- Hyposmia, dysosmia, anosmia
- Pneumocephalus
- Anterior cerebral artery injury
- Subarachnoid hemorrhage
- Brain abscess
- Death

Packing related
- Displaced packing
- Aspiration
- Infection
- Increased orbital pressure
- Toxic shock syndrome
- Myospherulosis
- Scar tissue formation

ethmoidectomy as "one of the easiest operations with which to kill a patient." Most of the catastrophic complications are related to ethmoidectomy and frontal sinus surgery. Table 44.2 lists the complications of sinus surgery. May et al. (12) studied the complications of sinus surgery among large populations of patients noting CSF leak and blindness were the common major complications; orbital hematoma the most common minor complication.

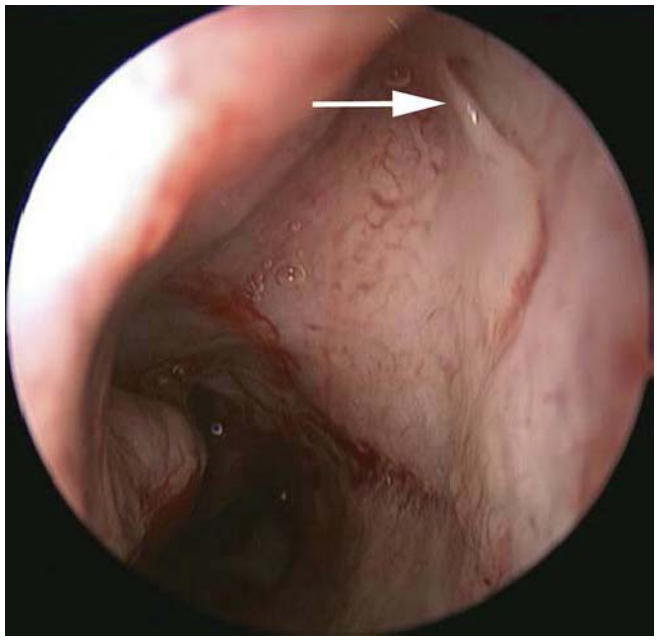

Figure 44.9 An endoscopic view of the inferior meatus. Hasner valve (*arrow*) is the termination of the lacrimal apparatus. Injury to Hasner valve can occur when performing an IMA as well as other procedures (turbinate fracture, turbinate resection, and endoscopic medial maxillectomy).

Inferior Meatal Antrostomy

Complications of inferior meatal antrostomy (IMA) include bleeding due to injury to the greater palatine artery, injury to Hasner valve (Fig. 44.9) and the lacrimal apparatus, dental injury, and functional complications due to synechia, or recirculation of infected mucus. IMA must be performed with great care in children since injury to the developing canines within the bony walls of the maxillary sinus can occur. The canine impression in the lateral nasal wall should be viewed before performing an IMA on children.

It appears that, although complications related to the development of the teeth, especially among children, and occasional bleeding can occur during IMA, the risk of permanent injury is low if care is taken during the procedure. Inferior meatal antrostomy is not commonplace in the era of endoscopic sinus surgery; however, it can be useful for obtaining cultures in the ICU setting, aid in removal of polyps or fungal disease, or aid in clearance of benign maxillary sinus tumors, such as inverted papilloma.

Caldwell-Luc Procedure

Complications of the traditional Caldwell-Luc operation are facial swelling, cheek discomfort, hemorrhage, facial asymmetry, facial paresthesia, oroantral fistula, gingivolabial fistula, dacryocystitis, devitalized teeth, recurrent polyps, and recurrent sinusitis. The most common immediate complications are facial swelling and cheek discomfort, which occur after almost 90% and 33% of procedures,

respectively (13) and resolve within 1 to 2 weeks of the procedure. DeFreitas and Lucente (13) reviewed 670 Caldwell-Luc procedures and found a 9.1% and 3% incidence of facial paresthesias and dacryocystitis, respectively. Yarington (14) reported on 271 Caldwell-Luc procedures with a 3% overall complication rate. The most common complications were postoperative hypesthesia, devitalized teeth, and postoperative ethmoiditis. Blindness can occur with the Caldwell-Luc procedure if the orbit is entered, but this is a rare complication. DeFreitas and Lucente (13) also noted a recurrence of sinusitis and polyps in 12% and 5% of patients as well.

Major long-term complications of chronic pain and numbness are not as common as one might believe (13,14). Modification in surgical technique, including the use of a triangular flap in the buccal mucosa and the use of a drill rather than an osteotome or rongeur to open the canine fossa, resulted in a decrease in long-term numbness and pain according to Yarington (14). DeFreitas and Lucente (13) found that paresthesia, numbness, and other complications such as facial asymmetry, oroantral fistula, dehiscence, and devitalized teeth persisted for about 1 year and then resolved or necessitated minor surgical procedures. Low (15) reviewed 216 Caldwell-Luc operations and found that facial swelling, facial pain and numbness, and dental pain and numbness were the most common complications among 30% to 60% of patients. Facial paresthesias can be minimized by understanding the regional anatomy of the infraorbital nerve, which is described nicely by Robinson et al. (16) and Singhal et al. (17).

Intranasal Ethmoidectomy

Intranasal ethmoidectomy can be performed with a headlight, microscope, or endoscope. As previously implied through the work of H. P. Mosher, ethmoidectomy has been described as perhaps the most dangerous of all otolaryngologic operations. Catastrophic complications such as blindness, permanent diplopia, CSF fistula with meningitis, brain injury, and major vessel injuries have been described. In more than 1,000 ethmoidectomies, Freedman and Kern (18) reported overall complication rates of less than 4%. Factors that contributed to complications included extensive sinus disease and factors that led to revision surgery included loss of landmarks. The most common complications were hemorrhage and orbital hematoma with an overall complication rate of 2.8%.

Lawson (19) also found a low (1.1%) incidence of complications following 1,077 intranasal ethmoidectomies over a 15-year period, the worst complications being three CSF fistulae. Included in this review of ethmoidectomy was an extensive review of complications of all ethmoid procedures.

Complications of endoscopic sinus surgery mirror those of traditional surgery. Stankiewicz (6), however, reported a 17% complication rate in 150 ethmoidectomies and indicated that endoscopic ethmoidectomy is extremely difficult for inexperienced surgeons. This discordance between endoscopic and traditional ethmoidectomy procedures most likely relates to the deployment of new surgical techniques at the time. Moreover, Stankiewicz (20) demonstrated in a group of 150 *subsequent* ethmoidectomies a decrease in complication rate to less than 2%, thus indicating that with experience, endoscopic surgery is safe and results in complication rates comparable to traditional ethmoidectomy and other endoscopic procedures. Stankiewicz (6,20) also found that CSF fistula specifically and orbital complications in general are more common among patients who are under general anesthesia for endoscopic ethmoidectomy. No experienced surgeon claims to have had a patient with blindness or double vision, although management of these patients certainly does occur. CSF fistulae with meningitis also are rare.

A meta-analysis of 6,801 patients reveals that the most serious complication of ethmoidectomy was CSF rhinorrhea. Serious complications occurred among almost 1% of patients. Orbital penetration was the most common minor complication. Complication rates were similar for endoscopic and traditional techniques except for a higher rate of orbital penetration in traditional surgery (12).

Intranasal ethmoidectomy in the hands of experienced surgeons has an overall complication rate of 4% or less (12,21). When comparing traditional and endoscopic ethmoidectomy, the rates of complication appear to be equivalent. Factors that appear to decrease ethmoidectomy-related complications include preservation of the middle turbinate. However, middle turbinate preservation may increase the risk of intranasal synechiae and iatrogenic obstruction of the ethmoid and frontal recess, ultimately leading to revision sinus surgery. Revision ethmoidectomy, advanced disease (particularly long-term chronic disease, polyps, or fungal disease), intraoperative hemorrhage, operations by a right-handed surgeons on the right side of the head, endoscopic procedures by a right-handed surgeons on the left side of the head and inexperience of the surgeon all appear to increase the risk of ethmoidectomy complications in some fashion.

Transantral Ethmoidectomy and External Ethmoidectomy

Complications of transantral ethmoidectomy and external ethmoidectomy are the same as for intranasal ethmoidectomy. However, because direct vision with or without a microscope is used, fewer major complications are found. Transantral ethmoidectomy necessitates a Caldwell-Luc operation; therefore, the complications include those of a Caldwell-Luc procedure (see earlier). It is also important that the distance to the ethmoidal and sphenoid sinuses through a transantral approach is half that of an intranasal approach. In 158 transantral ethmoidectomies on 98 patients, Malotte et al. (22) found increased blood

loss (average 384 mL) and an average hospitalization of 3.6 days. A total of 20.4% of patients had complications.

The adverse events of external ethmoidectomy really should be divided into expectations and risks. Because external ethmoidectomy produces an external scar, patients should expect some deformity, especially if the incision is extended for frontoethmoidectomy. Almost all patients have ecchymosis from an injury to the angular vessels and lid edema from the incision. Most complications are minor orbital problems such as periorbital edema and forehead anesthesia, which can occur via injury to the supratrochlear and supraorbital neurovascular bundles. Other problems include hemorrhage and wound infections that resolve in the majority of cases. Injury to the lacrimal apparatus can happen as well. Complications such as intracerebral hemorrhage, pneumocephalus, and CSF fistula occurred among 3.1% of patients (22). Minor complications such as infraorbital nerve numbness and pain, atrophic rhinitis, facial edema, crusting, epistaxis, diplopia, and epiphora also were found. Infraorbital nerve injury with numbness was the most common complication.

Neal (23) found optic nerve injury, corneal abrasions, exposure keratitis, trochlear and medial rectus injury, and diplopia from enophthalmos as potential orbital complications from external ethmoidectomy. The need for possible scar revision, especially if webbing of the incision occurs, was also mentioned in this study. In 41 frontoethmoidectomies, Dedo and Broberg (24) had no complications and a 97% success rate. Although complications occur frequently in transantral and external ethmoidectomy, most are minor and resolve. Major complications such as CSF leak and transcranial hemorrhage are rare owing to the excellent exposure afforded by these procedures but seem to be more common than with intranasal surgery.

Sphenoidotomy

Thirteen important structures, including the carotid artery, the cavernous sinus, the optic nerve, and the brain, are contiguous with the sphenoid sinus (Fig. 44.10). Many of these structures can be injured during sphenoidotomy, regardless of whether the operation is external, transantral, intranasal, or transseptal. These injuries can be catastrophic but rare. Malotte et al. (22) found no sphenoidotomy-related problems in 158 sphenoidotomies in conjunction with transantral ethmoidectomy. The sphenoid wall in transantral sphenoidotomy is only 4 to 5 cm from the antral opening compared with 7 cm in transnasal sphenoidotomy (Fig. 44.6). CSF leaks can occur when a sphenoidotomy is improperly performed, and these leaks can be repaired with a number of intrasphenoidal techniques. Injuries to the cavernous sinus and/or carotid artery are rare but can be fatal. Immediate management can be successful, and this includes packing the sphenoid sinus and nasal cavity and involving a neuroradiologist who is skilled at performing endovascular occlusion of the carotid artery either in the operating suite (if the patient is unstable) or in the interventional suite (25–27). Delayed formation of carotid artery pseudoaneurysm is uncommon but may also be treated with endovascular techniques. Sphenoidotomy can cause major complications, but these are rare. Minor complications include bleeding from the septal branch of the sphenopalatine artery, which is controlled with electrocautery, as well as mucus recirculation around a false ostium, ostial stenosis, and late mucocele formation.

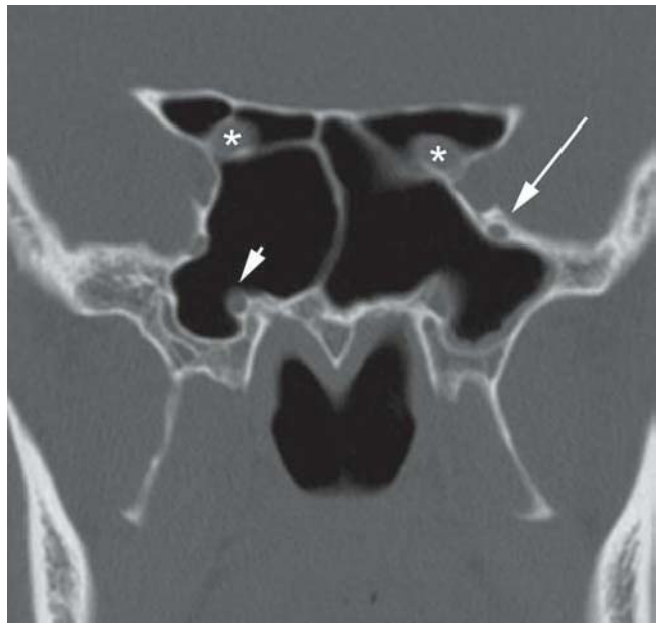

Figure 44.10 A coronal CT of the paranasal sinuses featuring the anatomy that relates to the sphenoid sinus. The optic nerve (*asterisk*), Vidian nerve (*arrowhead*), and maxillary nerve (*arrow*) can be easily seen in this image. Not as easily seen are the carotid arteries and the cavernous sinuses, which contain branches of the trigeminal nerve, the occulomotor nerve, the trochlear nerve, and the abducens nerve.

Frontal Sinus Trephination

Surgery on the frontal sinus varies in complexity. The simplest form of frontal sinus surgery is via external trephination, which was described by Ogston (28) and Luc (29) in the late 1800s as evacuation of the frontal sinus through a hole the size of a "six penny piece" (a.k.a. sixpence or half-shilling, 19 mm or 0.75 inch), which is typically larger than the modern day trephination. Trephination requires a small incision along the medial/superior brow line, and the sinus is entered with the aid of an osteotome or drill. Bleeding and numbness of the overlying skin are the most common adverse outcomes of this procedure; however, injury to the supratrochlear neurovascular bundle may occur or even injury to the orbital trochlea. The depth of the posterior table of the frontal sinus has been studied relative to the location of the anterior table, and while trephination is considered a safe procedure, up to 15% of patients may have relative radiologic contraindications (30).

Open Frontal Sinus Surgery

More advanced surgery of the frontal sinus requires either an extended Lynch, gullwing, mid-brow, or coronal incision. There are benefits and disadvantages to each type of incision. Obviously, the Lynch, gullwing, and mid-brow approaches require incisions that are visible on the face, some of which (i.e., gullwing, mid-brow) can lead to unsightly scars as well as numbness in the area. The coronal incision offers the distinct advantage of being hidden in the hair line, although considerations for future hair loss or existing hair loss in men must be made prior to choosing this approach. The major complication of this incision is hair loss around the area of the incision as well as numbness of this region of the scalp. Other complications related to this approach include those acquired during the elevation of the scalp flap: injury to the frontal branch of the facial nerve, injury to the supraorbital and supratrochlear neurovascular bundles, and laceration of the pericranial flap. Nevertheless, the coronal incision provides the surgeon with unprecedented access to the frontal sinus. It is through this approach that the surgeon can perform either a unilateral or bilateral ablative or osteoplastic frontal sinus procedure.

Various ablative frontal sinus procedures have been described throughout the late 1800s and early 1900s as means of treating chronic frontal sinusitis. The complete removal of the anterior table of the frontal sinus with removal of all diseased mucosa was originally described by Riedel-Schenke (31). This resulted in the often times unsightly collapse of the forehead skin into the frontal sinus defect. To avoid this rather hideous result, Killian (32) proposed leaving a 1 cm supraorbital bar to minimize the cosmetic defect; however, his procedure was criticized for high rates of recidivism, presumably due to retained mucosa posterior and inferior to the retained frontal bar. Both procedures suffer from all the usual complications related to the approach: scar, bleeding, and paresthesias. Long-term failures were criticisms mainly of the Killian procedure; however, incompletely ablated mucosa during the Reidel procedure would result in disease recurrence as well. To mitigate the poor cosmetic result and long-term failures, the osteoplastic frontal sinusotomy more or less replaced these procedures.

Ironically, the osteoplastic frontal sinusotomy was described only shortly after the Reidel procedure by Schonborn (33) in 1894. However, what we now consider to be the modern osteoplastic frontal sinusotomy was described by Macbeth (34) and popularized through the publication and follow-up performed by Goodale, and Montgomery (35–38). Osteoplastic frontal sinus surgery with or without fat obliteration is an extensive procedure performed most frequently on patients with refractory chronic sinusitis, frontal sinus fractures, mucoceles, or CSF rhinorrhea. Any procedure involving the ablation of the frontal sinus in which an allograft is taken obviously involves morbidity associated with the harvest procedure. Common donor sites include the scalp, abdomen, and lateral thigh.

Hardy (39) reviewed a series of 250 patients and found that 47 patients (18%) had early complications, including abdominal wound complications related to the fat graft harvest, such as hematoma, seroma, or abscess. Hematoma, seroma, or abscess also occurred within the frontal wound. In these reviews (37,39), Hardy and Montgomery found that some osteotomies intended to be within the sinus were in fact craniotomies that resulted in dural exposure without brain injury. Four cases of dural exposure were found when the mucous membrane was stripped, suggesting areas of dehiscence. Five dural lacerations occurred, two of which had to be repaired. Other complications included necrosis of the skin of the dorsum of the nose, anosmia, temporary ptosis, and temporary dysfunction of the frontalis muscle. After 8 years, 6% of 208 patients had persistent postoperative pain, and 1% had persistent neuralgia. These complications occurred most often with brow incisions, in which the supraorbital nerves usually are incised, as opposed to coronal incisions, in which the supraorbital nerves usually are preserved. Poor appearance of the incision scar occurred among less than 1% of patients. Six percent had depression or elevation (a.k.a. frontal bossing) of the osteoplastic flap. This complication can be avoided by beveling the osteotomies and by closing the wound meticulously with semi-rigid or functionally rigid fixation. Only 6% of patients needed revision surgery (37). Because of this low revision rate, frontal sinus obliteration with osteoplastic flap was considered the gold standard for treatment of chronic frontal sinus disease for many years until the era of endoscopic sinus surgery.

Hypesthesia and wound infection are the most common complications after osteoplastic flap surgery. Postoperative pain persists among 6% of patients, and almost 7% have scarring or forehead abnormalities. Although exposure of dura does occur, CSF leak, meningitis, or brain injury is unusual. After operations on 43 patients, Ulualp et al. (40) found that 6 patients had decreased sensation and 1 had CSF leak.

COMPLICATIONS SPECIFIC TO ENDOSCOPIC SURGICAL PROCEDURES

Middle Meatal Antrostomy

The complications of middle meatal antrostomy are bleeding, blindness, facial pain, numbness, nasolacrimal duct injury, and synechiae. Davis et al. (41) performed 310 middle meatotomies endoscopically with no serious surgical complications. Epiphora developed in 1 patient and synechia in 20 patients. However, Bolger et al. (42) found up to a 15% incidence of *occult* injury to the lacrimal apparatus during middle meatal antrostomy. A few anecdotal reports exist of temporary pain and numbness due to endoscopic

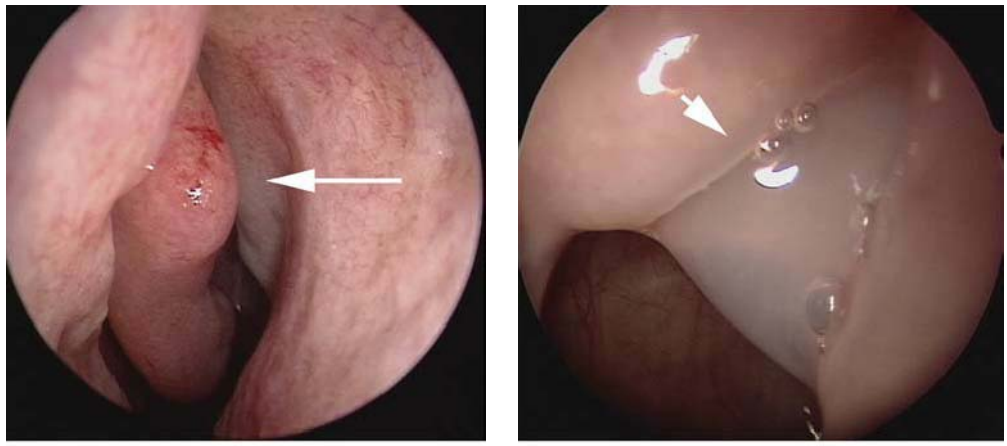

Figure 44.11 An endoscopic view of the middle meatus during revision sinus surgery for chronic maxillary rhinosinusitis. Inspection with a 0-degree telescope reveals a partially resected uncinate process. This middle meatus looks otherwise healthy; however, an inspection of the surgical antrostomy with a 45-degree telescope reveals recirculation of cloudy mucus (*arrowhead*) from the true ostium of the maxillary sinus into the surgical antrostomy.

middle meatal antrostomy. These complications were most likely caused by injury to the alveolar nerves lining the meatal wall of the maxillary sinus.

In 300 antrostomies, Stankiewicz (20) found two cases of epiphora. Today endoscopic middle meatal antrostomy is a relatively complication-free procedure with sporadic reports of numbness and pain. Although blindness is possible, it is usually associated with ethmoidectomy.

Improper identification of the true ostium of the maxillary sinus can result in the formation of a surgical ostium that does not properly treat maxillary mucosal disease. In his review of surgical failures, Parsons et al. (43) revealed that the largest cause of revision maxillary sinus surgery was the presence of a missed maxillary ostium. Missing the natural ostium can result in recirculation of mucus, potentially infected mucus; typically this is the result of incompletely removing the uncinate process and failing to identify the natural ostium prior to performing maxillary sinus surgery (Fig. 44.11).

Sphenoidotomy

Perhaps not unique to endoscopic sinus surgery, but certainly mistaken quite frequently during endoscopic sinus surgery is the sphenoethmoidal (a.k.a. Onodi (44)) cell. The sphenoethmoidal cell is an ethmoid cell that pneumatizes lateral and superior to the true sphenoid sinus. It may be identified preoperatively on coronal CT imaging where a transverse partition within the sphenoid sinus heralds the possibility of this cell (Fig. 44.12). The sphenoethmoidal cell is closely, if not intimately, associated with the optic nerve and the carotid artery. Mistaking the Onodi cell for the sphenoid cell, or proceeding distally to the Onodi cell with the assumption that the sphenoid sinus is directly behind this ethmoid cell are recipes for disaster. If the surgeon proceeds through the ethmoid and if he or she can see the floor easily of what he or she believes to be the sphenoid sinus, this is more likely to be an Onodi cell. Therefore, the superior turbinate can be used as a landmark for safe and successful entry to the sphenoid sinus. Bolger et al. (45) described a means by which the posterior ethmoid cavity was outlined by an imagined parallelogram with the boundaries being the skull base superiorly, *lamina papyracea* laterally, basal lamella of the superior turbinate inferiorly, and the superior turbinate and septum medially. Entry into the sphenoid sinus through the

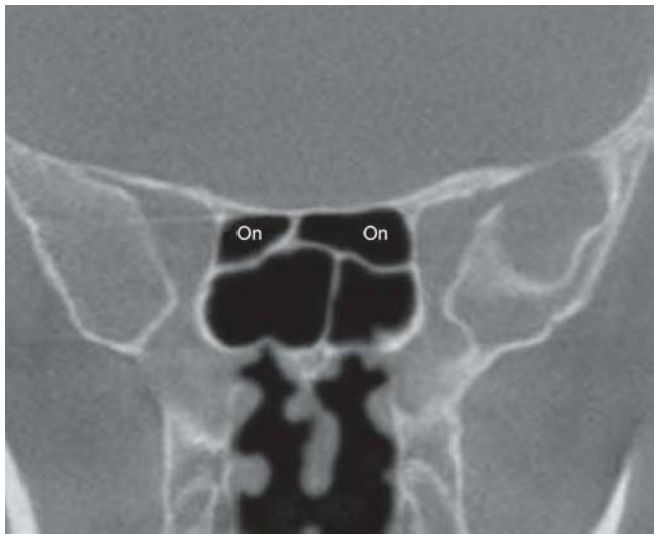

Figure 44.12 A coronal CT of the sphenoid sinus. Transverse partitions within the sphenoid sinus may indicate the presence of Onodi (sphenoethmoid) cells (*asterisk*). These ethmoid cells pneumatize the sphenoid bone lateral to and superior to the sphenoid sinus. They are typically related to the optic nerve and may feature the optic nerve prominently (see Fig. 44.2).

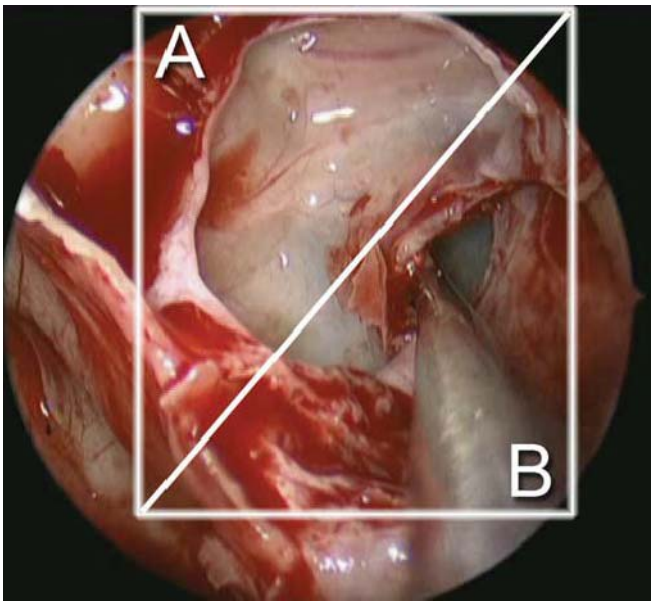

Figure 44.13 An endoscopic view of a patient undergoing primary endoscopic sinus surgery of the sphenoid sinus. Safe entry into the sphenoid sinus may be performed through the inferior and medial aspect of "Bolger's Box," which is an imagined box with the following boundaries: lateral being the *lamina papyracea*, superior being the skull base, inferior being the ground lamella, and medial being the septum and superior turbinate.

natural os or through the inferior and medial half of this "box" is considered safe and unlikely to injure the carotid artery or optic nerve (Fig. 44.13). Distances to the sphenoid sinus can be marked with a beaded probe (recalling that the distance to the os is ~7 cm) or with image-guidance probes.

Frontal Sinus Surgery

Postoperative synechiae, or ostia scarring due to middle turbinate lateralization or ostia manipulation are the most common complications resulting from endoscopic frontal sinus surgery. The more significant intraoperative complications, such as CSF leak, intracranial injury, hemorrhage, or orbital injury, are much less common, however. Of particular note is the increased incidence of complications associated with the use of the high speed drill, particularly during the transseptal frontal sinusotomy or Draf III (46) procedure. Because of the widespread surgery on the floor of the anterior skull base from orbit to orbit that is necessary, the potential for major complications, which include CSF leak, brain entrance with hemorrhage, smell loss, and orbital hematoma, is present. Samaha et al. (47) in a large series of 100 procedures had no intraoperative complications and 4 postoperative hemorrhages. The use of stereotactic navigation during these drill-out procedures is very helpful and ultimately may reduce complications in surgery on the frontal sinus, especially during revision cases.

Balloon Catheter Dilation Procedures

The use of balloon catheters as instruments to dilate the sinus ostia for treatment of medically refractory chronic rhinosinusitis is a relatively new phenomenon. Balloon catheter dilation can be performed via either the transnasal or transantral route, although the application of transantral balloon catheter dilation is more limited. Bolger et al. (48) reported the initial results of balloon catheter dilation on patients with 24 weeks of follow-up and no significant adverse events were noted. Vaughan (49) reviewed a number of uncontrolled studies pertaining to the use of transnasal balloon catheters and surmised that the number of serious complications was low; however, scattered reports (50,51) do indicate the possibility of catheter-related complications.

Transantral balloon catheters dilate the maxillary sinus os and infundibulum; however, they require a mini-trephination in the canine fossa. Therefore, the approach is subject to similar risks and complications as those previously described in the section pertaining to Caldwell-Luc procedures. Stankiewicz et al. (52) reported no significant adverse events after initial use after 1-year follow-up (53) in patients undergoing mini-trephination and transantral dilation of the maxillary os and infundibulum.

Therefore, when used as prescribed balloon catheters do not appear to carry with them a significant risk of major surgical complications; however, the long-term functional outcomes and minor complications have been incompletely described. The rates of revision surgery following balloon catheteronly surgeries have not been described either.

Powered Endoscopic Sinus Surgery

The use of the microdebrider (tissue shaver) is commonplace in endoscopic sinus surgery, as it accelerates the process of sharply removing diseased sinus tissue and bone while providing the surgeon with a relatively dry field through its suction capabilities. Ironically, the speed with which the microdebrider functions as well as its relative lack of tactile sensation can be considered two of its largest shortcomings. The microdebrider does not discriminate: It will aggressively resect orbital fat, muscle, and brain just as efficiently as it resects polypoid mucosa (Fig. 44.14). The onset of diplopia due to medial rectus injury has been attributed to microdebrider misadventures, and horror stories of parenchymal dissection and bilateral blindness are certainly present in discussion of these complications. Practically speaking, the microdebrider is a tool and is best used by a surgeon who is acutely aware of the location of the cutting blades. Therefore, the teeth of the microdebrider should *always* be in view so the surgeon can confirm what tissue is being resected. The microdebrider should never lead into unknown tissue and should never be operated in a pool of blood. When dissecting close to the orbit, the teeth should be pointed away from the *lamina papyracea*, especially if dehiscent areas are identified. Otherwise,

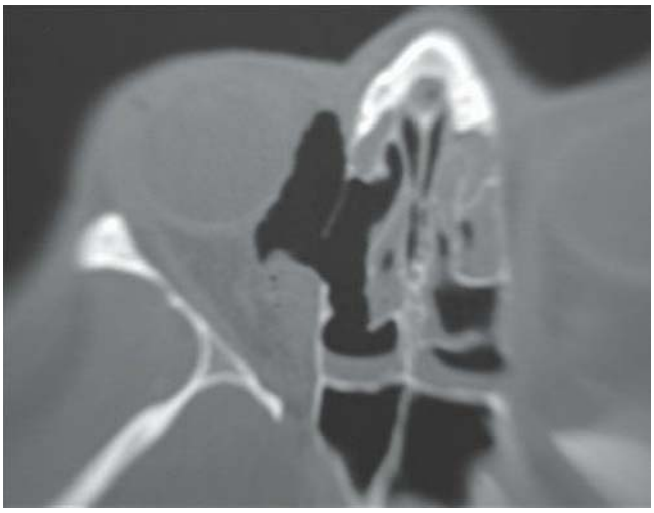

Figure 44.14 An axial CT of a patient who underwent endoscopic sinus surgery who complained of postoperative diplopia. The CT reveals a large dehiscence of bone along the right orbit and evacuation of the orbital contents. This injury was sustained when the surgeon violated the *lamina papyracea* with a microdebrider, which has strong suction and dissection capabilities. In this situation, the suction power of the microdebrider drew orbital fat as well as extraocular muscle far beyond the reaches of the microdebrider into the field of dissection.

in a few seconds, orbital tissue can be suctioned into the microdebrider, exposing or removing orbital fat, occasionally injuring the medial rectus muscle. Techniques for identifying the *lamina papyracea* and dehiscence have already been discussed in the Relevant Anatomy section and are further discussed under the upcoming Blindness section. Additionally, the microdebrider should be used only in short bursts along the skull base, and there is rarely any good reason to debride within the sphenoid sinus.

Image-Guided Endoscopic Sinus Surgery

Image-guided endoscopic sinus surgery (IGSS) was developed in the early 1990s. Truly practical systems for use with endoscopic sinus surgery were not available until the mid-1990s. There are two types of systems currently available: line-of-sight models and electromagnetic models. Line-of-sight models rely on the placement of headgear with reflective spheres that with an infrared emitter triangulate the position of a probe within the sinonasal cavity. Electromagnetic models rely on the creation of a magnetic sphere around the field and uses wired technology to track the position of a probe within the sinonasal cavity. Excellent review of this technology is described by Citardi (54,55).

The expansion of image-guidance systems is such that IGSS is commonplace (56,57). The American Academy of Otolaryngology—Head and Neck Surgery has drafted a policy statement (http://www.entnet.org/Practice/policyIntraOperativeSurgery.cfm) that describes the indications for computer-aided sinus surgery. The indications include the following: (a) revision sinus surgery; (b) distorted anatomy that is postoperative or traumatic in origin; (c) extensive polyposis; (d) frontal, posterior ethmoid, and sphenoid sinus disease; (e) disease of concern abutting skull base, orbit, optic nerve, or carotid artery; (f) CSF rhinorrhea or skull base defect/encephalocele; and (g) benign and malignant tumors.

Image-guided sinus surgery has the ability to reduce complications if used correctly (56), but the level of evidence supporting what is commonly maintained by surgeons is lacking (58). Truly long-term studies to evaluate outcomes would be very difficult to perform; therefore, the image-guided surgery is considered state of the art rather than standard of care, even for difficult or revision cases. Two problems have emerged that contribute to complications related to the use of image guidance. First, surgeons with marginal skills may use these systems to perform surgeries in areas in which they have little experience and are technically not experienced enough to avoid or deal with complications. Second, many surgeons may rely heavily on the accuracy of the computer and may not verify the computer images with what is observed. This is obviously hazardous and can lead to disastrous mistakes. The image-guidance systems should always be properly calibrated. Calibration errors can begin with the preoperative computerized CT scan, at the time of surgery registration, or during surgery. A protocol for CT scanning should be set in place at a surgeon's institution, and this protocol should be followed to the letter each and every time an image-guided protocol CT is performed. If using surface registration, the CT should be performed as close to surgery as possible to avoid minor changes in skin appearance, swelling, weight gain/loss, etc. If surface registration is performed on a patient, it should be performed prior to placement of eye tape and nasal pledgets, both of which may distort facial anatomy. Care must be taken to not place too much tape or traction on the endotracheal tube, as this may distort the facial anatomy as well. During the procedure, especially when changing instruments, verification of bony landmarks (frontozygomatic suture, anterior nasal spine, axilla of the middle turbinate, or posterior maxillary sinus wall) should always be performed. These systems are susceptible to registration errors and fiducial localization errors such that three-dimensional localization may contain a 1 to 2 mm margin of error (59–61). So the skull base or orbit should be given at least 2 to 3 mm as a buffer zone of safety. Any discrepancy between anatomic endoscopic visualization and the computer requires repeat registration and, if necessary, system recalibration. If still inaccurate, the computer should not be used for guidance and the surgeon should decide whether proceeding is essential under the circumstances.

ORBITAL COMPLICATIONS

Orbital Hematoma

Orbital hematoma is caused by entrance through the *lamina papyracea* and can occur whether or not the periorbita is injured. The risk of orbital hematoma with blood retention

in the retrobulbar space increases greatly with penetration of the periorbita. However, ecchymosis can occur in either situation if the *lamina papyracea* has been violated. Orbital hematoma is by definition a postseptal injury of the retrobulbar space (intraconal or extraconal). There are two types of orbital hematoma—fast (arterial) hematoma and slow (venous) hematoma (62,63). Orbital hemorrhage is caused most frequently by trauma to the orbital veins lining the *lamina papyracea* and rarely by injury to the anterior and posterior ethmoidal arteries (6,18,20,62,63). The difference between the two is the speed at which the clinical signs and symptoms of retrobulbar hematoma develop. Hematoma from ethmoidal artery injury occurs immediately. Orbital hematoma can be caused using forceps or a microdebrider (powered instrumentation).

The difference between postseptal and preseptal (such as hematoma from injury to the angular vessels with a needle injection) ecchymosis is that the preseptal hematoma is darker, is more diffuse, and produces more lid edema or evidence of subcutaneous emphysema (Fig. 44.15). A postseptal (or retrobulbar) hematoma, when clinically significant, is marked by proptosis, conjunctival changes such as chemosis (edema of the conjunctiva), and pupillary changes, such as mydriasis or a dilated pupil. Anisocoria (unequal pupillary size) can be caused by topical or injected local anesthesia and is self-limited. Proptosis is not present, and the eye is soft, unlike the situation with hematoma. Ecchymosis due to Caldwell-Luc external ethmoidectomy with a frontal osteoplastic flap usually is preseptal but can be postseptal if the orbit is entered. Ecchymosis related to intranasal ethmoidectomy is almost always postseptal. Most cases of orbital hematoma do not have associated proptosis and pupillary changes, but patients have to be observed closely so that these findings do not develop. These findings signal increased orbital pressure and potential damage to the optic nerve. Ecchymosis usually resolves in about 7 to 10 days.

A

B

Figure 44.15 Photographic depictions of patients who sustained injuries to the *lamina papyracea.* The patient featured on the top **(A)** developed orbital emphysema after blowing his nose. The patient on the bottom **(B)** developed superior lid ecchymosis due to a bony and soft tissue injury of the orbit. The outline of the ecchymosis extends along the arcus marginalis, which is contiguous with the orbital septum and periorbita.

Figure 44.16 A photograph of a patient about to undergo endoscopic sinus surgery. The surgeon gently presses on the orbit to accomplish two ends: (a) to determine how tense the globe is prior to surgery and (b) to view the middle meatus endoscopically to see if any orbital dehiscence is present. Areas suspicious for orbital dehiscence should be confirmed with CT imaging prior to the start of surgery. This bulb test can be performed at any time during the procedure. Also note that the patient's eyes are taped closed at the lateral canthus. This is preferred over placing the tape transversely across the lids or placing a bio-occlusive dressing, as a strip of tape along the lateral canthus often does not have to be removed to take a quick look at the sclera and pupil.

It is important to check the eyes with a simple bulb test (Fig. 44.16) prior to surgery to assess how much tension is present prior to the procedure. Therefore, there will be no confusion when the surgeon suspects a retrobulbar hematoma and the globe is tense. If an orbital hematoma does occur, there are multiple medical and surgical maneuvers to treat this complication. The normal intraocular pressure ranges from 10 to 20 mm Hg; a rise in the pressure to within the range of 30 to 40 mm Hg is extremely worrisome and implies hematoma until proven otherwise. General anesthesia lowers intraocular pressures; therefore, the surgeon should not rest assured if the reading on the tonopen is borderline. When the pressure is elevated in this range, orbital massage, administration of mannitol (2 g/kg of a 15% to 25% solution over 30 minutes), and 10 mg of dexamethasone are indicated. In an awake patient, one to two drops of timolol may be administered. These conservative measures are adjunctive and do not replace an active investigation of the site(s) of bleeding and immediate relief of the intraocular pressure. If necessary, the surgeon should not hesitate to perform a lateral canthotomy and cantholysis. This single maneuver can save a patient's vision. To perform this, a 1 to 2 cm incision is fashioned from the lateral commissure through the lateral canthal soft tissue. This will relieve pressure by itself and give approximately

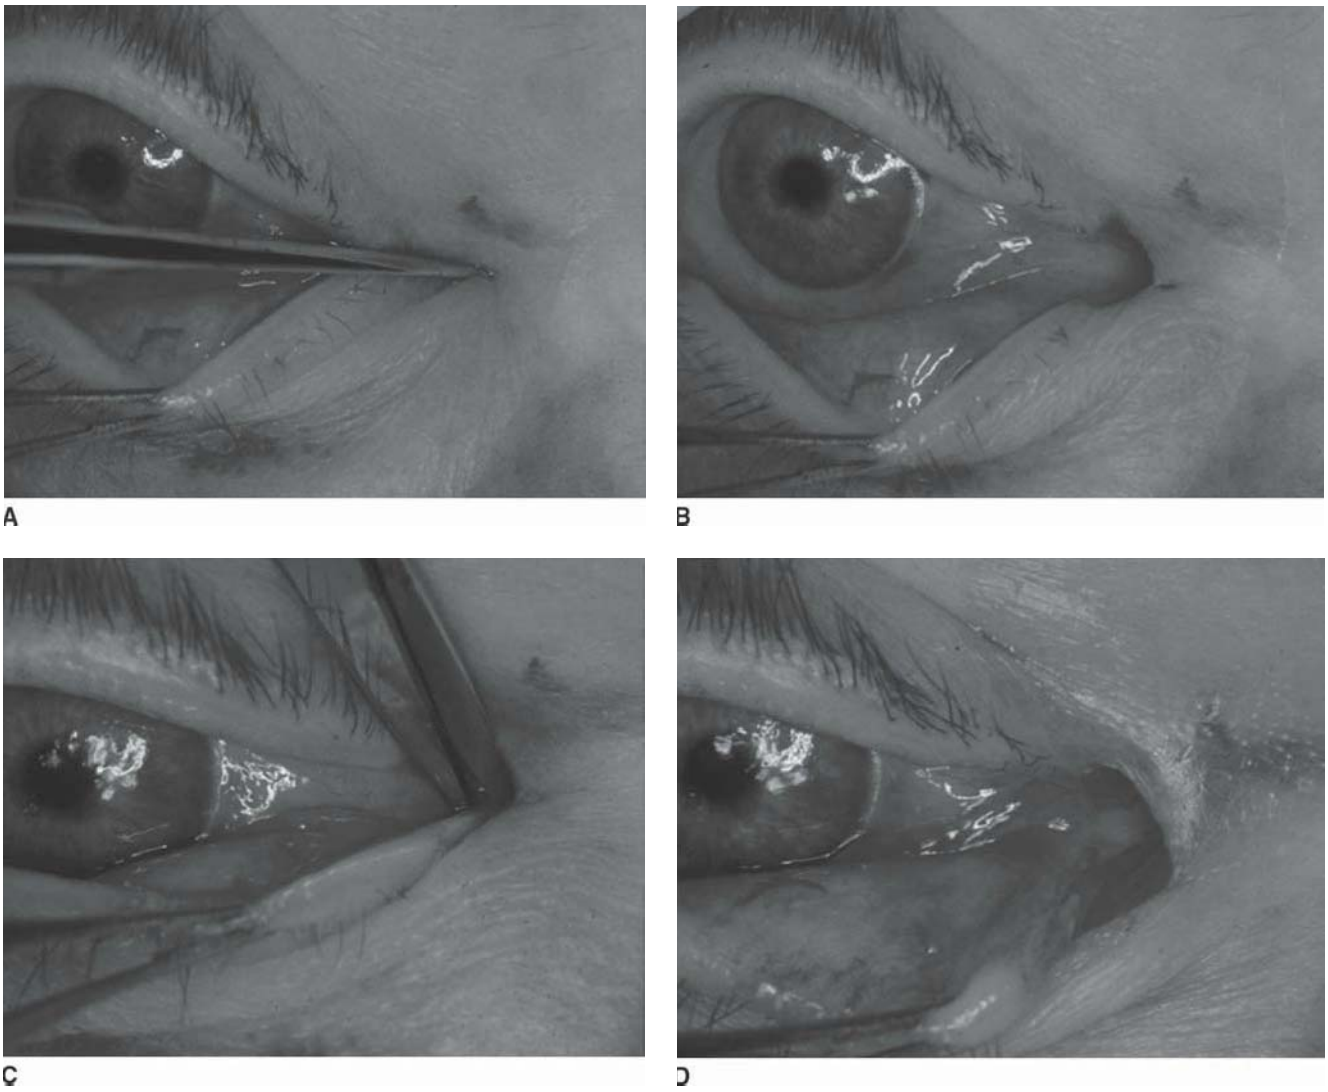

Figure 44.17 Photographic steps of a lateral canthotomy and cantholysis. Scissors or a blade is used to incise from the lateral commissure through the lateral canthus **(A)**. With the lid retracted **(B)**, this maneuver alone with help achieve up to 15 mm Hg release. If further relief of pressure is required, the superior and inferior ligaments are divided **(C)**. The result is a lateral canthotomy and cantholysis **(D)**, which can relieve up to 20 mm Hg of additional pressure. This maneuver can be performed in less than 1 minute. All surgeons performing endoscopic sinus surgery should know how to perform this relatively simple procedure, as it can save a patient's vision.

15 mm Hg leeway. If additional pressure needs to be relieved, a cantholysis should be performed; the superior and inferior portions of the lateral canthal ligament and their attachments to Whitnall tubercle are divided. This maneuver can attain up to 20 mm Hg relief (Fig. 44.17). If further relief of pressure is still necessary, an endoscopic orbital decompression can be performed by removing the *lamina papyracea* and incising transversely the periorbita to allow prolapse of extraconal fat into the sinonasal cavity.

Once the pressure is relieved, the source of bleeding should be identified. Any nasal packing should be removed to prevent pressure on the orbit and that would otherwise delay egress of orbital fluids into the nose. Monopolar cautery should absolutely be avoided around any dehiscent areas of the orbit, since the spread of cautery may injure the neurovascular structures or extraocular muscles. If necessary, bipolar cautery of bleeding from the periorbita or extraocular fat is preferred. If bleeding is suspected to have arisen from the anterior or posterior ethmoidal arteries, an attempt to ligate these vessels with bipolar cautery can be performed endoscopically. If the vessels are embedded within the skull base, as they are greater than 90% of the time, the surgeon may have to make an external excision to ligate the vessels with surgical clips or bipolar cautery.

It is advised that an ophthalmologist be involved in the steps of this process whenever feasible. If possible, an ophthalmologist may even perform these procedures. However, no delay in action should be taken by the sinus

TABLE 44.3 MANAGEMENT OF SUDDEN LOSS OF VISION

Immediate (fast arterial hematoma: >30 min decompression time)				
1. Orbital injury	Proptosis[a] Pupillary change[a] Vision loss[a] Yes ↓	No	→	Observe
2. Medical treatment	Eye consultation Mannitol[b] Orbital massage High-dose steroid[d] No success	Success	→	Observe; bed rest; sedation; acetazolamide[c]; ophthalmology follow-up
3. Surgical treatment	Lateral canthotomy Medial external (Lynch) Decompression Endoscopic decompression Control bleeding artery	Success	→	Observe as in medical treatment
Delayed (venous slow hematoma: 60–90 min decompression time)				
	Proptosis Vision loss Yes ↓	No	→	Observe
	Medical treatment (same as above) No success ↓	Success	→	Observe
	Surgical treatment (same as above)			

[a]Local or general anesthesia.
[b]Intravenous dose of mannitol, 1–2 g/kg.
[c]Acetazolamide used at discretion of ophthalmologist.

surgeon in order to wait for the ophthalmologist to arrive, and certainly any delay caused by confirming a hematoma by CT or MR imaging may ultimately result in a patient who has lost his or her vision. See Table 44.3 for the steps related to treatment of orbital hematoma.

Blindness

Blindness is a catastrophic complication of sinus surgery and can be temporary or permanent. Temporary blindness can be caused by injection of vasoconstrictive agents (especially if via the transoral, pterygopalatine route since the pterygopalatine fossa freely communicates with the inferior orbital fissure) or by orbital hematoma that has expanded to such an extent that it increases orbital pressure, consequently compromising vascular supply to the optic nerve, which is sensitive to ischemia. Studies with laboratory animals have shown that increased intraocular pressure gradually returns to normal within 2 to 3 hours. However, light perception may not return for several more hours and the pupillary reflex for 24 to 48 hours (62,63). In blindness caused by retrobulbar venous hematoma, the retina can tolerate these extreme pressures perhaps for 60 to 90 minutes; however, irreversible changes in vision may occur in 30 minutes or less if there is an arterial bleed. Intervention must take place within this time limit (63). In the case of fast arterial hematoma usually due to anterior ethmoid artery injury and retraction into the orbit, immediate high pressure on the optic nerve must be reduced in less than 30 minutes to avoid blindness.

Although compensatory mechanisms protect retinal blood flow, neural tissue is vulnerable to ischemic injury. Even transient interruption of the blood supply can cause neural tissue in the retina to become nonfunctional and unresponsive to light. Venous outflow obstruction of the vessels supplying the optic nerve induces hypoxia. Prevention of blindness begins preoperatively with a history and physical examination that exclude potential problems (previous surgery, complicated surgery, or long-standing disease) and patients who have bleeding problems or are taking medications such as aspirin that can affect bleeding. Inquiries should be made regarding pathologic conditions of the eye that can be related to blindness, such as glaucoma, amblyopia, diabetic retinopathy,

and retinal vascular disease. Scrutiny of radiologic studies, primarily CT scans, for evidence of dehiscence or other problems is important.

Surgical planning commensurate with the ability and experience of the surgeon is necessary. Operative prevention involves selection of appropriate anesthesia. Surgeons operating on the ethmoid sinus should keep the eye taped closed at the lateral canthus and be scrutinized frequently in order to detect any early proptosis, ecchymosis, or eye movement during the surgical procedure. Although with an external procedure structures are apparent under direct vision or with stereoscopic (binocular) vision, the use of an endoscope can distort anatomic features and misrepresent depth of field, allowing entrance into the orbit.

A technique helpful for endoscopic ethmoidectomy but also practical for microscopic or traditional intranasal ethmoidectomy is the intraoperative bulb press test or simultaneous eye palpation and intranasal examination (62,63) (Fig. 44.18). This simple maneuver readily identifies movement of the periorbita or orbital contents and prevents entrance into the orbit. This test should be performed prior to the procedure and during the procedure. This is also useful for identifying the lacrimal sac when removing agger nasi cells. Identification of the maxillary sinus ostium and proceeding with the maxillary antrostomy before performing the ethmoidectomy also help with delineation of the *lamina papyracea* early in the procedure. An assistant or scrub nurse/technician can be asked to monitor the eye as an additional layer of protection.

Tissues such as fat float in fluid, whereas others such as those encountered in sinus disease and polypoid disease do not. The instrument nurse always should place fluid in the specimen containers and should immediately inform the surgeon whether anything floats. It should be noted that extraocular muscles, especially the medial rectus muscle, will sink. Before any biopsy of the lamina papyracea is taken, one should perform the bull test to determine if there is any dehiscence and fat is visible. If orbital fat is found, it should be left alone and not tampered with. In most cases, ecchymosis forms intraoperatively or

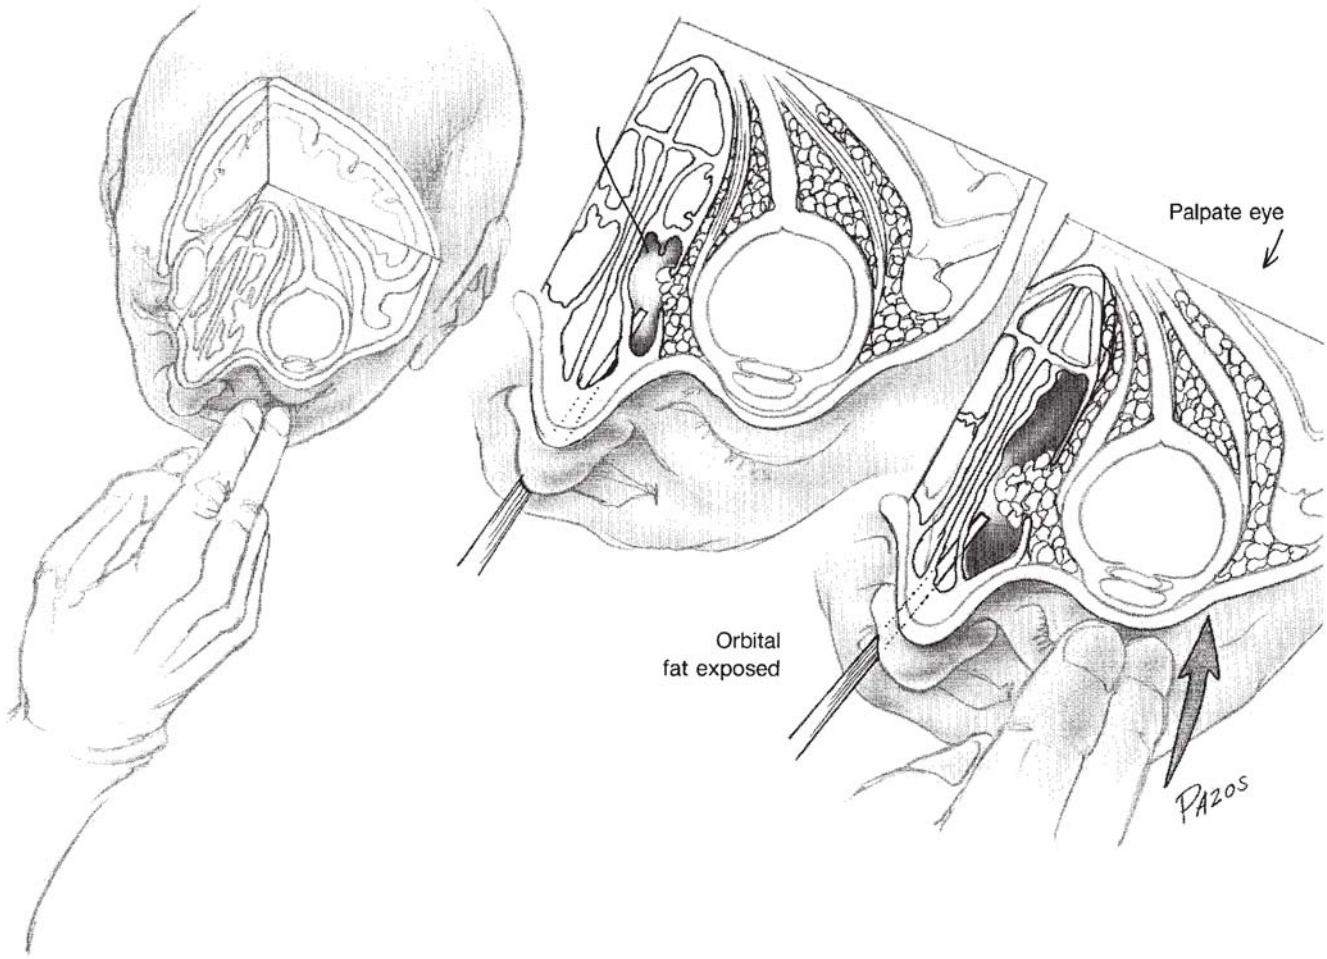

Figure 44.18 Bulb press test. Endoscope is in place for examining the middle meatus and the lateral wall of the ethmoid sinus. A hole in the lamina papyracea is visible. Simultaneous eye palpation and endoscopic visualization to find periorbital fat or fat exposure as early as possible. (Redrawn from Stankiewicz JA. Blindness and intranasal endoscopic ethmoidectomy: prevention and management. *Otolaryngol Head Neck Surg* 1989;101:320, with permission.)

postoperatively, and the patient should be watched closely for orbital hematoma. The nose should not be overly packed; in fact, it may be advisable to instill a hemostatic gel or paste within the nasal cavity to perform hemostasis. If a dehiscence is present, the packing itself can press into the periorbita and posterior chamber, increase pressure, and cause proptosis. Frontal sinus procedures, especially with obliteration, often encounter the orbit from above. Orbital hematoma can occur with increased pressure if orbital fat is present. Most eye swelling is otherwise preseptal.

Postoperative prevention revolves around informing the patient, nurse, and family about what to expect and what to do if vision problems occur. Slow venous hematoma can accumulate over 24 to 48 hours. Surgical outpatients need rigid guidelines for monitoring and need inpatient observation if signs of orbital complications develop. When evidence of orbital changes appears during any sinus-related procedure, especially ethmoidectomy, immediate action must be taken. Blindness has been reported as a complication of all forms of sinus surgery. Optic nerve injury is not reversible, but it is sometimes difficult to separate the signs and symptoms of expanding retrobulbar hematoma, which can be corrected, from those of optic nerve injury because in almost all cases there is evidence of orbital hematoma.

Diplopia

Double vision is caused by injury to the extraocular muscles most intimately related to the sinuses, chiefly the medial rectus and the superior oblique muscles (8). The medial rectus is immediately lateral to the periorbita along the transverse midpoint of the *lamina papyracea*. The superior oblique muscle is higher in the orbit just lateral to the ethmoidal roof; it is more difficult to reach via an intranasal approach. However, during an external ethmoidectomy, the periorbita may be violated higher in the orbit and as a result, injury to the superior oblique may occur. (The surgeon should note that the convergence of the superior oblique and the medial rectus muscles is the location of the extraconal portion of the anterior ethmoidal artery and more posteriorly, the take-off of the ophthalmic artery. Injuring these vessels is even more severe than muscle injury.) Muscle injury can be caused by direct muscle injury or injury to the nervous or vascular supply to the eye muscle. Indirect muscle injury theoretically can occur as a result of heat conduction from a cautery or laser through a dehiscence in the *lamina papyracea*; therefore, bipolar cautery is advised when topical thrombotic agents are ineffective. No published reports of this type of injury are known. Unintentional injection of local anesthesia into the orbit can traumatize the medial rectus muscle and cause temporary diplopia or anisocoria. Powered instrumentation has recently been noted to be related to medial rectus injury. If a dehiscence occurs in the *lamina papyracea*, the high suction used by a microdebrider can pull the periorbita, orbital fat, and medial rectus into the microdebrider chamber causing injury (64,65). Persistent diplopia necessitates ophthalmologic evaluation and possibly surgery, which has a poor prognosis.

Epiphora

The lacrimal gland and sac are contiguous with the ethmoidal sinuses in almost 90% of patients. The agger nasi cells are adjacent to the lacrimal sac, whereas the ethmoid sinus and natural maxillary sinus ostia are related to the lacrimal duct. To reiterate, the true maxillary sinus ostium is less than 5 mm posterior to the nasolacrimal duct, and Hasner valve opens the lacrimal apparatus into the inferior meatus within 1 cm of the anterior end of the inferior turbinate or pyriform. As a rule, the ethmoid sinuses or the maxillary ostia should not be opened anterior to the anterior end of the middle turbinate or into the hardened bone separating the maxillary os from the nasolacrimal duct. An IMA is made after identification of Hasner's valve and performed posterior and inferior to this structure.

Patients should be observed initially because most cases of epiphora resolve. However, prolonged epiphora is associated with persistent injury to the lacrimal system. Both intranasal and external ethmoidectomy and inferior middle meatal antrostomy are associated with this complication. Dacryocystitis can be associated with the Caldwell-Luc procedure as well. If recovery does not occur, a dacryocystorhinostomy with or without placement of drainage tubes can be performed endoscopically with little difficulty (66).

SUBCUTANEOUS EMPHYSEMA

When a fracture or perforation occurs in the *lamina papyracea* during external, intranasal, or endoscopic ethmoidectomy, subcutaneous emphysema can occur (6,20). This complication usually is caused by bag ventilation while the patient is emerged from anesthesia, coughing, nose blowing, emesis, or straining, all of which allow air to enter the soft tissue surrounding the eye (Fig. 44.14). Observation for orbital hematoma is necessary, especially if the periorbita has been violated. In rare instances subcutaneous emphysema is considerable, even extending into the mediastinum. Treatment in most cases is simple observation and reassurance. The emphysema usually reabsorbs within 7 to 10 days, but some puffiness can persist for a few months (6,20).

CEREBROSPINAL FLUID FISTULA

CSF fistula occurs with all techniques of ethmoidectomy, frontal sinus procedures (both open and endoscopic) and, in rare instances, sphenoidotomy. During ethmoidectomy the dura can be entered anywhere from the anterior ethmoid sinus base to the sphenoid sinus skull base (*planum sphenoidale*) or *sella turcica*. The variability in skull base anatomy makes certain areas more susceptible

to injury and the complication can be devastating. Along the anterior skull base in the anterior ethmoid region, the cribriform plate is lower than the *fovea ethmoidalis* and the lateral lamella. It is important that the surgeon stay away from the middle turbinate attachment and operate laterally within the ethmoid. The slope of the skull base is in a downward (Fig. 44.4) fashion as one progresses inferiorly and becomes more horizontal as the posterior portion of the anterior skull base (8,9). The medial part of the roof of the base of the skull posterior to the medial portion of the anterior ethmoidal artery to the sphenoid sinus is almost 10 times thinner than the rest of the bone and can be easily penetrated. The dura is tightly attached, and the base of the skull usually tears if bone is removed. The bone of the base of the skull is hard laterally and not easily penetrated above the sphenoid sinus. In the sphenoid sinus, removing disease from the superior wall or roof can cause a CSF fistula. Endoscopic surgery is especially dangerous because of monocular vision and loss of depth of field.

CSF fistula during frontal sinus usually occurs when using a drill during the performance of a Draf IIb or Draf III procedure or during an open osteoplastic procedure when the osteotomies are made outside the boundaries of the frontal sinus or where the depth of the posterior table is shallow (usually at the apex or lateral aspect of the sinus). The bone incision is made outside the frontal sinus. Although a template is made to help delineate the bone cut, the template is subject to human error during the setup of the x-ray (the patient should be 6 feet from the beam), printing, and with surgeon placement. Although safe and accurate, using an inaccurate image-guidance probe can also lead the surgeon outside the confines of the frontal sinus if the anatomy is not fully appreciated. When this occurs, dural exposure is found, but rarely a CSF fistula is present.

CSF fistula as a result of ethmoidal or sphenoid surgery can be repaired transantrally, externally, or intranasally during the operation if the leak is found intraoperatively. Almost any type of living tissue membrane can be used to patch a fistula; examples are fascia temporalis, septal or turbinate mucosa, and fascia lata (67–69). Local flaps of septal mucosa, inferior turbinate or middle turbinate also are successful. An endoscope or microscope provides excellent intranasal visualization. The nature of the injury, including defect size, intracranial complications, and whether the patient has the potential for elevated intracranial hypertension all play a role in selecting the graft type and number.

Delayed fistula identification and location are important. CT with intrathecal contrast agent helps to localize an active leak. Alternately, the injection of 0.1 mL of 10% fluorescein mixed with 10 mL of autologous CSF or bacteriostatic saline can be located with an endoscope after 20 to 30 minutes to help locate a CSF fistula (67,69). Endoscopic examination alone may suffice to localize a CSF fistula. Delayed fistulae can be repaired in the same fashion as those repaired in the acute setting. Adjunctive help from a neurosurgeon with the placement of a subarachnoid drain may be beneficial along with the mandatory bed rest. A failed closure mandates either a different approach (endoscopic or open), a change in adjunctive therapy, or referral to a more experienced surgeon. Use of antibiotics is controversial and should be used with caution so as not to select out resistant organisms.

HEMORRHAGE

Hemorrhage is one of the most common complications during or after sinus surgery. Transantral or external procedures have more bleeding associated with them than do intranasal procedures, although occasionally intranasal ethmoidectomy bleeding can be profuse. Hemostasis for intranasal surgery has to be controlled before the operation begins. Appropriate sedation, blood pressure control, anesthesia, administration of topical and injectable anesthetics, vasoconstriction, and waiting time before the operation is begun are important to decreasing risk of intraoperative hemorrhage.

Preoperative sedation and vasoconstriction with a topical spray in the surgical preparation area improve blood pressure control and decongestion and diminish any systematic reaction to topical vasoconstrictors. The use of total intravenous anesthesia with remifentanil and propofol with maintenance of bradycardia and relative hypotension can significantly reduce cardiac output and improve venous bleeding within the sinonasal cavity. The patient should be positioned at 15 degrees to decrease peripheral venous pressure. Irrigation with warm saline helps maintain platelet function. Frequent topical decongestion with 4% cocaine, cocaine powder, or 1:1,000 to 1:10,000 epinephrine ±10,000 units of thrombin significantly helps with mucosal bleeding. Greater palatine foramen injections placed prior to surgery can also help to control bleeding (70); the surgeon must take care to aspirate frequently during injection to ensure that the placement of the drug is not intravascular.

Only diseased tissue should be removed rather than widespread mucosal sacrifice (6,20). Although bleeding from the ethmoidal artery usually is not a problem given its location and the infrequent need to perform a skull base dissection in routine disease, the sphenopalatine artery and septal branch of the sphenopalatine artery running along the anterior face of the sphenoid sinus, below the os, can cause marked intraoperative and postoperative hemorrhage. Unipolar and bipolar endoscopic or microscopic cauterization provides good control of these vessels (6,20); however, the effect of cautery can lead to postoperative crusting and if performed near the sphenoid os, stenosis of the sphenoidotomy. If turbinates are removed, the remnant also should be prophylactically cauterized. Visualization is essential (6,20). Epinephrine diluted to 1:10,000 or even 1:1,000 placed topically during surgery often is helpful. Any topical solution should be marked appropriately so it is not inadvertently injected. If bleeding is too great

for intranasal surgery, especially endoscopic surgery, the procedure should be terminated on that side or altogether. Often it is safer to come back another day when bleeding usually is much less of a problem. Packing is placed at the end of the operation if oozing continues. Use of polyvinyl acetal sponge or perforated film absorbent dressing causes much less patient discomfort than does a nose full of petrolatum gauze or iodoform, and both materials are easily removed without significant bleeding.

There are multiple products available as topical dressings that can aid in bleeding control. When needed, these dressings can be helpful. While usually excellent sources of hemostasis, several of these topical hemostatic agents may cause problems with healing (71,72) and can be difficult to debride in the postoperative setting.

SYNECHIA

The most common complication of endoscopic sinus surgery is synechia formation. Synechia is especially common in functional or limited endoscopic sinus surgery with preservation of the middle turbinate. Prevention of synechia involves meticulous surgical technique with minimal manipulation of the middle turbinate and compulsive postoperative care. Even so, the slightest abraded surfaces can form synechiae. Most of these slight synechiae are not troublesome. If the middle turbinate adhesion to the lateral nasal wall is predictable following endoscopic sinus surgery, often the placement of a vinyl-wrapped sponge, gelfilm, or other absorbable or nonabsorbable packing material in the middle meatus or suture medicalization of the middle turbinate should be performed. If the septum appears to be the cause of middle turbinate lateralization, a septoplasty should be performed. The presence of a large symptomatic concha bullosa or polypoid middle turbinate necessitates reduction, which is performed along the lateral side of the concha bullosa. Again, if there appears to be contact between the cut edges of the concha bullosa and the lateral nasal wall, a middle meatal stent should be used or the concha bullosa medialized either with suture or by fashioning a controlled synechia to the septum.

Severely polypoid or atrophic middle turbinates can be part of the disease process and preservation may cause more problems than resolving; on occasion, these degenerated middle turbinates must be partially or completely removed. Spacers are helpful to separate the middle turbinate from the lateral wall. The ideal spacer is not yet available, but perforated film absorbent dressing works well and is fairly nonreactive. Polyvinyl acetal sponge is satisfactory for a few days, but tissue reaction and granulation occur if the material is left in place for a prolonged period. Steroid-impregnated middle meatal stents (73) as well as bioabsorbable sponges, which can be impregnated with steroid solution, are available on the market but can be expensive. Use of bioabsorbable materials can, however, reduce patient discomfort since they do not need to be removed.

Many surgeons routinely amputate the anterior end of the middle turbinate and find this avoids synechia without *sequelae*. It is important to understand that any reduction or undermining of the middle turbinate can predispose it to weakness, giving it a natural tendency to lateralize, blocking the anterior or posterior ethmoidal sinus, frontal recess, or antrostomy and precipitating infection (Fig. 44.19). Patients with turbinate reduction have to be observed for

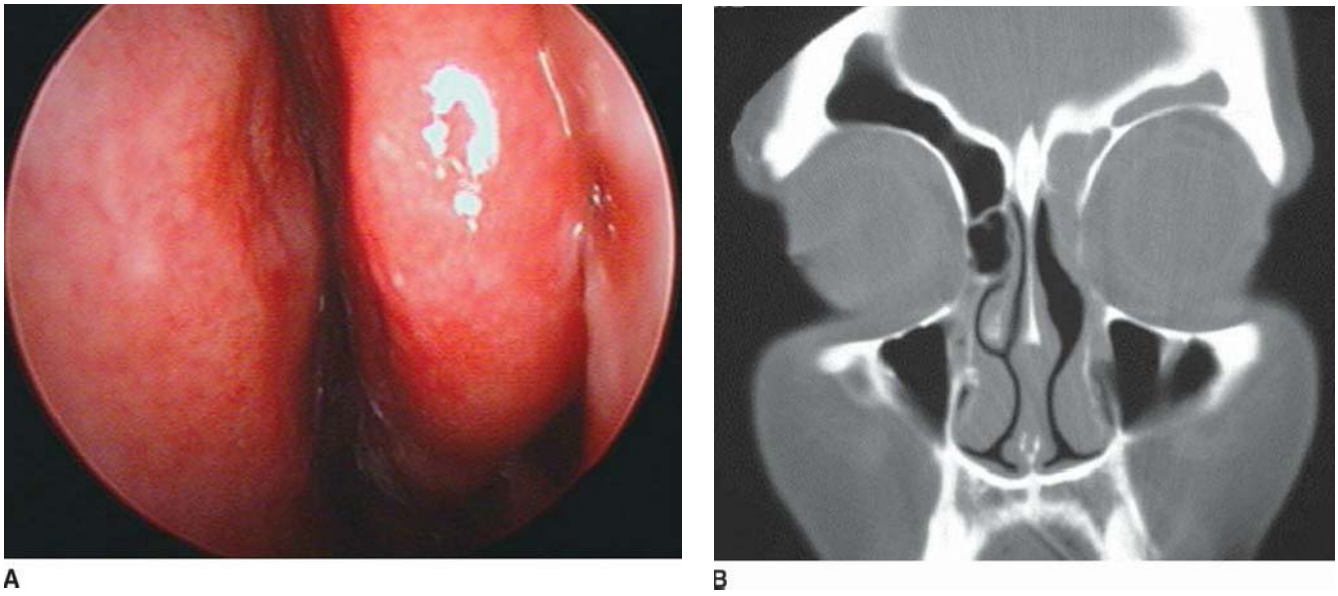

Figure 44.19 An endoscopic view **(A)** of a middle turbinate adhesion to the lateral nasal wall. The adhesion of this middle turbinate has caused frontal sinus obstruction **(B)**. Adhesion of the middle turbinate to the lateral nasal wall can be prevented by placing a middle meatal spacer consisting of absorbable or nonabsorbable material or by suture medialization of the middle turbinates with absorbable suture.

any evidence of lateralization. Removal of the agger nasi cells, if present, often opens the meatus, dramatically reducing the chances of middle turbinate lateralization. Middle turbinates can be attached to the septum by means of light scoring of opposing tissue to set up a scar adhesion, which can be divided after ethmoidal healing has occurred.

An antistaphylococcal antibiotic is used to prevent toxic shock syndrome, which can occur in an acute or delayed manner owing to the presence of packing or retained crust. Gelatin foam sheets, folded polymeric silicone, or hyaluronic acid gel ointment or packing can be helpful in operations on children and adults. These are expensive and often not necessary. Mitomycin-C has been used successfully to control scarring or synechia of the larynx but has had mixed results when topically applied to the nose and sinuses and is not recommended at this time (74–76). It is important for any foreign material to be appropriately anchored to avoid aspiration. Newer studies regarding the use of drug-eluting middle meatus stents (73) may offer promise in the reduction of these adhesions as well. Children may need follow-up examination under anesthesia for debridement of the nose, to take down synechia, and to make sure the maxillary ostium and anterior ethmoids remain open (77).

PARESTHESIA AND HYPESTHESIA

Paresthesia and hypesthesia are two of the most common complications of the Caldwell-Luc procedure, external ethmoidectomy, and frontal sinus surgery (13–15). For the most part, these are temporary complications that resolve 3 to 6 months after surgery. Obvious nerve transection as in frontal sinus obliteration causes permanent numbness. A small percentage of patients who undergo Caldwell-Luc procedures continue to have permanent numbness or paresthesia. This can signal recurrent sinusitis or dental injury, and medical treatment or revision surgery is needed to alter this problem if it is persistent. Medical therapy includes antibiotics, systemic and injected steroids, and medications such as phenytoin or carbamazepine to avoid neurologic problems. Yarington's (14), Low's (15), and Duncavage's modifications to avoid these complications are discussed (78). Paresthesia and/or hypesthesia during endoscopic sinus surgery can be due to injury to the infraorbital nerve or the branch of the fifth nerve supplying the medial wall of the maxillary sinus. Modifications to avoid these complications were discussed earlier.

OLFACTORY LOSS

There have been increasing injuries to the olfactory pathways after intranasal sinus surgery. Removal of the middle turbinate—whole or in part—may contribute to loss of smell. Obviously, direct damage to the cribriform plate(s) will compromise smell. Scarring or synechiae pulling the middle turbinate medially may affect smell. Certainly, the most common cause of smell loss is disease recurrence. Especially, in the case of recurrent nasal polyps and repeated surgeries, smell will diminish over time. The emphasis must be on prevention of olfactory injury and control of disease.

BRAIN INJURY AND MAJOR VESSEL INJURY

Injury to the brain and major blood vessels is rare during sinus surgery. The anterior communicating artery and its feeding vessels can be injured through the cribriform plate. These vessels are surprisingly close once the cribriform is penetrated. They can also go into spasm, resulting in serious central nervous system injury and sometimes death. Frontal lobe syndrome with loss of memory, forgetfulness, and behavioral change also can be caused by entrance through the roof of the nose into the brain (Fig. 44.20). Sphenoid surgery and injury to the carotid artery can occur (79,80). The carotid artery can be dehiscent in as many as 20% of sphenoid sinuses. Carotid cavernous sinus fistulae also can occur.

Prevention of brain and vessel injuries necessitates that the surgeon be aware of anatomic details, especially during operations on patients with structures compromised by disease or previous surgery. If appropriate visualization is impossible because of bleeding, the operation should be terminated. Sometimes radiologic evaluation in the operating room with a cross-table lateral radiograph, fluoroscopy, or computerized stereotaxis can help to establish the precise location of the nasal roof, base of the skull, and sphenoid sinus. Marked hemorrhage during superior or posterosuperior approaches can herald entrance through the nasal roof and brain injury.

All these conditions necessitate neurologic surgical intervention. Slight injury to the brain can be managed quickly and with minimal deficit. Serious injury is always life-threatening. Most patients who survive have a disruption of olfactory fibers with loss of smell and can have persistent neurologic *sequelae*. The more quickly intervention takes place, the better the chances for a good outcome. These types of injuries occur much less frequently under local anesthesia. Neurologic changes with general anesthesia are not found until the patient is awakened and even then can be delayed until the patient is wide awake. In the case of carotid artery injury, action must be taken immediately. A carotid drill should be established to aid in management of this problem (Table 44.4). It is possible that with quick action a life can be saved (79,80).

ABNORMALITY OF FACIAL GROWTH AND SINUS DEVELOPMENT

Although growth disturbance and retarded sinus development have occurred in animals (primarily pigs), no clinical study has shown growth problems (77). Therefore, sinus surgery should be deployed in children on a case-by-case

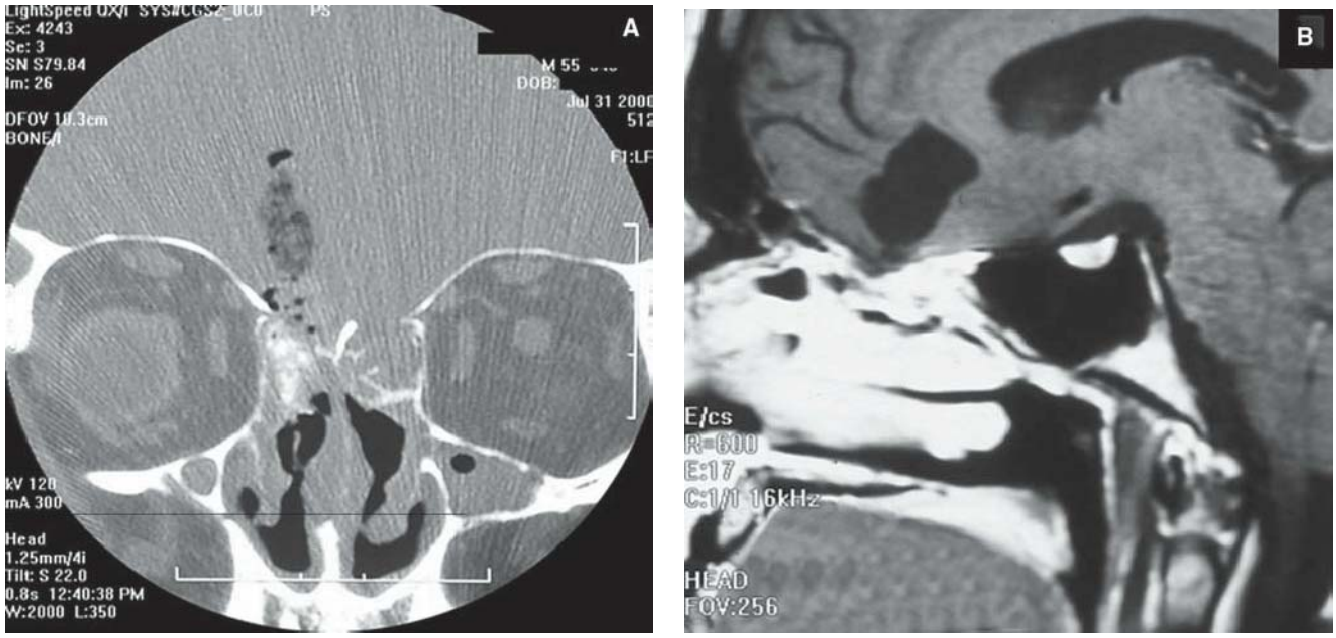

Figure 44.20 CT **(A)** and MR **(B)** images of a patient who sustained bilateral skull base injuries and brain injury during endoscopic sinus surgery performed with a microdebrider. As stated previously, the microdebrider is an excellent instrument for quick, precise removal of diseased sinus tissue; however, the utility of this instrument can be undone by a surgeon who is not present to his location within the sinuses.

TABLE 44.4 ℞ **TREATMENT CAROTID DRILL**

Tertiary care center

1. For every sinus operation, have available, on momentary notice, two long polyvinyl acetate (Merocel) sponges, petroleum-impregnated gauze, two 18F Foley catheters and umbilical clamps for nasal packing.
2. Pack nose immediately at the first sign of severe hemorrhage.
3. Compress the carotid artery in the neck on the affected side.
4. Begin anesthesia to induce controlled hypotension.
5. Ready blood for transfusion.
6. Call neurosurgeon immediately.
7. If the patient's condition is unstable, the neuroradiologist should perform intraoperative arteriography. If the patient's condition is stable, transfer the patient to the neuroradiology suite.
8. Perform balloon occlusion under EEG surveillance.
   a. If there is no evidence of a change in perfusion or lateralization, ligate the carotid artery.
   b. If changes are present on the EEG (dangerous recording), deflate the balloon, maintain packing, and observe.
9. Insert Swan-Ganz catheter. Put the patient in a hyperdynamic state by using high molecular weight starch (hetastarch) to increase cerebral perfusion.
10. After cerebral perfusion has been increased, reinflate the balloon and check the EEG.
    a. If lateralization occurs, try carotid bypass or barbiturate coma.
    b. If bypass is possible, reinflate the balloon and ligate the carotid artery.

Nontertiary hospital

1. Call neurosurgeon.
2. Expose the carotid artery in the neck.
3. Temporarily occlude the carotid artery with a clamp or tape.
4. Ligate the carotid artery.
5. Perform a trapping procedure: Clip the carotid artery below the anterior communicating artery to isolate this segment from blood flow.

EEG, electroencephalogram.

basis, with the full understanding that most children with chronic rhinosinusitis benefit from medical management, allergy management, and adenoidectomy prior to progression to sinus surgery. The previously mentioned anatomic variation related to growth and development of the face (i.e., canine teeth position, molar position) should be investigated prior to surgery.

MYOSPHERULOSIS AND TOXIC SHOCK

Myospherulosis, which is a foreign body reaction to ointment on nasal packing, can occur after sinus surgery and can lead to impaired healing due to increased risk of postoperative adhesion scarring (81). Likewise toxic shock syndrome due to specific staphylococcal organisms can occur in susceptible patients up to 1 month postoperatively even without nasal packing if fixed clot or crust is present (82,83).

HIGHLIGHTS

- There are no easy sinus operations.
- Practical knowledge of anatomy correlated with sinus CT scanning is most important in avoiding complications.
- The *lamina papyracea* and middle turbinate should be identified early in intranasal surgical procedures on the ethmoidal sinus.
- Knowledge of distance relations aids in finding important intranasal structures.
- All sinus procedures have common minor complications that resolve in most cases.
- Major complications in sinus surgery are rare; however, when they occur they often are catastrophic.
- The complications of paresthesia and hypesthesia from the Caldwell-Luc procedure can be avoided with alterations in technique.
- Distances to important structures in transantral sphenoethmoidectomy are less than they are in intranasal procedures.
- Blindness related to retro-orbital hematoma can be reversed or prevented if managed immediately.
- CSF fistula can occur with almost any surgical procedure on the sinuses and can be corrected during the operation.
- Operative or postoperative hemorrhage, especially during or after intranasal surgery, can be prevented if a judicious combination of anesthesia and surgery is used.
- Intracranial or major vascular injury, if managed immediately, can be minimized in some cases.
- Blind trust in image-guided (computerized) surgery without visual anatomic correlation may result in serious injury.

45 Endoscopic Evaluation and Treatment of CSF Leaks

Pete S. Batra

HISTORY OF CSF LEAK SURGERY

The history of surgery for cerebrospinal fluid (CSF) rhinorrhea has witnessed evolution from an entity historically managed by neurosurgeons via open approaches to one largely in the rhinologic domain amenable to endoscopic techniques. The initial description of CSF leak management was provided by Dandy (1) in 1926, who repaired a case of pneumocephalus resulting from a frontal dural tear suffered from trauma via a frontal craniotomy approach. In 1948, Dohlman (2) reported the first extracranial repair of cribriform plate CSF leak using muscle and nasal mucosa via a nasoorbital incision. In 1952, Hirsch (3) repaired a sellar CSF leak resulting from resection of a pituitary tumor by a transnasal transseptal approach. In 1981, Wigand (4) provided the initial description of endoscopic repair of CSF leaks; he repaired six intraoperative leaks encountered during 300 ethmoidectomy procedures. In 1996, Lanza et al. (5) reported endoscopic repair of 36 skull base defects, codifying the endoscopic technique as the method of choice for treatment of CSF rhinorrhea.

CSF PHYSIOLOGY AND INTRACRANIAL PRESSURE BASICS

Normal CSF is a clear colorless fluid nearly iso-osmotic to plasma. CSF serves several key functions, including protecting the central nervous system, providing an alternate circulation for distribution of micronutrients, and mediating intracranial compliance in physiologic and pathologic states. Majority of CSF is produced from the choroid plexus of the ventricular system (70%). The remainder is produced extrachoroidally by capillary ultrafiltration (18%) and metabolic water production (12%). In an adult, the total CSF volume equals approximately 140 to 150 mL. The ventricles hold about 30 mL, while the brain and spinal subarachnoid spaces contain 80 and 30 mL, respectively. Traditional teaching holds that CSF production occurs at a constant rate of 500 mL daily. However, quantitative magnetic resonance (MR) imaging has estimated daily production rates as high as 650 mL based on variations with circadian rhythm, with maximal production at 2:00 AM and nadir at 6:00 PM. CSF absorption is a hydrostatic pressure–dependent event that occurs at the arachnoid villi juxtaposed to the dural sinuses. These villi act as pressure gradient one-way valves that transmit CSF into the venous system when the intracranial pressure (ICP) increases 3 to 6 cm H_2O greater than venous pressure (6,7).

Normal ICP ranges from 5 to 15 cm H_2O at the lumbar cisterns with the patient in a supine position. ICP is a dynamic measurement with activities, such as change in position, straining, and sneezing, transiently increasing it to 40 cm H_2O. Further, the pressure can vary depending on time of day, patient age, respiratory phase, and cardiac cycle. Sustained increases or frequent spikes in the 20 to 30 cm H_2O range can result in neurologic symptoms and requires measures to reduce the ICP. For example, patients with ICP exceeding 20 cm H_2O in the setting of traumatic brain injury is strongly associated with mortality (6).

ETIOLOGY

A number of important etiologies may result in CSF rhinorrhea. The most common include accidental trauma, surgical trauma, congenital, tumors, and spontaneous (or idiopathic). Though earlier studies cited accidental trauma as the most common etiology, recent reports have noted spontaneous CSF leaks to be the most common cause of CSF leakage. Banks et al. (8) reported on 193 cases repaired over 21 years; the most common etiologies included spontaneous (40%), iatrogenic trauma after endoscopic sinus surgery (ESS) (26%) or endoneurosurgical procedures (20%), accidental trauma (8%), and congenital (4%). Careful understanding of these etiologies is a prerequisite

prior to devising a comprehensive diagnostic and management strategy for effective surgical repair of CSF rhinorrhea.

Accidental Trauma

The reported incidence of posttraumatic CSF leaks ranges from 2% to 4% in cases of blunt head injury. Eighty percent of leaks will occur within 48 hours after injury, and 95% will manifest in 3 months. However, a small but important subset may have a delayed presentation months, or even years, after the initial injury. Though 70% will present with active CSF rhinorrhea, the remainder will only develop pneumocephalus or ascending meningitis as part of the initial presentation. The most common locations of skull base fractures in descending order include the ethmoid–cribriform plate region, posterior table of the frontal sinus, orbital roof, and sphenoid sinus. The fractures can range from linear fractures to massive communication of the entire skull base, based on the extent of traumatic force. Concomitant facial fractures and intracranial lesions, such as cerebral contusion and epidural or subdural hematoma, are not uncommon.

Approximately 60% to 70% of traumatic leaks will close with conservative measures, such as bed rest, stool softeners, and lumbar drain (LD). However, the dura does not regenerate in these cases and the skull base may only be covered by a thin monolayer of nasal mucosa or fibrous tissue. Further, this layer may break down over time by sinonasal inflammatory processes or by the pulsatile effect of the brain. The risk of ascending meningitis in this setting has been noted in 30% to 40% of cases. This underscores the need for a proactive strategy with early detection and repair of persistent posttraumatic CSF leaks. All cases of suspected trauma should undergo high-resolution thin-cut computed tomography (CT) imaging to delineate the extent of skull base fracture. The management strategy should be highly individualized given the heterogeneity of these fractures. Cases with linear disruption of the ethmoid or sphenoid roof are good candidates for an endoscopic approach. Cases with extensive skull base disruption, especially with associated skull fractures or intracranial injury, may require an open neurosurgical approach. Penetrating skull base trauma from gunshot wounds or other projectile missiles can also result in significant skull base comminution and may be associated with extensive granulation tissue in the path of the foreign body (Fig. 45.1A and B). Close multidisciplinary coordination among subspecialty services is imperative to optimize care in these challenging cases (9,10).

Surgical Trauma

Surgical trauma from ESS or neurosurgical procedures represents the most common causes of iatrogenic CSF leaks. With the advances in image-guided surgery and sophisticated surgical instrumentation, the risk profile of ESS

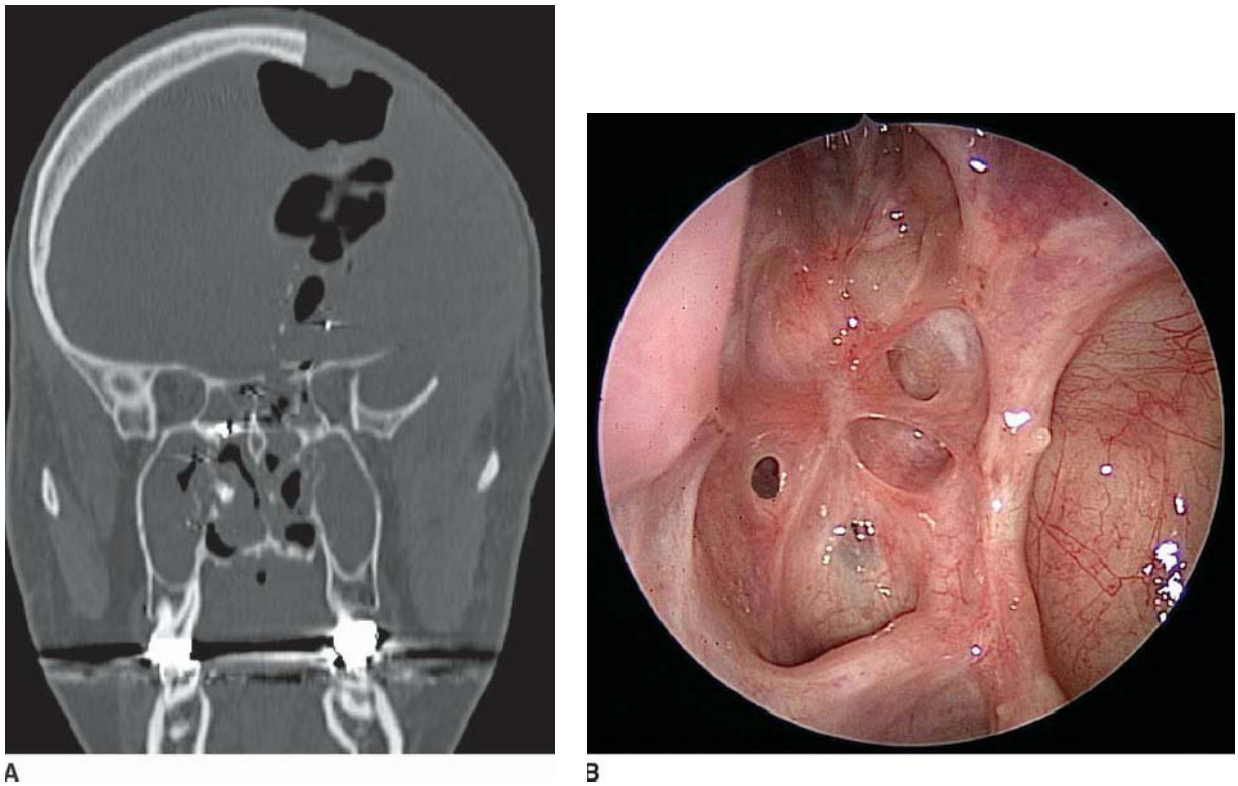

Figure 45.1 **A:** Reformatted coronal bone window CT scan demonstrates disruption of the left posterior ethmoid roof and resulting pneumocephalus from a self-inflicted gunshot wound. **B:** Endoscopic view of the left side with 0-degree endoscope demonstrates a healed posterior ethmoid roof after endoscopic repair 1-year postoperatively.

has improved dramatically with the general incidence in the 0% to 3% range. In a recent review of 6,908 endoscopic sinus surgeries at a single institution, 32 (0.46%) intraoperative CSF leaks were reported (11). Approximately 70% of the leaks were evident at the time of surgery, while 30% manifested postoperatively. The side distribution was right in 56%, left in 41%, and bilateral in 3% of cases. The leaks were commonly to result in hands of residents and novice attending surgeons. Further, asymmetry and low-lying skull base have been recognized as potential risk factors for iatrogenic leaks.

The two most common locations for CSF rhinorrhea include the lateral lamella of the cribriform plate (LLCP) and posterior ethmoid roof as it transitions to the sphenoid sinus. LLCP represents the thinnest portion of the skull base with mean thickness of 0.5 mm; this decreases 10-fold at the ethmoidal sulcus, the entrance of the anterior ethmoid artery into the olfactory fossa. The region is more at risk on the right side, especially in right-handed surgeons, given tendency to drift medially during the ethmoid dissection. Aggressive resection of the vertical attachment of the middle turbinate to the skull base also risks injury to the cribriform plate. The posterior ethmoid roof is at risk in scenarios where the maxillary sinus is extensively aerated; this excessive pneumatization encroaches more medially and superiorly, resulting in inversely proportional decrease in total inferior to superior height of the posterior ethmoid. High entry into the basal lamella poses a significant risk of injury to the posterior ethmoid roof (Fig. 45.2). The size of the skull base defect can vary from millimeters to greater than 2 cm, especially in cases of use of powered instrumentation. Underlying dural and intraparenchymal brain injury may result from breach of the skull base boundary, especially in cases of significant anatomic disorientation and delay in recognition of this violation.

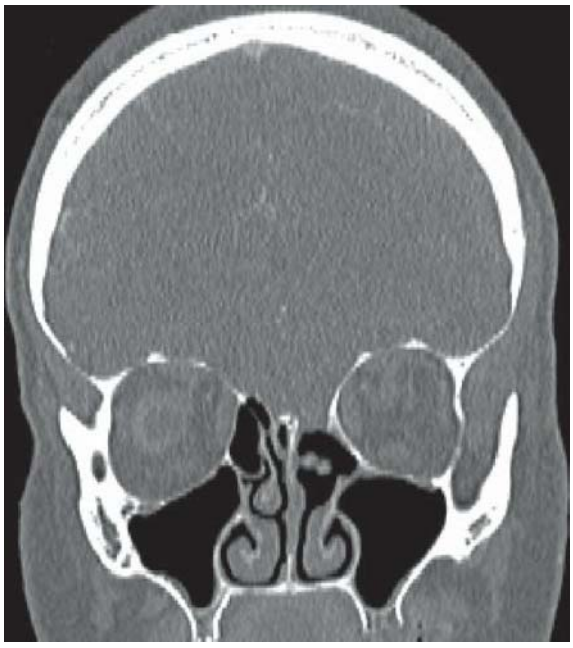

Figure 45.2 Reformatted coronal bone window CT scan illustrates bony defect in the left posterior ethmoid roof incurred during previous ESS. The patient had an asymmetric low-lying skull base that likely contributed to injury during the ethmoid dissection.

A variety of neurosurgical procedures can result in intraoperative CSF leaks. Historically, rhinologic involvement in this setting has been limited to addressing inadvertent postop leaks resulting from open transsphenoidal hypophysectomy or transcranial approaches to the anterior skull base (ASB) for neoplasm resection. Paraclinoid aneurysm clipping complicated by postop CSF rhinorrhea also represents another clinically challenging scenario given the narrow confines of the opticocarotid recess in the sphenoid sinus. In rare cases, a CSF leak from lateral skull base surgery may manifest as CSF rhinorrhea as it egresses via the eustachian tube. Management of the leak at the primary site represents the treatment of choice, though eustachian tube closure may be required in select cases.

The advent of advanced endoscopic techniques has greatly facilitated the surgical management of skull base neoplasms. Endoneurosurgical procedures, including transcribriform and transethmoid approaches to the anterior cranial fossa and transclival approaches to the posterior fossa, may result in large skull base defects with high-flow CSF leaks. This surgical paradigm involves close coordination between rhinology and neurosurgery for access to the skull base, combined tumor resection, and planned repair of the skull base defect with multilayered closure or vascular pedicled flap. Thus, the iatrogenic leaks in these cases are expected sequelae of the surgical procedure and addressed as an integral component of the surgery.

Spontaneous

Spontaneous CSF leaks represent an important clinical subset of leak patients whose prevalence may be increasing. No obvious definable etiology such as trauma, surgery, or neoplasm can be identified in this group. Emerging data have demonstrated that these represent a distinct clinical entity, being typically observed in middle-aged females with elevated body mass index. Common presenting symptoms include headaches, pulsatile tinnitus, and vertigo, along with CSF rhinorrhea. CT imaging may demonstrate a broadly attenuated skull base or arachnoid pit formation, while MR imaging may show partially or completely empty sella. This group also has the highest rate of encephalocele formation, being noted in 50% to 100% of cases. Many of these patients may have elevation of ICP or carry an underlying diagnosis of benign intracranial hypertension (BIH). The etiology of elevated ICP is not known but may be related to impaired CSF absorption at the arachnoid villi. Chronic elevation of ICP results in transmission of hydrostatic forces along the areas of least resistance such as the cribriform plate or lateral pterygoid recess of the sphenoid sinus causing erosion of the skull

base and ensuing herniation of meninges or brain and associated CSF rhinorrhea. Alternately, the forces may be exerted at the optic nerve sheath causing papilledema and visual loss (12,13).

Spontaneous CSF leaks represent the most challenging group for surgical repair and have been historically associated with the highest failure rate. This may in part be related to technical hurdles from a broadly, thinned skull base and associated encephalocele formation, along with underlying elevated ICP. The current surgical algorithm entails meticulous repair of the skull base defect and management of associated intracranial hypertension. Methods to accomplish the latter include administration of oral acetazolamide (ACTZ) to reduce the ICP. Ventriculoperitoneal (VP) shunting may be considered in severe cases.

Congenital

Congenital encephaloceles are herniation of meninges and/or brain through a skull base defect that maintain an intracranial connection. Though occipital lesions comprise 70% of these lesions, the otolaryngologist is most likely to encounter sincipital (20%) or basal (10%) encephaloceles. Sincipital encephaloceles are further subdivided into naso-frontal, nasoethmoidal, and naso-orbital lesions that exit anterior to the cribriform plate, typically presenting as a mass over the nose, glabella, or forehead. Basal encephaloceles present as an intranasal mass, with the defect being at the level of the cribriform plate or just posterior in the superior or lateral sphenoid. The mean age of presentation is 6 years, with common symptoms being nasal obstruction, CSF rhinorrhea, meningitis, or facial mass with hypertelorism.

Timely repair of the skull base defect is imperative to stop the CSF leak, to minimize risk of meningitis, to alleviate nasal obstruction, or to prevent further facial deformity. Traditional approaches have relied on combined extra- and intracranial repair by otolaryngology and neurosurgery. The advent of endoscopic techniques has facilitated minimally invasive resection of encephaloceles with layered skull base reconstruction and avoidance of external incisions with high success rate. Nonetheless, the technical challenges should not be understated given the narrow confines of the pediatric sinonasal anatomy and need for appropriate rigid scopes and instrumentation. In select cases, surgical management may need to be deferred till age of 2 to 3 years to allow for adequate facial growth to accommodate an endoscopic approach (14,15).

Tumors

Skull base neoplasms can result in CSF rhinorrhea in rare circumstances. Primary brain parenchymal or pituitary neoplasms can cause extensive bone erosion at the skull base with a resultant CSF leak. Conversely, aggressive sinonasal malignant neoplasms can invade the skull base and cause a CSF leak. Moreover, intracranial neoplasms may cause communicating or noncommunicating hydrocephalus, leading to CSF leakage. Management of the underlying neoplasm and elevated ICP are imperative in these scenarios. CSF leak repair, if clinically warranted, should only be undertaken after the underlying etiology is addressed.

PATIENT WORKUP

Patient History

The classic presentation of a CSF leak involves unilateral clear rhinorrhea that worsens with straining or bending over. Many patients with a spontaneous leak may recall a history of antecedent viral upper respiratory infection or significant sneezing or coughing as the inciting event. Patients may report a salty or metallic taste from posterior drainage of the CSF rhinorrhea. Headaches are a common symptom from sudden changes in the ICP from the CSF leakage. Careful history should ascertain for previous trauma and sinonasal or neurosurgical procedures. In select cases, sudden onset of meningitis may be the only presenting symptom of a skull base defect without associated CSF rhinorrhea. It is imperative for the otolaryngologist to evaluate for defects in the skull base as a potential etiology of unexplained meningitis. Equally importantly, any patient with an active CSF leak should be carefully counseled on the warning signs of meningitis until successful closure is performed.

Physical Examination

Complete head and neck examination is an integral component of the evaluation. Patient may be able to produce the clear rhinorrhea by leaning forward. The otologic evaluation may reveal a middle ear effusion suggestive of a possible temporal bone leak via the eustachian tube. An ophthalmologic examination may be necessary if papilledema from BIH is suspected. Rigid nasal endoscopy is crucial for accurate diagnosis of CSF rhinorrhea. Endoscopy may demonstrate a glistening pulsatile mass in the olfactory cleft (Fig. 45.3). Further, pooling of clear secretions in the nasal cavity may be noted that rapidly fills with suctioning.

Laboratory Testing

Historically, glucose strip testing has been employed as a rapid test to assay for CSF rhinorrhea. False positives are common given the reducing substances in nasal mucus. It represents a nonsensitive and nonspecific study and should not be relied upon in the contemporary diagnostic strategy for the CSF leaks. β2-Transferrin is a protein produced by the neuraminidase activity in the brain and is detectable almost exclusively in CSF. Low levels of β2-transferrin are found in the perilymph of the cochlea and aqueous and vitreous

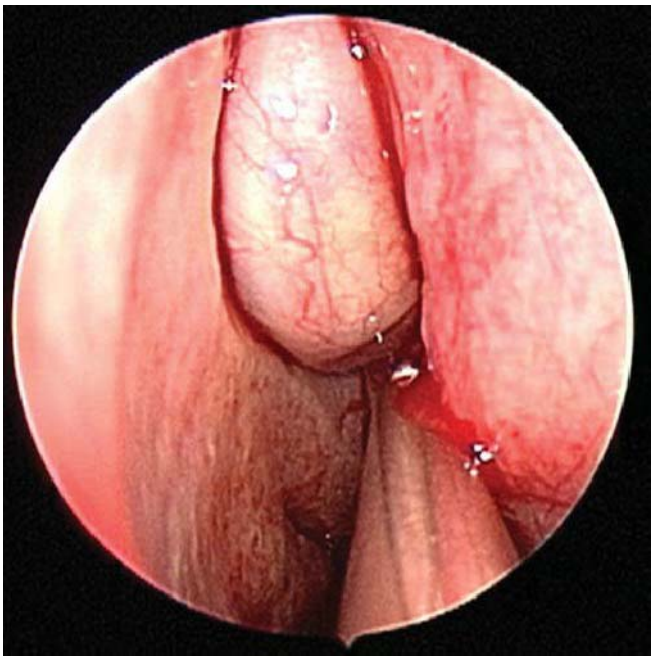

Figure 45.3 Endoscopic view on the left side with a 0-degree endoscope demonstrates an olfactory cleft encephalocele.

humor of the eye. It is a highly sensitive and specific noninvasive test that has been used successfully as a primary screening modality for suspected CSF leakage. Minimal volume of 0.5 mL is required for the assay, which may prove problematic in patients with slow or intermittent leaks. Further, the test is only performed at select laboratory facilities across the country, thus resulting in a delay of a few days to confirm diagnosis. The result should be interpreted with caution in patients with liver failure due to derangements in serum protein levels in this pathologic state. β-trace protein is synthesized primarily by the epithelial cells of the choroid plexus and is found in concentrations 35-fold higher in CSF than in plasma. It may represent a quantitative alternative to β2-transferrin for testing for CSF rhinorrhea. The test is available in Europe for commercial usage. It must be remembered that these biochemical tests can only prove the presence of CSF in the tested specimen, but are unable to directly demonstrate the CSF leakage or leak site (16).

Imaging Studies

Radiographic studies are an essential component of the diagnostic workup. The objectives of imaging for CSF rhinorrhea include to tentatively confirm the diagnosis, to precisely localize the defect site, and to evaluate for potential underlying etiologies. High-resolution CT imaging (1 mm or less) with triplanar coronal, axial, and sagittal views represents the initial study of choice to evaluate CSF rhinorrhea. Direct or reformatted coronal images are ideal for evaluation of the ethmoid roof, cribriform plate, and planum sphenoidale. Axial images are best for assessing posterior wall of the frontal sinus, posterior and lateral walls of the sphenoid sinus, and clivus. CT scanning facilitates close understanding of the underlying paranasal sinus anatomy, helps identify the skull base defect and any associated areas of bone disruption in iatrogenic or traumatic leaks, and serves as a roadmap for image-guided surgery. In cases of spontaneous leaks, CT imaging may demonstrate a soft tissue density in the olfactory cleft, ethmoid roof, or lateral pterygoid recess of the sphenoid sinus (Fig. 45.4A and B). Broad attenuation or arachnoid pits of the skull base may be seen from chronic ICP elevation. Careful review of the entire sinus CT scan is critical to identify multiple simultaneous defects. The sensitivity and specificity of CT scanning for CSF rhinorrhea has been demonstrated to be greater than 90% (17).

MR imaging can serve as an important adjunct in select cases of CSF rhinorrhea. It can facilitate differentiation of postobstructive secretions from herniated intracranial contents in an opacified cell adjacent to the skull base defect. Further, CSF can be distinguished from brain parenchyma in the meningoencephalocele sac on T2-weighted coronal images. Associated intracranial abnormalities, such as aberrant vessels or adjacent areas of encephalomalacia, can be appreciated prior to embarking on surgery, especially in cases of significant skull base trauma. MR imaging can also help establish presence of partially or completely empty sella in cases of spontaneous CSF leaks. Empty sella syndrome likely results from chronic ICP elevation with ensuing dural herniation through the sellar diaphragm and filling of the sella with CSF. This leads to perceived appearance of an empty sella, a finding that has been noted in 82% to 92% of cases of spontaneous CSF leaks (18).

The dilemma arises when the patient has a positive β2-transferrin and high-resolution CT is unable to identify the precise site of the leak. A variety of imaging techniques have been advocated for patients with intermittent or slow CSF leaks that remain elusive despite appropriate workup. CT cisternography has been utilized since 1970s to help isolate the site of sinonasal and temporal bone leaks. The procedure involves intrathecal injection of contrast material followed by high-resolution triplanar CT imaging, thus providing the ability to confirm the presence of active leak and to establish the exact location of the skull base defect. The study is especially useful for frontal or sphenoid leaks as these act as reservoirs of contrast material. The diagnostic capability is limited by its inability to identify intermittent leaks, with reported sensitivity for active and inactive leaks being 92% and 40%, respectively. MR cisternography involves T2-weighted fast spin-echo sequences with fat suppression and image reversal to define the CSF fistula. The technique is noninvasive that may be particularly helpful in patients with multiple skull base defects. Studies describing utility of MR cisternography have demonstrated sensitivity of 87% and accuracy ranging from 78% to 100% (17,19).

Radionuclide cisternogram, commonly known as the pledget study, involves endoscopic placement of multiple pledgets in the paranasal sinus confines followed by intrathecal injection of the radioactive tracer. Typically, these are

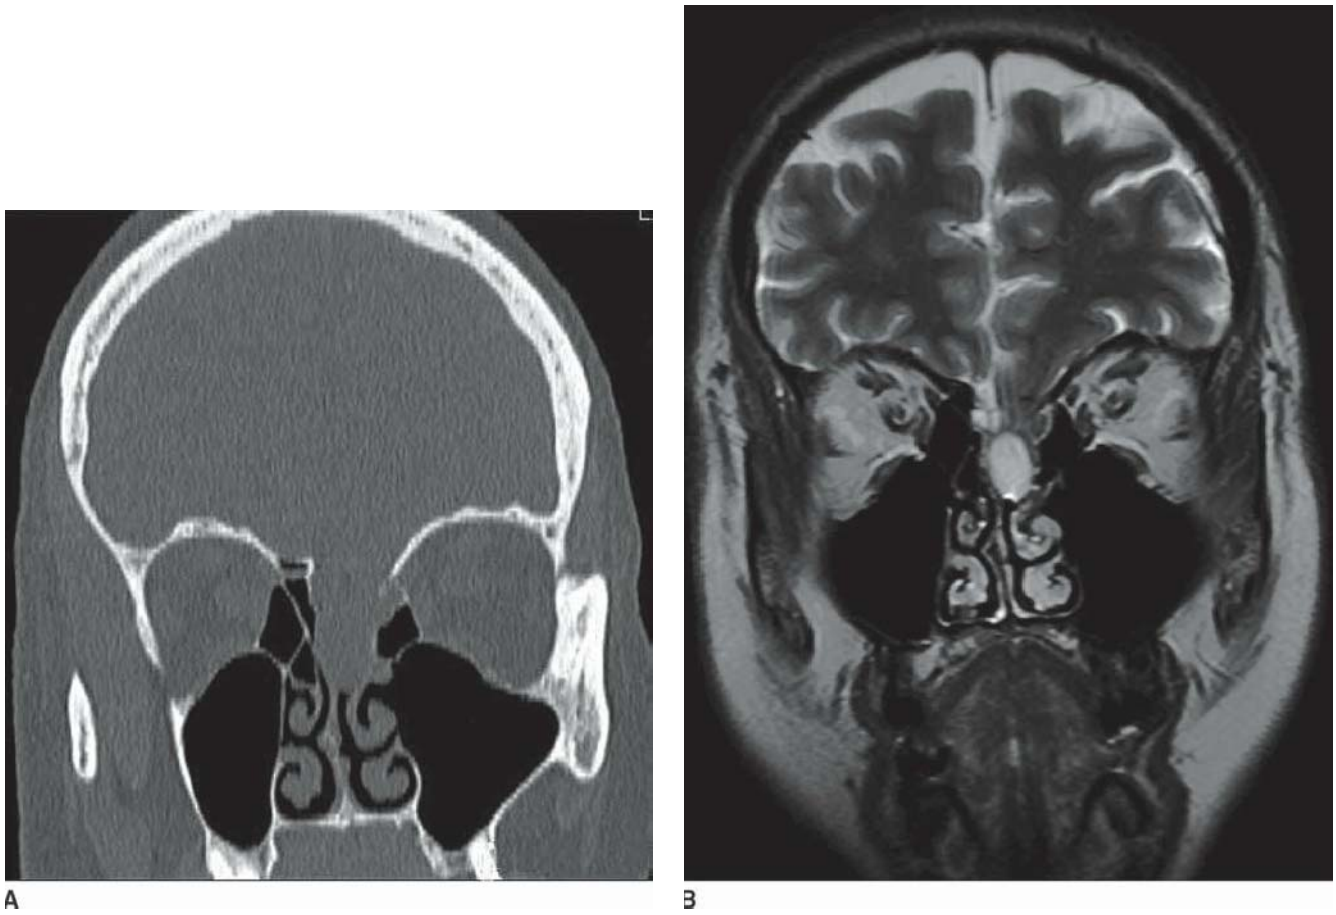

Figure 45.4 **A:** Corresponding reformatted coronal CT scan in patient from Fig. 45.3 demonstrates an extensive cribriform plate/ethmoid roof defect with resultant meningoencephalocele. **B:** Coronal T2-weighted MR shows that the mass contains both CSF and brain parenchyma.

placed in the olfactory cleft, middle meatus, and sphenoethmoid recess on both sides. The pledgets are removed 6 to 24 hours later and radiotracer activity is measured and compared to serum. A pledget:serum ratio of 1.5 to 3.0:1 is indicative of a leak. The primary advantage of this modality is in patients with very slow or intermittent leaks since the pledgets are left in place for many hours and can continuously collect CSF. The study is limited by its inherent inability to precisely localize the site of the leak; the reported sensitivity ranges from 62% to 76%. The breadth of laboratory and radiographic modalities available for diagnosis underscore the diagnostic dilemmas in accurately identifying CSF leaks. Since no gold standard study exists, the clinician should selectively order diagnostic laboratory and radiographic studies as dictated by careful history and physical examination.

PERIOPERATIVE ISSUES

Intrathecal Fluorescein

Fluorescein by intrathecal injection has been used to facilitate CSF leak identification and to ensure watertight closure. It may be particularly helpful in cases of multiple skull base defects or cases with significant alteration of skull base anatomy from accidental or iatrogenic trauma. Standard intrathecal injection entails use of 0.1 mL of 10% fluorescein mixed in 10 mL of patient's CSF, which is infused into the subarachnoid space through the LD over 10 to 15 minutes. An additional 5 mL of patient's CSF is utilized to flush the line. Intrathecal fluorescein (ITF) turns a bright green color when combined with CSF. It is generally visible endoscopically, though a blue light filter may be used to localize dilute fluorescein in select cases (Fig. 45.5). The sensitivity and specificity of ITF has been reported at 74% and 100%, respectively. The 26% false-negative rate underscores the potential diagnostic limitations of ITF; the surgeon should continue to look for the site of skull base defect based on preoperative imaging studies (20).

ITF is not approved by the Food and Drug Administration for intrathecal usage; thus, its utility in this setting represents an off-label usage. Informed consent is essential to ensure proper patient counseling in the preoperative period. Overall, the risk of adverse events with careful usage at lower doses is quite low at rate of 0.1%. Doses less than 100 mg are generally safe but can be associated with

Figure 45.5 Endoscopic view of left ethmoid cavity with 0-degree endoscope illustrates fluorescein-stained CSF from a spontaneous cribriform plate CSF leak.

headaches, nausea/vomiting, or dizziness in 2% to 10% of cases. Doses between 100 and 700 mg have resulted in neurologic deficits, grand mal seizures, pulmonary edema, and death (21). Pretreatment with steroids and diphenhydramine may be used to minimize the risk of untoward effects.

Lumbar Drain

Traditionally, LD placement has been considered an integral step in repair of CSF leaks. Possible advantages for usage include to inject the ITF, to obtain baseline ICP measurement in cases with suspected BIH variant, and to provide CSF drainage in the postoperative period. The CSF diversion may theoretically decrease risk of CSF leak by allowing for better apposition of the graft to the recipient site and attenuating sudden ICP changes that may result from bucking during extubation and vigorous coughing, sneezing, and movement in the postoperative period. These potential benefits must be carefully weighed against the risks posed by LDs. Associated risks include minor complications such as spinal headaches and paresthesias and major complications such as meningitis and pneumocephalus. Excessive CSF drainage has been linked to transtentorial herniation. With continued accrued experience, the practice of routine LDs in the perioperative period has evolved to selective use of lumbar drainage for special circumstances. Mounting evidence suggests that LD is not a prerequisite to achieving CSF leak repair; indeed, many skull base defects can be successfully reconstructed without use of LD (22). Specific situations that may require LD include high-pressure or high-flow leaks, problematic skull base reconstruction, or persistent postoperative CSF rhinorrhea.

LD may be placed while the patient is awake or after induction of general anesthesia. In the awake patient, the CSF pools in the lumbar cistern, thus facilitating easier placement of the LD. This may also be advantageous in the patient with chronic leak and relative CSF depletion. Alternately, LD placement may be deferred until anesthesia is achieved, especially in an anxious patient. Patients with large body habitus or previous spine surgery may require LD placement under fluoroscopy by interventional radiology. Postoperatively, the LD is drained at 5 to 10 mL/h with the patient in the recumbent position. The LD may be drained continuously, or may be drained as specified and then clamped for remainder of the hour. The typical duration of lumbar drainage should be 24 to 48 hours. The benefits of longer placement are unclear and may be associated with higher rates of infection. Ideally, patients should be monitored on a neurosurgical floor with nurses familiar with diligent care of LDs.

Antibiotics

Antibiotics have been historically utilized after traumatic CSF fistula to decrease risk of infectious intracranial complications. A recent Cochrane review evaluating use of antibiotics in patients with CSF rhinorrhea after skull base fractures failed to demonstrate any significant differences for reduction of frequency of meningitis, all-cause and meningitis-related mortality, and need for surgical repair of CSF leakage between antibiotic prophylaxis and control groups (23). Similarly, the putative benefits of long-term prophylactic antibiotics after CSF leak repair are unclear. Nonetheless, grafts are placed into and adjacent to the intracranial compartment through a contaminated sinonasal space. Perioperative antibiotics for 24 hours may be used to minimize risk of bacterial seeding of the intracranial space. Third-generation cephalosporins with good blood–brain barrier penetration, such as cefotaxime or ceftriaxone, may be used, with levofloxacin or vancomycin being reserved for penicillin allergic patients. In addition, all graft materials are soaked in a gentamicin solution to minimize risk of bacterial contamination.

SURGICAL MANAGEMENT

Rationale for Repair

Timely repair of CSF rhinorrhea and separation of intracranial from sinonasal contents is imperative to minimize risk of intracranial complications. Previous studies have demonstrated history of ascending meningitis in 19% to 36% of patients with an active CSF leak presenting for surgical management. The risk of developing meningitis has been estimated at 0.3 episodes per year.

Additional complications that may result from CSF rhinorrhea include pneumocephalus and cerebral or epidural abscess. Successful surgical repair decreases the risk of infectious intracranial complications to 0% to 0.9%, attesting to the timely efficacy of the endoscopic approaches (24).

Basic Surgical Principles

The surgical strategy should be tailored to each individual case based on the site and etiology of the leak. Certain key dictums must be followed to achieve successful repair of CSF rhinorrhea. Preoperative imaging review should guide the best endoscopic surgical route for repair. Potential surgical corridors that may be used include transcribriform, transethmoid, transsphenoid, transpterygoid, or combination thereof based on the site of the defect. The procedure is started with induction of general anesthesia. Standard surgical scrub is performed to reduce bacterial counts. Cotton pledgets soaked with oxymetazoline are placed in both nasal cavities to obtain maximal vasoconstriction. The sphenopalatine region and lateral nasal wall are injected with 1% lidocaine with 1:100,000 epinephrine. The paranasal sinuses are subsequently opened as dictated by the leak site. Adjacent paranasal sinuses should also be addressed to minimize risk of postoperative mucocele formation, since postoperative debridement adjacent to the reconstruction is deferred for 4 to 6 weeks.

Precise identification of the leak site is an absolute requisite to attaining good closure. This may be accomplished through use of preoperative CT imaging or intraoperative surgical navigation, along with intraoperative ITF in select cases. Systematic evaluation of all potential leak sites should continue, given risk of multiple leak sites in cases of trauma and spontaneous leaks. Once identified, careful cautery of the meningocele or meningoencephalocele is also critical prior to any reconstruction. Bipolar cautery is used for this objective; unipolar devices should be avoided as the depth of heat penetration cannot be controlled and may result in dural or brain parenchymal injury. The stalk and base of the encephalocele should only be resected after careful fulguration; aggressive manipulation of the base should be avoided. This may result in bleeding at the skull base interface; any vessel that retracts superiorly can potentially result in an intracranial bleed and stroke. Meticulous preparation of the graft recipient site is also an essential ingredient to success. All mucosa at the defect should be removed circumferentially for 2 to 4 mm. Gentle drilling of the bone adjacent to the defect may stimulate osteoneogenesis and further facilitate the closure. In most cases, multilayered reconstruction is required for optimal repair of the defect, though single-layer closure may suffice in select cases. Large dural high-flow defects, especially in the setting of endoscopic skull surgery, often require repair with pedicles flaps.

SITE-SPECIFIC REPAIR STRATEGY

Cribriform Plate/Ethmoid Roof

Both the cribriform plate and ethmoid roof are amenable to repair by a purely endoscopic approach. For ethmoid roof defects and larger cribriform plate defects, standard maxillary antrostomy and total ethmoidectomy is required for most cases. Frontal sinusotomy and sphenoidotomy may be required to enhance exposure to the anterior and posterior ethmoid roof, respectively. Further, these sinuses often need to be opened to minimize risk of scarring and mucocele formation. The one exception to this approach is small cribriform plate encephaloceles that resides strictly in the olfactory cleft. Often, the middle turbinate can be lateralized and the CSF leak can be addressed via transnasal approach to the olfactory cleft. The middle turbinate can be partially resected to increase exposure, if necessary. The reconstruction of these two areas differs given the variation in bony thickness. The bone at the ethmoid roof is much thicker, and a bone graft can often be placed in the epidural space. This facilitates the most robust reconstruction. On the other hand, the bone of the cribriform plate is quite thin and is frequently attenuated in spontaneous leaks. Attempts to place underlay grafts can further disrupt the bone and substantially increase the size of the skull base defect. Overlay grafts should suffice for these olfactory cleft meningoceles (25).

Sphenoid Sinus

Central sphenoid leaks can be managed via an endoscopic transnasal or transethmoid approach. A wide sphenoidotomy extending from the planum sphenoidale to the floor of the sphenoid and from the lateral sphenoid wall to the intersphenoid septum is essential to gaining wide exposure. Great care must be exercised during surgical maneuvers inside the sphenoid given close proximity of internal carotid artery (ICA) and optic nerve. Careful fulguration of the herniated dura and brain and circumferential removal of the mucosa around the defect remain key steps. Defects of the planum may be repaired with use of epidural bone grafts, along with other tissue arrays (Fig. 45.6A and B). In select cases, the nasoseptal flap may be used for skull base reconstruction of the central sphenoid. One surgical technique with limited clinical utility in the current surgical paradigm is fat obliteration of the sphenoid sinus. This approach entails removal of all sphenoid sinus mucosa to irreversibly obliterate the sphenoid sinus. Realistically, complete removal of mucosa is difficult and may pose risk to the ICA and optic nerve. Moreover, any residual mucosa may result in mucocele formation.

Lateral recess leaks pose a significant surgical challenge as they are not amenable to standard transnasal or transethmoid approaches. The transpterygoid approach affords access to the lateral sphenoid sinus. Wide maxillary

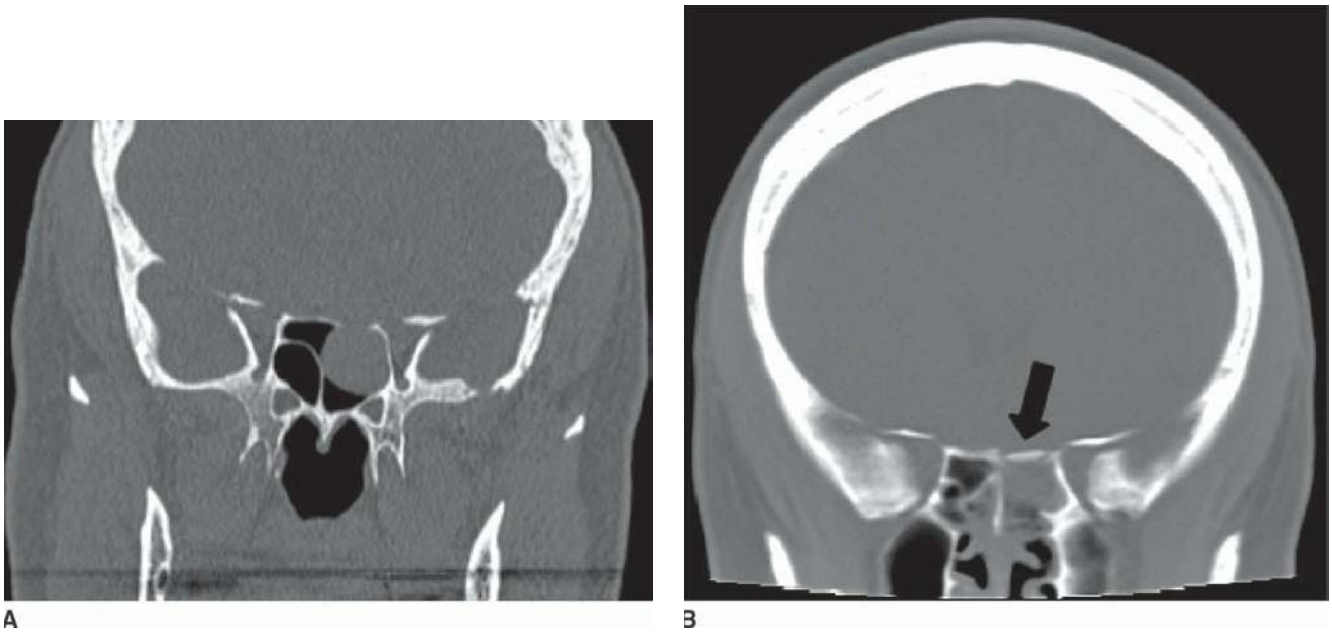

Figure 45.6 **A:** Reformatted coronal bone window CT shows a soft tissue mass in the left sphenoid sinus with a planum sphenoidale defect. **B:** Postoperative reformatted coronal bone window CT demonstrates septal bone graft (*arrow*) in the epidural space. The associated soft tissue density in the sphenoid sinus represents packing and mucus in the early postop period.

antrostomy, ethmoidectomy, and sphenoidotomy are performed to establish initial landmarks. The bone from the posterior maxillary sinus wall is removed to expose the pterygomaxillary fossa (PMF). Dissection in the PMF will expose the internal maxillary artery, which is either divided or reflected inferiorly. Great care must be taken to preserve the sphenopalatine ganglion, along with vidian, greater and lesser palatine, and infraorbital nerves. The pterygoid process that forms the anterior wall of the lateral recess is gently drilled to gain exposure. The skull base defect is then managed as per standard technique. Since spontaneous CSF rhinorrhea form majority of the leaks in this region, placement of a bone graft in the epidural space is preferred as a component of the definitive reconstruction (26).

Frontal Sinus

Frontal sinus CSF leaks represent a surgical challenge given the narrow anatomic confines of the frontal recess and proximity to critical structures, including the skull base and orbit. Traditionally, frontal sinus leaks have been managed by extracranial approaches such as osteoplastic flap with or without fat obliteration. The advances in endoscopic techniques, refinement of frontal instrumentation, and advent of image-guided surgery have afforded the ability to manage these leaks endoscopically. The two most common locations of frontal leaks include the frontal recess and posterior table of the frontal sinus. Frontal recess leaks can be repaired via an endoscopic frontal sinusotomy or Draf IIB approach if greater exposure is required. Posterior table leaks can be managed via an endoscopic modified Lothrop procedure providing broad exposure of the frontal sinuses orbit to orbit. Defects in an extreme superior or lateral frontal sinus location restrict the ability to address these endoscopically. An adjunct endoscopic frontal trephination or osteoplastic flap may be required to address these leaks. Great care must be taken to preserve uninvolved mucosa to minimize risk of frontal sinus stenosis and mucocele formation (27).

Anterior Skull Base

The CSF leaks are expected sequelae of minimally invasive endoscopic resection (MIER) of ASB neoplasms. Careful separation of the sinonasal and intracranial compartments and minimizing risk of potential cross-contamination are crucial steps in the success of MIER. A variety of surgical techniques have been employed to achieve skull base reconstruction with acceptable results. The surgical paradigm of multilayered reconstruction has also been applied to ASB reconstruction. After circumferential elevation of the dura, the initial two layers are placed in an underlay fashion in the epidural space. Autogenous tissues, such as temporalis fascia or fascia lata, or synthetic tissue arrays, such as acellular dermis or dural substitutes, can be used for this purpose. Additional layers of tissue may be placed in an overlay fashion, with the final layer being free mucosal graft from the floor of nose or septum (Fig. 45.7). Cartilage and bone grafts are avoided given risk of infection and possible extrusion in cases requiring postoperative radiation therapy. Alternately, single layer acellular dermis has been advocated for ASB reconstruction. Intuitively, a single layer

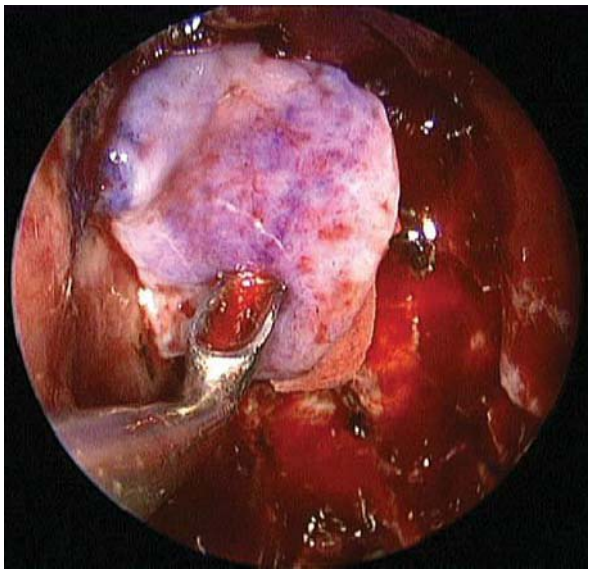

Figure 45.7 Endoscopic view of left ethmoid cavity with 30-degree endoscope illustrates mucosal graft as one component of multilayered reconstruction after minimally invasive resection of left ethmoid adenocarcinoma. The mucosal side is inked with a marking pen to facilitate orientation.

of tissue may increase the surgical challenge to achieve watertight closure. Moreover, this approach delays mucosalization by 6 months. Pedicled vascularized flaps represent a significant advance in reconstruction of the ASB. The nasoseptal flap provides robust vascularized tissue for ASB reconstruction, accelerating healing, and minimizing risk of postoperative leak, especially in cases of high-flow leaks (28,29).

Sella and Clivus

Intraoperative CSF leaks are encountered in pituitary adenoma surgery in 20% to 50% of cases, while postoperative leaks are seen in 1% to 10% of cases. A graduated approach is required for management of sellar leaks. For patients with no intraoperative leaks, no formal reconstruction is required. Alternately, a small amount of absorbable hemostatic gauze may be placed to fill the sellar defect. Patients with a small intraoperative leak without an obvious diaphragmatic defect can be managed with absorbable hemostatic gauze and abdominal fat within the sellar cavity followed by a free mucosal graft that can be harvested from the nasal septum, sphenoid sinus, or floor of nose. Patients with definite diaphragmatic or dural defect with high-flow sellar and clival leaks represent the most challenging group and pose the highest risk of postoperative persistent leak and meningitis. In these cases, the sellar cavity or clival defect should be packed with abdominal fat and absorbable hemostatic gauze followed by reconstruction of the sellar face or clivus with septal bone or cartilage or a resorbable microplate. A vascularized nasoseptal flap is subsequently placed over the entire reconstruction to facilitate healing (30,31).

RECONSTRUCTIVE TECHNIQUES

Multilayered Reconstruction

A variety of surgical techniques and graft materials have been employed over the years for management of CSF rhinorrhea. Meticulous surgical technique is more critical than the actual choice of reconstructive tissue for successful repair. Multilayered skull base reconstruction is preferred for most cases; one exception is small olfactory cleft meningoceles that only require a free mucosal graft as an overlay technique. The size of the skull base defect is determined by gentle probing to ascertain the full extent of the defect. Careful circumferential elevation of the dura should be performed in these cases. Frontal sinus seekers or otologic instruments can be used for this purpose. The initial layer consisting of collagen matrix, acellular dermis, temporalis fascia, or fascia lata is tucked along the edge of the exposed dura and brain as an underlay. A second layer of the same tissue array may be used to reinforce the first layer if deemed necessary. Tensor fascia lata as a bilayer button or abdominal fat graft as a bath-plug closure has also been described for this primary layer. An intervening graft that provides rigid support is important for cases of spontaneous leaks, especially if underlying elevated ICP is expected. Septal bone would be the graft of choice for this purpose; alternate options include cartilage (septal or conchal) or mastoid bone. The final tissue layer consists of a free mucosal graft from the nasal septum, floor of nose, or middle or inferior turbinate. The mucosal side should be inked to facilitate orientation at the skull base. Fibrin sealants or gelatin–thrombin matrix and absorbable packing, such as oxidized regenerated cellulose or absorbable gelatin sponges support the tissue grafts. The entire reconstruction is further supported by nonabsorbable polyvinyl alcohol sponges (32,33).

Pedicled Flaps

The nasoseptal flap based on the posterior septal artery, a terminal branch of the sphenopalatine artery, represents a significant advance in reconstruction for skull base surgery. It provides robust vascularized tissue, facilitating faster healing and tissue integration and decreasing risk of postoperative leaks to less than 5% in this setting. The flap can be harvested endoscopically and can avoid morbidity of a second donor site. One potential limitation is that the nasoseptal flap is not reliably available in cases of sinonasal and skull base malignancy as the septum is often infiltrated by the neoplasm. Thus, a backup plan should always be available if use of vascularized tissue is contemplated for reconstruction. Alternate flaps including transpterygoid temporoparietal fascia flap, endoscopic-assisted transglabellar pericranial flap, posterior pedicle inferior turbinate flap, and middle turbinate flap have been described for skull base reconstruction (34).

POSTOPERATIVE CARE

Traditionally, patients have been kept on strict bed rest for 3 to 5 days after CSF leak repair. However, the rationale for this approach is not born out in the literature; furthermore, a prolonged period of inactivity may increase the risk of pulmonary and venous thromboembolism complications. Typically, strict bed rest for 24 to 48 hours in the postoperative phase should suffice. If a LD is utilized, this is drained at 5 to 10 mL/h. This short period of inactivity will facilitate the healing process and avoid any sudden pressure changes or Valsalva maneuvers that may significantly elevate the ICP and compromise the reconstruction. The head-of-bed is elevated to 15 degree during this time period. This position will decrease the ICP at the ASB and the brain parenchyma may actually help maintain the position of the underlay grafts. Antibiotics are continued for 24 hours or until the LD is removed. A longer period of antibiotics are only required if the patients have permanent packing, given the theoretical risk of toxic shock syndrome. Stool softeners and antitussives are important adjuncts to minimize ICP spikes during this crucial period.

The LD is clamped at 24 to 48 hours. The patient is carefully observed for any signs of CSF leakage in the bed rest position. Patients may slowly be elevated to a sitting position and then to a standing position so long as there is no sign of CSF leak or postspinal headache. A similar approach is used even if no LD is utilized. Patients are generally discharged on postoperative day 2 on antibiotics (if nasal sponges in place), pain medication, stool softeners, and saline sprays. Patients are seen in the office 5 to 7 days after surgery. Any nasal tampons are removed at this time. Postoperative debridement is conservative at this juncture and is limited to suctioning of mucus or debris in the dependent sinuses to maintain patency. Debridement of the skull base reconstruction commences 4 to 6 weeks after surgery and continues until all healing has taken place. Patients are instructed to avoid any vigorous activity for 6 to 8 weeks. The activity restrictions are lifted based on the endoscopic examination rather than a rigid timeline (25).

LONG-TERM MANAGEMENT

Patients are followed long-term by serial endoscopy to ensure the success of the reconstruction and continued patency of the adjacent sinuses. The subgroup of spontaneous CSF leaks requires a postoperative management strategy to address elevated ICP, if present. Baseline elevation of ICP may be established in the early postoperative period by obtaining an ICP measurement with the LD clamped. However, it is unclear if this will accurately reflect ICP over the ensuing weeks to months. The reliability of this single measurement is further challenged given significant positional and diurnal variations of this data point. Continuous CSF pressure monitoring has been advocated as a more reliable technique to ascertain ICP in this patient population (35). Alternately, baseline ICP measurement can be obtained 6 to 8 weeks after surgery. This in turn can guide any additional measures to target the ICP into the normal range and minimize risk of recurrent leak in the same or different location.

Management of spontaneous leak patients should account for both elevated ICP (less than 15 cm H_2O) and patient symptomatology, that is, headaches, pulsatile tinnitus, imbalance, and visual disturbances, prior to instituting medical measures. ACTZ is a carbonic anhydrase inhibitor that has the ability to decrease CSF production. It has been demonstrated to decrease ICP by mean of 10 cm H_2O in spontaneous leak patients. The exact dosage for this indication is not clear but could range from 250 mg two to four times a day. An important side effect of ACTZ is development of hyperchloremic metabolic acidosis with hypokalemia. Thus, careful electrolyte monitoring is imperative during chronic ACTZ therapy, along with replacement of potassium and bicarbonate to maintain normal electrolyte values. VP shunting may be considered in patients who develop recurrent CSF leaks or continue to display persistent ICP elevation and BIH symptoms despite ACTZ therapy. Given the invasive and irreversible nature of VP shunting, this should be considered a last resort measure (12,36).

OUTCOMES

The data accrued in the literature from multiple studies attest to the efficacy of the transnasal endoscopic approach for management of CSF rhinorrhea. The success rate after initial attempt ranges from 90% to 95%, with success rate increasing to 95% to 100% after second attempt for releaks (37,38). This is accomplished with extremely low risk of serious intracranial complications, such as meningitis (less than 1%). Spontaneous leaks represent the most challenging subgroup; however, recent work has demonstrated that a comprehensive management approach directed against the leak and the underlying pathophysiology with ACTZ or VP shunting in selected cases can lead to a low failure rate (12). A variety of graft techniques have been employed for skull base reconstruction; data are unable to definitively demonstrate superiority of one tissue array over another. A repair strategy employing multilayered reconstruction is more important, irrespective of the choice of graft materials. Vascularized pedicled flaps represent a significant advance in endoscopic skull base surgery and should be incorporated in the reconstructive strategy for high-flow large skull base defects, when technically feasible. In general, a rigid cookbook approach is unlikely to replicate this high success rate; an individualized approach carefully considering the underlying etiology and site of leak are critical to optimize outcomes.

HIGHLIGHTS

- The most common etiologies of CSF rhinorrhea include accidental trauma, surgical trauma, spontaneous, congenital, and tumors.
- The risk of iatrogenic CSF leaks from ESS has decreased to 0% to 3% in clinical series, with the two most common locations being the LLCP and posterior ethmoid roof as it transitions to the sphenoid sinus.
- Spontaneous CSF leaks represent an emerging clinical entity that is likely related to underlying elevation of ICP, typically being observed in middle-aged females with elevated body-mass index.
- β2-Transferrin is a protein detectable almost exclusively in CSF, perilymph of the cochlea, and aqueous and vitreous humor of the eye. It is a highly sensitive and specific noninvasive test for suspected CSF leakage.
- High-resolution triplanar CT imaging (1 mm or less) represents the initial study of choice to precisely localize the skull base defect for CSF rhinorrhea.
- Key surgical dictums for successful CSF leak repair include precise identification of the leak site, careful cautery of the herniated intracranial contents, meticulous preparation of the graft recipient site, and multilayer reconstruction with variety of tissue arrays.
- Endoscopic management of CSF rhinorrhea has demonstrated success rate of 90% to 95% after initial attempt and 95% to 100% after second attempt for releaks, with low risk of serious intracranial complications, such as meningitis (less than 1%).

Frontal Sinus Surgery

46

Yuresh S. Naidoo *Peter-John Wormald*

Endoscopic sinus surgery (ESS) has been accepted as the treatment of choice for chronic sinusitis refractory to medical treatment. However, surgery of the frontal sinus is perhaps the most technically demanding of all ESS. The complex and varied anatomy, acute nasofrontal angle, and proximity to critical structures such as the olfactory fossa, skull base, and orbit contribute to the surgical difficulty. These narrow confines, and a penchant for postoperative scarring, make surgical treatment of chronic frontal sinusitis challenging.

The literature and evolution of endoscopic frontal sinus surgery supports a graduated stepwise approach to tackling disease in the frontal sinus (1–4). A wide spectrum of defined endonasal surgical procedures of the frontal sinus has been developed. These are based on the drainage or sinusotomy classification of Draf (1) (Table 46.1).

Our philosophy is an all-or-nothing approach to frontal sinus surgery once maximum medical treatment has failed. Limited surgery in the frontal recess places raw surfaces in close proximity to each other, which increases the likelihood of scarring and failure. Draf IIA sinusotomies are performed for primary surgery on the frontal sinus. Failed frontal sinus surgery is treated with a Draf III sinusotomy (otherwise known as endoscopic modified Lothrop procedure [EMLP] or frontal drillout procedure). At present, a primary EMLP is not performed for chronic rhinosinusitis.

SURGICAL ANATOMY

The key to successful frontal sinus surgery is a fundamental understanding of its anatomy.

Development of the frontal sinus begins in the fourth fetal month when the entire nasofrontal area is represented by the frontal recess. It is the last paranasal sinus to develop. At birth, the sinus has usually not formed. At around 2 years of age, the most anterior ethmoidal sinus invaginates into the frontal bone and continues its vertical growth trajectory at an average annual rate of 1.5 mm until the 15th year. Final growth is completed before 20.

The sinus is compartmentalized by the intrasinus septa, which divides the sinus into halves. The frontal sinus has the most complex and variable drainage of any paranasal sinus. The frontal recess itself can be considered to be bordered by the frontal beak anteriorly, the anterior face of the bulla ethmoidalis posteriorly, the middle turbinate medially, and the lamina papyracea laterally (Fig. 46.1).
These limits are altered by the variable pneumatization of anterior ethmoidal cells. Along the frontal beak, the agger nasi cell and other frontoethmoidal cells protrude into the frontal recess and sinus to alter the drainage pathway. Along the skull base, suprabullar cells may protrude anteriorly compressing the drainage pathway. When a suprabullar cell pneumatizes along the skull base into the frontal sinus, it is called a frontal bulla cell. Frontal bulla cells can considerably narrow the frontal sinus drainage pathway.

The types and variability of cells that can be found in the frontal recess and frontal sinus, which can markedly alter the frontal sinus drainage pathway, were first described by Kuhn (5) in a landmark paper. He described four basic cells: the agger nasi cell, the frontoethmoidal cell(s), the intersinus septal cell(s), and the cell(s) originating from the bulla ethmoidalis/suprabullar region.

This classification was modified by Wormald (6), who more clearly defined the frontoethmoidal cell and redefined type 3 and 4 cells (Table 46.2).

The three-dimensional (3D) reconstruction of the frontal recess anatomy using the building block model, with each block representing a cell within the frontal recess, is an excellent aid to the surgeon in understanding the anatomy of the frontal sinus. It allows the surgeon to carefully

TABLE 46.1 DRAF CLASSIFICATION OF ENDONASAL FRONTAL SINUS PROCEDURES

Type	Extent of Surgery	Indication
I	Anterior ethmoidectomy with drainage of the frontal recess by removal of obstructing disease inferior to the frontal ostium. The frontal ostium itself and any cells protruding into it are not touched	• History, endoscopy, and CT findings suggest chronic frontal sinusitis is due to sinus outflow tract obstruction at the level of the frontal recess
IIA	Removal of all ethmoidal cells protruding into the frontal sinus thereby creating an opening between the middle turbinate medially and the lamina papyracea laterally	• Complicated frontal sinusitis or failed Draf I • Recommended in frontal sinuses with a large A–P diameter (anticipated minimum diameter of frontal neo-ostium 5 mm or more), hypoplastic internal nasal spine (small frontal beak), and a broad ethmoid
IIB	Removal of the frontal sinus floor between the nasal septum medially and the lamina papyracea laterally	• Complicated frontal sinusitis in frontal sinuses with a small A–P diameter, hyperplastic internal nasal spine (i.e., large frontal beak), or narrow ethmoid
III	Bilateral Draf IIB with removal of the upper part of the nasal septum and intersinus septum	• As for Draf IIB recommended over type II sinusotomy for cases with severe polyposis

From Weber R, Draf W, Kratzsch B, et al. Modern concepts of frontal sinus surgery. *Laryngoscope* 2001;111:137–146.

plan the surgical approach and to identify each cell to be dissected as well as to understand the drainage pathway of the frontal sinus allowing the dissecting instruments to be placed along the drainage pathway facilitating a safe dissection. This should allow a stepwise cell removal with complete exposure of the frontal ostium.

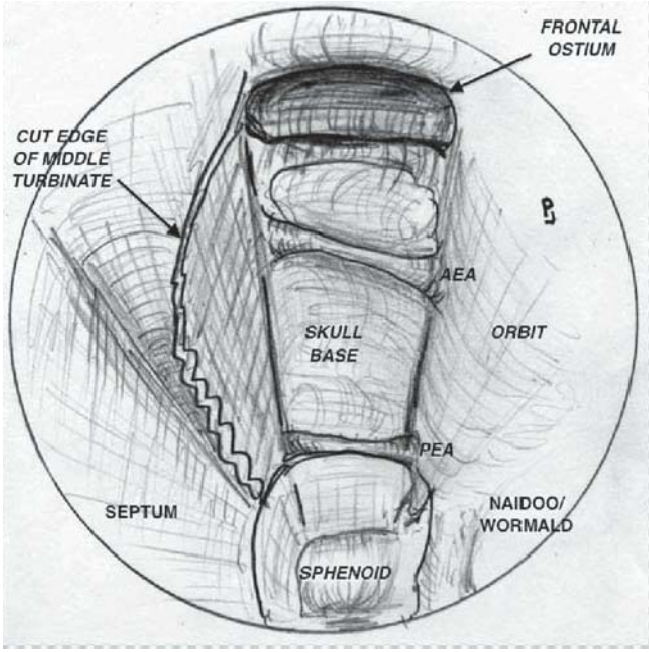

Figure 46.1 Boundaries of frontal recess. The frontal ostium is bounded by the lamina papyracea laterally, the middle turbinate medially, the skull base posteriorly, and the frontal beak anteriorly. All of the cells impinging on this ostium must be removed to maximize the frontal ostium. AEA, anterior ethmoidal artery; PEA, posterior ethmoidal artery.

The first step in the reconstruction is to identify on the coronal computed tomography (CT) scan, the first cell anterior to and directly above the insertion of the middle turbinate. In most cases, this is the agger nasi cell (Fig. 46.3A). This is confirmed on the parasagittal scan (Fig. 46.3B). A building block is placed for the agger cell. The cell above the agger nasi cell is then identified and confirmed by cross reference with the parasagittal scan. This is a T1 cell and a block is placed to represent this. A cell is noted above this cell and on the parasagittal scan this cell is seen to extend above the frontal beak. This is a T3 cell and a block is placed to represent this cell.

Similarly, blocks are placed for the ethmoid bulla and suprabullar cell, which are seen on the coronal and parasagittal scans (Fig. 46.3B).

The final aspect of the reconstruction is to identify how the frontal sinus drains in relation to these cells. This is done by following the frontal sinus from superiorly to inferiorly on sequential axial scans. In this way, the frontal sinus itself can be distinguished from cells that protrude into the sinus. An asterisk (*) marks the frontal sinus on the sequential scans (Fig. 46.3C). This shows an anterior and medial drainage pathway. The completed building block model is shown in Figure 46.3D.

OPERATIVE TECHNIQUE

Mucosal sparing and maximizing the size of the frontal sinus tract are the crucial elements to successful surgery. Where maximum medical therapy including systemic steroids has failed to resolve mucosal thickening in the frontal sinus or recess, our institution's philosophy is to make the frontal sinus outflow tract as wide as possible by removing *all* cells that impinge on this drainage pathway

TABLE 46.2 WORMALD CLASSIFICATION OF FRONTAL RECESS AND FRONTAL SINUS CELLS

Cell	Description
Agger nasi	Cell that is either anterior to the origin of the middle turbinate or sits directly above the most anterior insertion of the middle turbinate into the lateral nasal wall (see Fig. 46.2a - Small agger and Fig. 46.2b - large agger cell)
Frontal ethmoidal	Anterior ethmoidal cell that needs to be in close proximity or touching the frontal process of the maxilla
Type 1	Single cell above agger nasi, not extending above the frontal beak (see Fig. 46.2c)
Type 2	Tier of frontal ethmoidal cells above agger nasi, not extending above the frontal beak (see Fig. 46.2d)
Type 3	Frontal ethmoidal cell pneumatizing cephalad into the frontal sinus but extending less than 50% of the vertical height of the frontal sinus (see Fig. 46.2e)
Type 4	Frontal ethmoidal cell that extends more than 50% of the vertical height of the frontal sinus (see Fig. 46.2f)
Frontal bulla	Suprabullar cell that pneumatizes along the skull base into the frontal sinus along its posterior wall (see Fig. 46.2g)
Suprabullar	Cells above the ethmoid bulla that do not extend into the frontal sinus (see Fig. 46.2h)
Intersinus septal	A medially based cell related to the frontal sinus septum which opens into the frontal recess (see Fig. 46.2i)

Adapted from the Kuhn classification.

EXAMPLES OF FRONTO-ETHMOIDAL CELLS

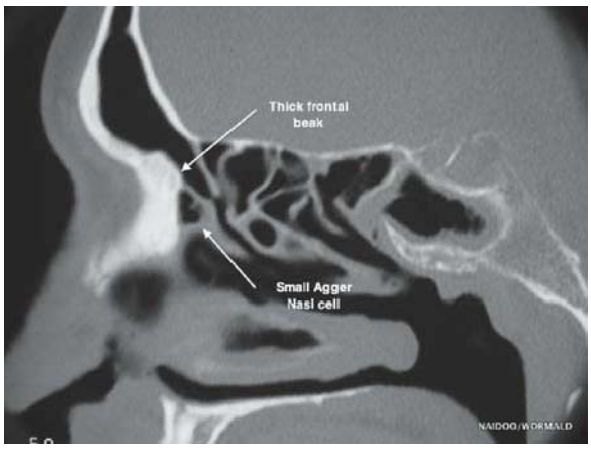

Figure 46.2a Small agger cell: A small agger cell is usually associated with a prominent frontal beak, which narrows the A–P dimension of the frontal ostium

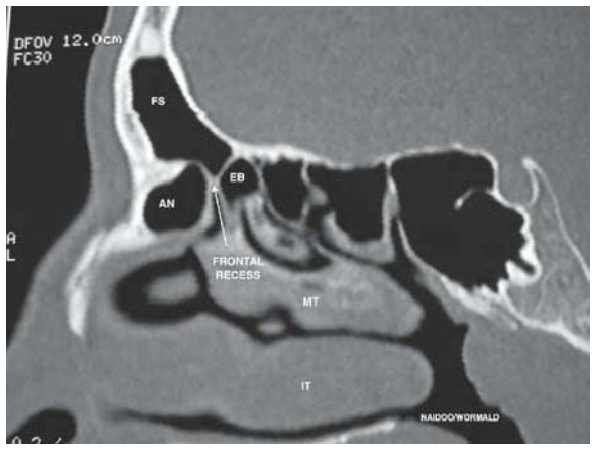

Figure 46.2b Large agger cell: A large agger cell tends to push the frontal drainage pathway more posteriorly. In general, it is associated with a less prominent frontal beak, making the A–P diameter of the frontal ostium larger. AN, agger nasi; EB, ethmoid bulla; FS, frontal sinus; MT, middle turbinate; IT, inferior turbinate

Figure 46.2c T1 cell. One cell above the agger nasi cell. This cell does not protrude superior to the frontal beak

C

Figure 46.2h **A–C:** Coronal, axial, and parasagittal scans showing a frontal bulla (FB) cell. It is a suprabullar cell that pneumatizes along the skull base into the frontal sinus along its posterior wall. Finally, the intersinus septum itself might pneumatize in the midline and push the frontal recess laterally

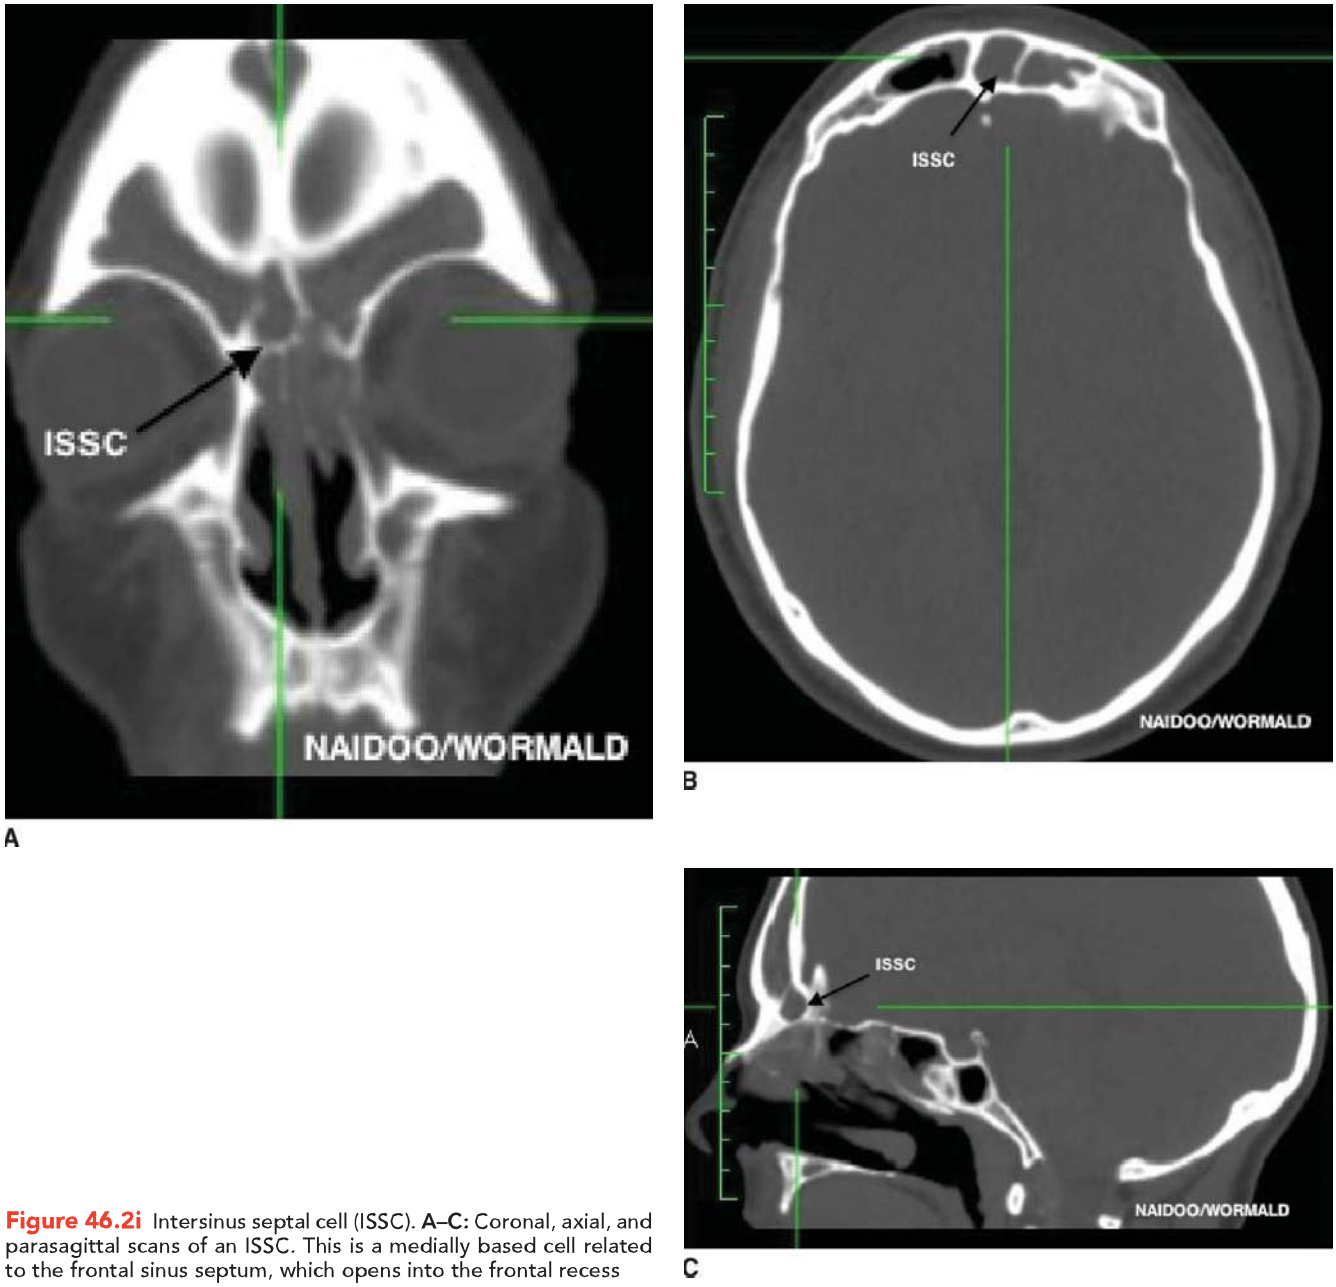

Figure 46.2i Intersinus septal cell (ISSC). **A–C:** Coronal, axial, and parasagittal scans of an ISSC. This is a medially based cell related to the frontal sinus septum, which opens into the frontal recess

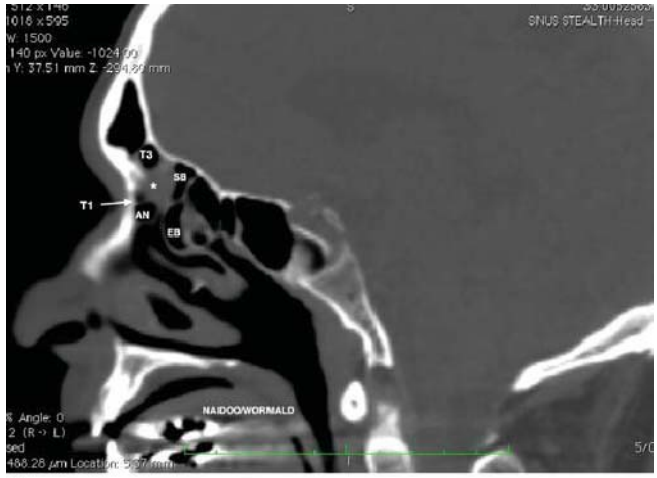
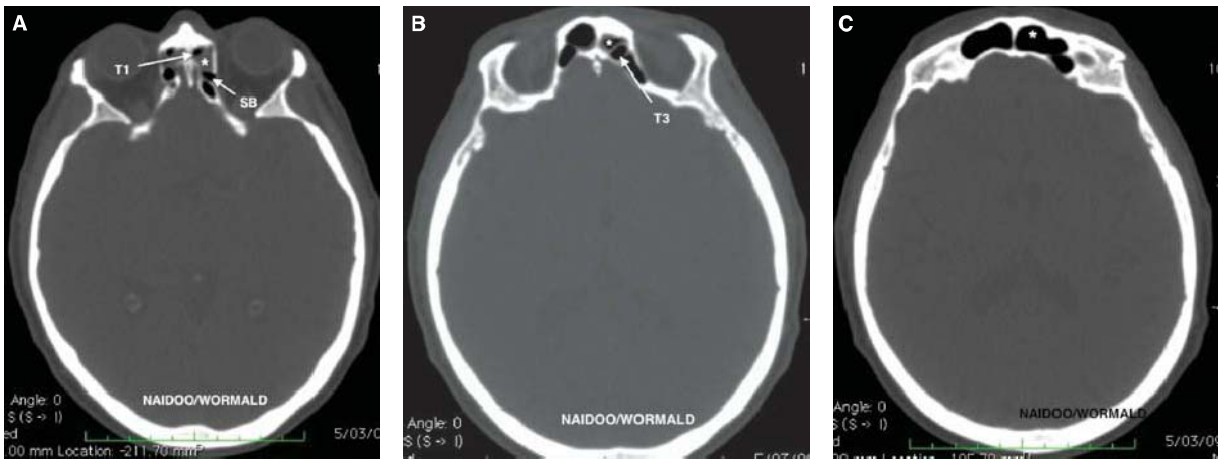
(Draf IIA approach). The cells in the frontal recess are in close approximation and partial clearance predisposes the formation of adhesions with obstruction of the drainage pathway. Frontal sinus surgery, therefore, is an all-or-nothing consideration. The frontal sinus is either left alone or *all* cells are removed so that the frontal ostium is completely visualized.

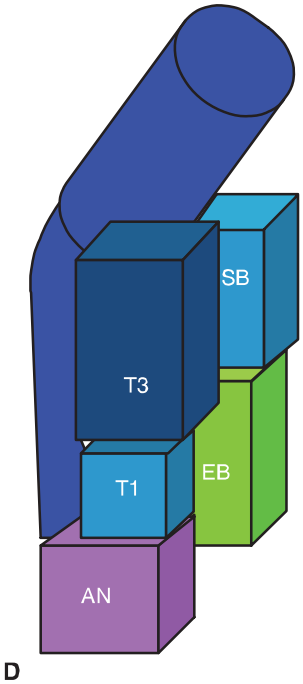


Should this fail, an EMLP is the procedure of choice (a.k.a. Draf III/frontal drillout). The Draf IIB approach for chronic sinusitis is only performed in patients with isolated frontal sinusitis with little disease in the other sinuses. In our experience, Draf IIB has a high failure rate when performed for pansinus disease as the wide exposure of bone in the frontal ostium results in extensive scarring and closure of the neo-ostium. For example, a small medially positioned frontal osteoma might be readily addressed by a unilateral Draf IIB procedure. The key difference here is that the mucosa and underlying bone is unlikely to be chronically inflamed, as it is in cases of chronic sinusitis. This reduces the chance of healing by secondary intention with an intense, predominantly fibroblastic reaction.

Indications for Frontal Sinus Surgery in Chronic Rhinosinusitis



Frontal sinus surgery is indicated in chronic rhinosinusitis (CRS) when there is clinical and radiologic evidence of disease in the frontal recess and sinus that is nonresponsive to medical therapy. Patients in our department, only undergo surgery if they have previously failed at least a 2-month



A

B

course of maximal medical treatment that includes culture-directed antibiotics, saline douches, topical nasal steroids, and oral steroids.

Frontal sinusotomy is only performed if there is objective evidence of persistent posttreatment mucosal thickening in the frontal recess or frontal sinus on paranasal CT scans, and endoscopic evidence of ongoing disease such as polyposis, mucosal edema, or mucopurulence.

Our philosophy is that the frontal sinus should be treated no differently to any of the other sinuses. Frontal pain or headaches should not be thought of as the only surgical indication for endoscopic frontal sinusotomy. Mucosal disease in the frontal sinus without symptoms of headache can still contribute to the other symptoms of CRS such as nasal obstruction, anosmia, postnasal drip, and rhinorrhea. The philosophy that frontal sinus disease should not be treated without specific frontal sinus pain being present has no scientific basis in the literature and is not supported by our experience.

Preoperative Planning and Assessment

Surgery is planned preoperatively using a CT scan of the paranasal sinuses performed in three orthogonal planes. Each cell is confirmed by reference to the coronal, sagittal, and paranasal planes and the building block model created.

The scan is then assessed routinely for surgical danger points:

- Location and course of the anterior and posterior ethmoidal arteries
- Height and more importantly symmetry of the lateral lamella of the cribriform plate (Keros classification)
- Angle and potential breaches of the skull base
- Dehiscence of the lamina papyracea
- Location and potential dehiscence of carotid artery and optic nerve

The nose is prepared topically with 2 mL of 10% cocaine, 2 mL of 1:1,000 adrenaline, and 2 mL of saline soaked onto neuro patties. The septum and lateral nasal wall is injected with 2 mL of 2% lignocaine and 1:80,000 adrenaline. Total intravenous anesthesia is used preferably, with the aim of having the mean arterial pressure no higher than 60 mm Hg and pulse rate of approximately 50.

Complications of Frontal Sinus Surgery

Complications in frontal sinus surgery are due to the technically demanding nature of the surgery and the proximity of the frontal sinus to the lamina papyracea, anterior ethmoidal artery (AEA), cribriform plate, and skull base. The most common complications are orbital entry (with potential damage to the eye, ocular muscles, optic nerve), hemorrhage (from AEA either from the nose or into the eye with proptosis), and cerebospinal fluid (CSF) leak from inadvertent intracranial entry. Without a thorough knowledge of the anatomy of the frontal recess, these structures are likely to be placed at risk with potentially catastrophic results. Iatrogenic injury with scarring of the frontal recess and/or incomplete removal of all cells in the frontal recess can also lead to persistence or worsening of symptoms. Frontal sinus surgery is technically the most demanding aspect of ESS and is best undertaken by experienced sinus surgeons.

Axillary Flap

The axillary flap technique allows use of a 0-degree endoscope to approach the frontal sinus (6,7). By improving (reducing) the angle of attack and the distance to the frontal ostium, cells pneumatizing into the frontal sinus are more easily removed with standard endoscopes and instruments. A similar technique without preservation of mucosa was described by Pletcher et al. (8) for accessing the frontal recess.

Surgery begins with removal of the middle third of uncinate process. The maxillary ostium is identified and then opened as indicated by the extent of disease involving this sinus. The maxillary ostium allows identification of the medial orbital wall and floor of the orbit and should be the first step in all sinus surgery.

An 8-mm incision superior to the axilla of the middle turbinate is extended anteriorly for 8 mm. The scalpel is turned vertically and the incision is continued inferiorly to the level of the axilla. The inferior limb is taken back to the root of the middle turbinate. A suction Freer elevator is used to raise the flap, which is tucked medial to the middle turbinate. A forward-biting Hajek-Koeffler punch is used to remove bone at the junction of the anterior attachment of the middle turbinate and lateral nasal wall. The Hajek punch is oriented in a vertical direction, parallel to the middle turbinate, so as to avoid destabilizing this structure. Typically one or two "bites" with the rongeur are sufficient to remove the anterior face of the agger nasi cells allowing for direct visualization into the frontal recess. A frontal sinus probe or malleable suction curette is placed behind the posterior wall of the agger nasi cell into the previously identified drainage pathway. If the drainage pathway is posterior, cells are curetted from a posterior to anterior direction (away from the skull base) and if it is medial then curettage is medial to lateral (away from the lateral lamella of the cribriform plate) to enlarge the frontal sinus drainage pathway. Curetted fragments of bone and soft tissue are removed with a microdebrider or an up-biting Blakesley or giraffe sinus forceps.

With the anterior face, posterior wall and roof (cap) of the agger nasi cell removed, the frontal sinus drainage pathway should be identified as per the 3D reconstruction. The pathway is probed using the building block model as a map. The curette or probe is gently slid up the pathway and once in position, the wall of the obstructing cell is fractured and removed. This process is repeated until all the cells in the frontal recess and protruding through the frontal ostium are removed. At the end of the dissection,

the frontal ostium should be clearly visible, and no cells should remain in the frontal drainage pathway or ostium. The surgical limits, therefore, is the frontal "beak" anteriorly, the skull base posteriorly, middle turbinate medially, and lamina papyracea laterally.

Surgery then proceeds to the bulla ethmoidalis with its complete removal. Care should be taken not to damage the AEA. The AEA is generally found behind the anterior face of the bulla ethmoidalis unless a suprabullar cell or recess exists. The AEA must be identified radiologically prior to surgery and incorporated into the building block model if necessary.

MINI-TREPHINATION

Frontal sinus mini-trephination is a particularly helpful technique when the drainage pathway is not seen. A cannula placed in the frontal sinus allows the instillation of fluorescein-stained saline. The stained fluid can then be followed in the frontal recess, allowing a malleable probe to be passed into the frontal sinus, facilitating careful clearance of the frontal recess.

Technique of Placing Mini-Trephines

Safe placement of the mini-trephines requires assessment of the CT scans to assess the superior extent and pneumatization of the frontal sinuses. Placement of the mini-trephine too high can result in intracranial penetration by the drill. The CT is also assessed for dehiscences of the posterior table of the frontal sinus, which might allow fluorescein-stained saline to enter the intracranial cavity.

If the CT confirms the presence of a sufficiently pneumatized frontal sinus, the skin landmark is 1 cm lateral to the midpoint of an imaginary line between the medial end of the eyebrows. To camouflage the skin incision, the incision is best made in a vertical frown line or in the medial hairs of the eyebrow. The skin over the frontal bone is mobile and the mini-trephine guide is easily placed into the correct position onto the frontal bone by moving the overlying skin.

It is important to place the mini-trephine guide carefully through the skin without "cookie-biting" an ellipse of skin, and directly onto bone with the teeth of the guide firmly engaged so that it does not move when drilling. Cooling the drill meticulously will reduce the chance of burning the skin and bone, which can leave an unsightly circular scar and local osteitis.

The trephine burr is designed to penetrate not more than 11 mm beyond the guide. Properly placed, it should not be able to penetrate the posterior table of the frontal sinus. Occasionally, it might not be able to penetrate the anterior table. This is dealt with by moving the guide together with the overlying skin inferomedially to an area of the thinner bone of the anterior table.

Once the drill enters the frontal sinus, the guide is held in place and a wire stylet is introduced. The guide is removed and the frontal cannula introduced over the wire stylet and gently rotated into the skin. A syringe partially filled with fluorescein-stained saline is attached to the cannula and aspiration is attempted. The aspiration of pus, mucus, or air admixed with blood is expected. Clear fluid should alert the surgeon to intracranial penetration. If the frontal sinus is completely blocked, nothing will be aspirated and a vacuum will be created within the syringe. As long as clear fluid has not been aspirated, the frontal sinus can be flushed gently with the fluorescein-stained saline and the frontal recess is observed for its emergence. This area can then be probed to identify the frontal ostium and clear the frontal recess.

IMAGE-GUIDED SURGERY

Image-guided surgery uses CT or Magnetic Resonance Imaging (MRI) (or both CT and MRI) data presented to the surgeon in three planes: coronal, axial, and parasagittal. By placing the cross-hair on a particular cell, this cell can be identified in each plane. This facilitates the 3D building block reconstruction. It also allows intraoperative confirmation of critical areas such as the skull base, orbit, optic nerve, carotid, and AEA. This is particularly relevant in revision cases where many, if not all, landmarks have been altered. It is also useful in patients with extensive polyps and pansinusitis where erosion of the cellular lamina makes clear differentiation of cells difficult. It is used routinely for all Draf III/EMLP/drillout procedures, for paranasal sinus malignancies, and for difficult revision sinus cases in our department.

Draf III/Modified Lothrop/Frontal Drillout Procedure

The efficacy of the EMLP, otherwise known as a Draf III or Frontal Drillout Procedure, is now well established. It is an effective intranasal approach to the treatment of frontal sinus disorders. The operation aims to reestablish normal or near-normal frontal sinus function. Anderson et al. recently reviewed EMLP outcomes. They noted frontal ostium patency rates of greater than 95% with a significant improvement in symptoms noted in 82%. The overall failure rate was 13.9%. Only 1.2% of patients reported a worsening of symptoms. In addition, this review confirmed the safety of this procedure with a serious complication rate of less than 1% (9).

Draf III/EMLP has proved effective in the treatment of following (10):

- Failed prior ESS
- Frontal sinus mucocele
- Fractures of the frontoethmoid complex
- Repair of CSF leaks and meningoencephaloceles
- Failed osteoplastic flap frontal sinus obliteration
- Resection of sinonasal neoplasms

Technique

All Draf III/EMLPs are performed in our department with image guidance. The placement of frontal mini-trephines provides additional help by delineating the posterior limit of the dissection intraoperatively, and facilitating irrigation of the neo-ostium postoperatively. Identification of the posterior limit is crucial, as dissection anterior (but not medial) to this puts the skull base at minimal risk.

Surgery begins by revision ESS to address disease in maxillary, ethmoid, and sphenoid sinuses. The frontal ostium is identified and confirmed with the aid of image guidance and fluorescein flushes.

The mucosa above the middle turbinate up to the roof of the nose is removed with a microdebrider. The mucosa of the septum anterior the middle turbinate is then removed bilaterally, and the intervening cartilage excised to create a superior septal window (Fig. 46.4).

The limits of this window are dictated by the access required to perform the drillout. Superiorly, the septum is removed to the roof of the nasal cavity (which in this region corresponds to the floor of the frontal sinus and frontal beak). Inferiorly the window is lowered sufficiently to allow a straight 3.2-mm bur to pass across the septal window to enter under the axilla of the middle turbinate of the contralateral side. Similarly, the anterior limit of the window must allow the 3.2-mm bur to be passed from the ipsilateral nostril, across the window, to the contralateral frontal process of the maxilla, which is where drilling is initiated. Posteriorly, the septum is removed to the anterior border of the middle turbinate. Usually, the window measures 3 cm by 2 cm, but the key issue here is one of access to all the aforementioned areas.

Drilling starts laterally on the frontal process of the maxilla. Optimum access is achieved by passing instruments (0-degree nasendoscope and 3.2-mm cutting bur) across the septal window. The bone of the frontal process is removed until a small area of skin is exposed to define the lateral limit of the resection (Fig. 46.5).

The bur is swept from the ostium anteriorly and laterally widening the ostium until the frontal sinus is entered. Once the frontal sinus has been clearly defined, drilling proceeds anteriorly and medially removing bone of the floor of the sinus and frontal beak, until the septum is reached. (At this point a Draf IIB procedure has been completed) (Fig. 46.6).

It is important to not proceed medially until the frontal sinus is clearly identified, as the skull base might be placed at risk further posteriorly (Fig. 46.7).

The opposite side is then addressed in a similar manner such that a bilateral Draf IIB has been performed. The intersinus septum is then removed. The neo-ostium is now crescent shaped and further bone removal is required in the anteroposterior (A–P) plane to maximize its size, and convert this to an oval-shaped cavity (Fig. 46.8).

The posterior limit of the dissection is the bone over the forward projection of the skull base. This bony projection forms the frontal "T" formed by the superior attachment of the middle turbinates to septum and skull base (Fig. 46.9).

The amount of bone that can be removed here is determined by the level of the first olfactory neuron. This is identified by carefully reflecting the mucosa of the olfactory cleft with an olive tipped curved sucker until the first olfactory neuron is seen. This is then confirmed by image guidance. Note that the image guidance is used to confirm our clinical landmarks. Clinical correlation is vital as the reference frame for the image guidance can shift during the

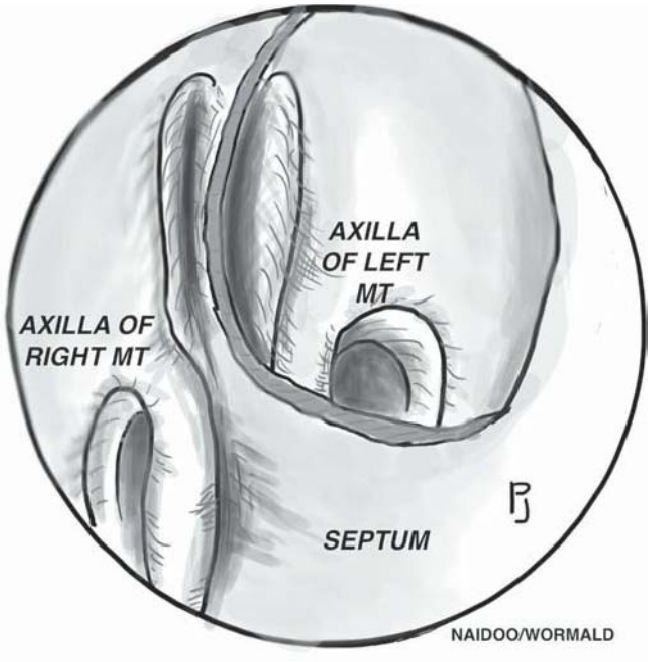

Figure 46.4 Septal window. The superior septal window allows access for the bur to pass across the nasal septum. Its boundaries are determined by the access required to the frontal recess and frontal process of the maxilla.

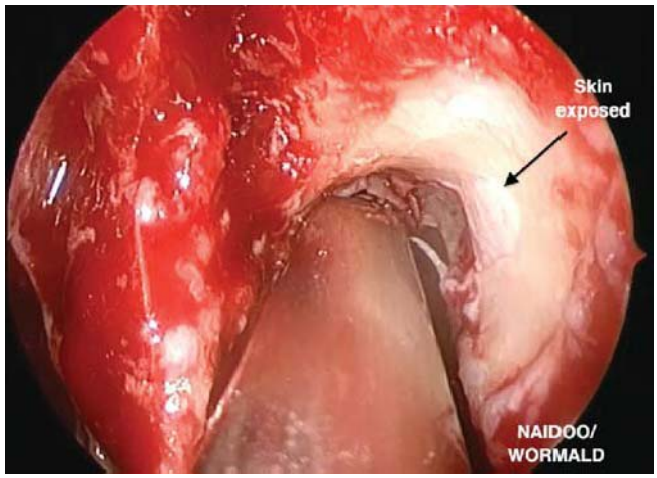

Figure 46.5 Skin exposed laterally. To maximize the lateral dimensions of the neo-ostium and to create space for the bur, the bone should be removed over the frontal process of the maxilla until a small amount of skin is exposed.

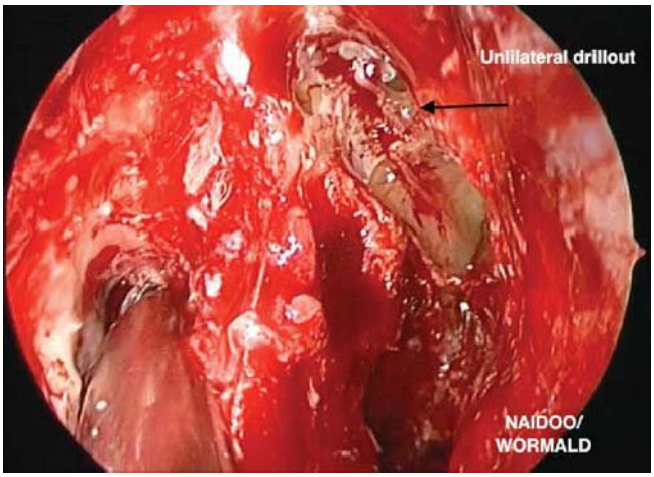

Figure 46.6 Draf IIB. A unilateral drillout has been performed. The frontal ostium has been widened from the orbit laterally to the septum medially.

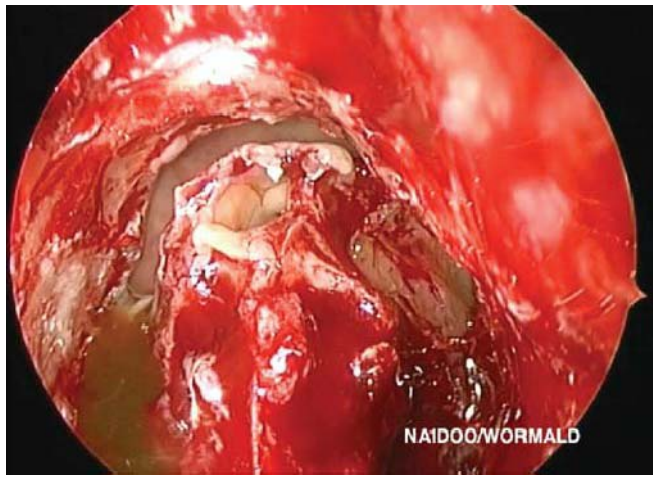

Figure 46.8 Crescent-shaped ostium. A bilateral Draf IIB has been performed. However, the frontal neo-ostium is still quite small and prone to stenosis.

procedure. The bone of the "T" is then removed to within 1 mm of the first olfactory neuron.

The bur is now changed to an angled bur and for the first time, a 30-degree telescope is used to tackle the anterior aspect of the frontal neo-ostium. This thick bone of the frontal beak is removed until there is no lip of bone separating the frontal sinus from the nasal cavity. The transition from frontal sinus to nasal cavity should be smooth.

At the end of the procedure, an oval-shaped neo-ostium is created. The ultimate dimensions are determined by the patient's anatomy and average ~approximately 18 mm from frontal beak to first olfactory neuron and 20 to 24 mm from skin to skin laterally. It should always be made as large as possible. The *major* risk factor for restenosis has been shown to be the initial size of the neo-ostium (11) (Fig. 46.10).

Hemostasis is achieved by bipolar cautery, and particular care is taken at the posterior edge of the septal window and the mucosa overlying the forward projection of the skull base where septal branches of the AEA can cause postoperative bleeding.

POSTOPERATIVE CARE

Careful postoperative management is crucial. The postoperative regimen we use is:

- Oral antibiotics for 10 days for frontal sinusotomy and 3 weeks for EMLP. Intraoperative cultures are checked and the antibiotic regimen changed to culture-directed antibiotics if required.

Figure 46.7 Axial CT scan at olfactory fossa. This scan illustrates the dangers of passing the bur medially before you enter the true frontal sinus. If the bur is not in the frontal sinus, movement of the bur medially will place the skull base at risk.

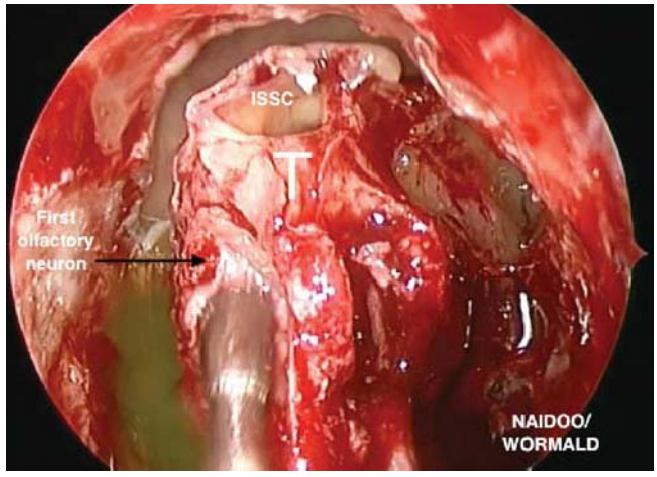

Figure 46.9 Defining the frontal T and first olfactory neuron. A curved sucker is used to carefully reflect the mucosa in the olfactory cleft until the first olfactory neuron is seen. The bone overlying the frontal "T" must be removed to about 1 mm of this neuron.

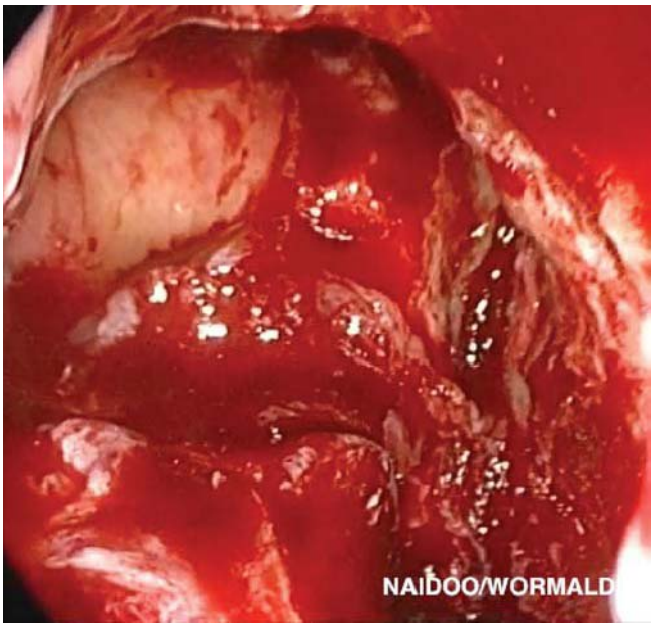

Figure 46.10 Final oval shape of neo-ostium. A large neo-ostium has been created. Its final dimensions are dictated by the underlying patient anatomy. The limits are always the skin laterally and anteriorly, and first olfactory neuron posteriorly.

- Saline irrigation four to six times daily.
- Oral steroids for 3 weeks on a tapering schedule for sinonasal polyposis.
- Where mini-trephines are placed for frontal sinusotomies, 5 mL of saline flushes every 2 hours via each cannula are started immediately after surgery. With every second flush, 0.5 to 1 mL of prednisolone solution is instilled. The trephines are left in place for up to 3 days.
- For EMLP, 5 mL of steroid and antibiotic *cream* are injected via the cannula just prior to removal. This coats the cavity and decreases the amount of crusting. (Note, ointment should not be used as it is lipid based and causes a granulomatous reaction in the sinus mucosa—*myospherulosis*.)
- The patient is reviewed at 10 to 14 days postoperatively, where the sinuses are examined endoscopically and crusts removed and adhesions divided. A thin-curved suction is passed into the frontal sinus and the sinus cleaned while minimizing mucosal trauma. If significant crusting or adhesion formation is noted, an early revisit is scheduled. If all appears to be healing well, the patient is reviewed 4 to 6 weeks later.

CONTROVERSIES IN FRONTAL SINUS SURGERY

The extent of frontal sinus surgery in CRS is controversial. Techniques such as Balloon Sinuplasty (Acclarent) offer a minimally invasive approach to the sinuses but is not, as yet, supported by the literature. The extent of frontal recess dissection varies from surgeon to surgeon across the world with some surgeons only performing endoscopic frontal sinusotomy when patients have symptoms of frontal headache or congestion. Our philosophy is that the frontal sinus should be treated no differently to any of the other sinuses. Mucosal disease in the frontal sinus without symptoms of headache can still contribute to the other symptoms of CRS such as nasal obstruction, anosmia, postnasal drip, and rhinorrhea.

The evidence base for frontal sinus dissection is limited but growing. In our experience, careful and complete clearance of the frontal sinus using the 3D building block model and the axillary flap technique produces excellent long-term results.

Our department is currently looking at the evidence for the extent of surgery in CRS. In particular, the extent of frontal sinus surgery required for high-risk CRS patients such as Samter triad is being investigated. These patients have a higher rate of failure from standard endoscopic frontal sinusotomy and appear to do better with more extensive surgery such as the EMLP (unpublished data). Data collected in the department suggest that these patients might be best served with a primary EMLP.

HIGHLIGHTS

- Understanding the complex anatomy of the frontal recess is key to safe and complete dissection.
- Frontal sinus surgery should be an all-or-nothing consideration. The narrow confines of the frontal recess predispose this area to adhesion formation if only partial clearance is performed.
- The use of a 0-degree endoscope reduces the angle of attack and distance to the frontal ostium. The axillary flap technique facilitates the use of a standard 0-degree endoscope and standard ESS equipment to dissect in the frontal recess. Replacement of the flap after dissection limits adhesion formation.
- The 3D building block model of the frontal recess aids surgical dissection. Cells are removed in a stepwise fashion to completely clear the frontal recess.
- Mini-trephination of the frontal sinus is a useful adjunct to frontal sinus surgery. It can be used for:
  - Intermittent flushing of the frontal sinus with fluorescein-stained saline to safely identify the natural drainage pathway of the frontal sinus
  - Postoperative irrigation of the frontal ostium to prevent adhesion formation and stenosis
- The EMLP is an extended frontal sinus approach, which creates a single frontal sinus draining into the nose via a superior septectomy. Its safety and efficacy in treating recalcitrant frontal sinusitis is now well established.
- Optimum results with the Draf III/EMLP are achieved by creating the largest possible neo-ostium and meticulous postoperative care.

Anatomy and Physiology of the Salivary Glands

47

Rohan R. Walvekar *Bridget C. Loehn* *Meghan N. Wilson*

The major salivary glands of the head and neck consist of the parotid glands, submandibular glands, and sublingual glands. There are also hundreds to thousands of minor salivary glands located throughout the upper aerodigestive tract concentrated mainly in the buccal, labial, palatal, and lingual regions. The main function of the salivary glands is the production of saliva for lubrication and protection, buffering action and clearance of food, maintenance of tooth integrity, antibacterial activity, taste, and digestion. It is important for a head and neck surgeon to understand the anatomy, embryology, function, and imaging of salivary glands to assist in the diagnosis and surgical management of benign and malignant disease of the salivary gland.

EMBRYOLOGY

The salivary glands share an overall common embryogenesis in that they all develop from outpouchings of oral ectoderm into the surrounding mesenchyme and they have a similar anatomic structure (Fig. 47.1). The major salivary glands develop during the sixth to eighth weeks of embryonic life. The parotid anlagen are the first to develop, followed by the submandibular glands, and then the sublingual glands. The primordia originate at the site of the eventual ductal orifice and the gland develops into an elaborate tubuloacinar system. The parotid gland is unique in that as its epithelial buds are growing and branching, they extend between the divisions of the facial nerve, eventually surrounding the nerve. This phenomenon has clinical and surgical relevance, explaining why neoplastic processes may often extend both superficial and deep to the facial nerve rather than honoring traditional definitions of superficial and deep parotid lobes. During development, all three of the major salivary glands become encapsulated. Although the parotid gland is the first to develop, it is the last to become encapsulated in loose connective tissue. This becomes important in the adult parotid anatomy as the lymphatic system develops prior to the encapsulation of the parotid but after the encapsulation of the submandibular and sublingual glands. Therefore at the completion of embryogenesis, the parotid gland has lymph nodes and lymphatic channels within the capsule whereas the submandibular and sublingual glands do not. This fact has driven recent studies that examined the feasibility of submandibular gland preservation in patients with oral cancer, demonstrating a lack of direct metastasis to the submandibular glands in neck dissection specimens (1,2). The minor salivary glands develop from oral ectoderm and nasopharyngeal endoderm in the 12th week of intrauterine life.

Parotid Gland Anatomy

The parotid gland is the largest of the three major salivary glands with an average weight of 25 g. The parotid gland is an irregular, wedge-shaped, unilobular gland found overlying the mandibular ramus and anterior inferior to the external ear (Fig. 47.2). It is located within the parotid space. This space is bound superiorly by the zygomatic arch, posteriorly by the external auditory canal, inferiorly by the styloid process, styloid muscles, internal carotid artery and jugular vein, medially by the lateral parapharyngeal space and laterally by the dermis of the skin. Anteriorly, the parotid gland extends superficial to the masseter muscle. This space not only contains the parotid gland but also the parotid lymphatics, blood vessels, and nerve supply. A small tail of parotid extends posteroinferior toward the mastoid process and overlies the sternocleidomastoid. Histologically, the parotid gland contains purely serous secreting acinar cells. The serous secreting cells are mainly spherical in shape and secrete a protein-rich fluid.

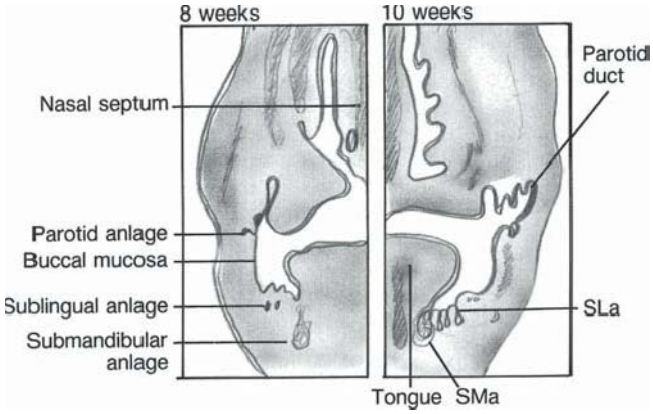

Figure 47.1 Development of the major salivary glands in 8- and 10-week embryos (axial section). SMa, submandibular anlage; SLa, sublingual anlage. (From Meyerhoff WL, Rice DH. Salivary gland anatomy and physiology. In: Paparella MM, Shumrick DA, Meyerhoff WL, eds. *Otolaryngology-head and neck surgery*, 3rd ed. Philadelphia, PA: WB Saunders, 1992, with permission.)

The parotid gland is encapsulated in its own dense connective tissue, which is continuous with the superficial layer of the deep cervical fascia. The parotid fascia consists of a superficial and deep layer. The superficial layer extends from the sternocleidomastoid and masseter muscles to the zygoma. This fascia sends septae into the glandular tissue. These septations make it difficult to separate the parotid gland from its investing fascia. The deep layer extends from the fascia of the posterior belly of the digastric muscle and forms the stylomandibular membrane, which separates the parotid and submandibular glands (Fig. 47.3). Occasionally the parotid tissue can herniate through the stylomandibular ligament and present as a parapharyngeal space mass.

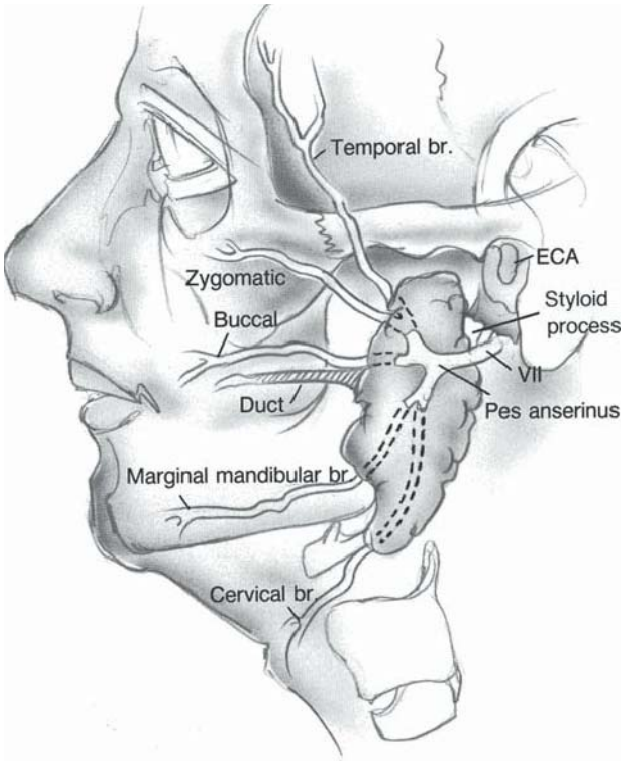

Figure 47.2 The parotid gland and the facial nerve. Note that the nerve exits the stylomastoid foramen lateral to the styloid process. Also note the relationship of the nerve branches to the surrounding structures.

The main parotid duct (Stensen duct) arises from the anterior border of the gland and runs parallel to the zygomatic arch. It is located approximately 1.5 cm below the zygomatic arch. The duct travels superficial to the masseter muscle, then turns 90 degrees and pierces the buccinator muscle to enter the oral cavity at the level of the second maxillary molar. The buccal branch of the facial nerve normally travels along with the parotid duct (Fig. 47.4). The parotid duct is approximately 4 to 6 cm in length. The diameter of the duct is approximately 0.5 to 1.4 mm and the narrowest portion is located at the ostium (3). The parotid duct tends to be more readily amenable to dilation and access. However, its course around the masseter can be difficult to navigate from the perspective of performing endoscopic procedures like salivary endoscopy. This curve has also been termed the "masseteric bend" in sialendoscopy literature (4).

Accessory parotid gland tissue is present in 21% of the population. It is salivary tissue adjacent to Stensen duct that is separate from the main body of the parotid gland (5). The duct of this accessory tissue empties directly into the parotid (Stensen) duct. Its histology is comprised of mucinous acinar glands in addition to the serous acinar gland that dominate in the parotid gland. The accessory parotid gland can be present and may be asymptomatic (Fig. 47.5) or be a site for neoplastic transformation similar to other major salivary glands (6).

The arterial blood supply to the parotid gland is from the external carotid artery. The external carotid artery terminates into two branches (maxillary and superficial temporal artery) in the deep aspect of the parotid gland behind the neck of the mandible. The transverse facial artery, a branch of the superficial temporal artery, supplies the parotid gland, Stensen duct, and the masseter muscle. This artery travels anteriorly between the zygomatic arch and Stensen duct accompanied by the transverse facial vein.

The venous drainage is located in the middle section of the parotid gland, deep to the facial nerve. The venous drainage is provided by the retromandibular (posterior facial) vein. The retromandibular vein, formed by the joining of the superficial temporal vein and the maxillary vein, exits the parotid gland lateral to the carotid artery and joins the postauricular vein to form the external jugular vein, which eventually drains into the internal jugular vein.

The superficial compartment of the parotid gland contains the neural structures including the facial nerve (cranial nerve VII), the great auricular nerve, and the auriculotemporal nerve.

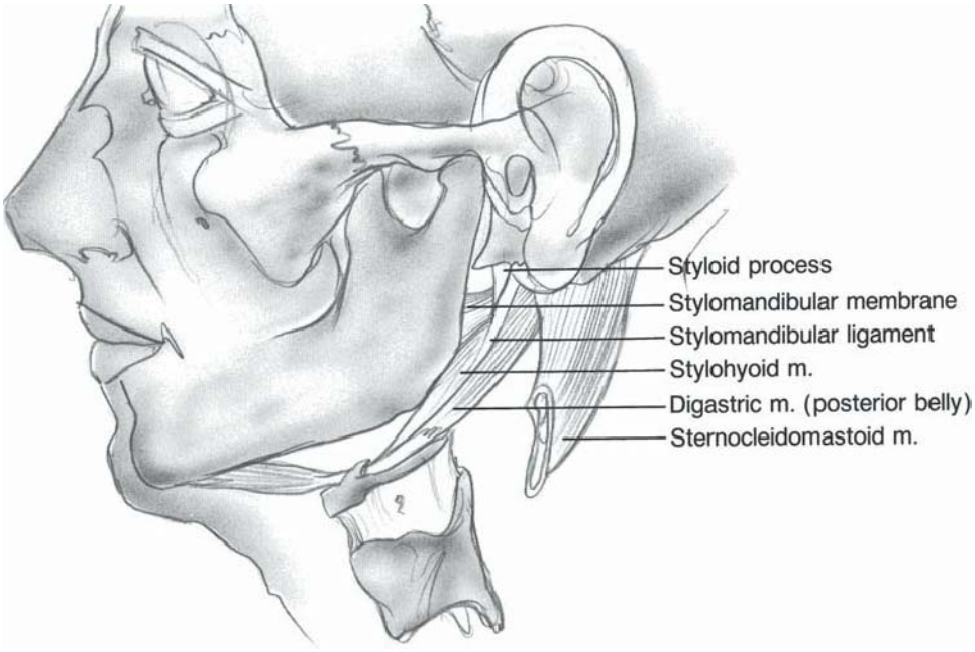

Figure 47.3 Stylomandibular membrane (deep layer of parotid fascia). Herniations of parotid tissue through this membrane can result in a parapharyngeal mass.

The *facial nerve*, as previously stated, is intimately associated with the parotid gland. It divides the gland into two surgical zones (superficial and deep lobes). The facial nerve exits the skull base through the stylomastoid foramen. It immediately gives off three motor branches: the nerve to the stylohyoid muscle, the nerve to the postauricular muscle, and the nerve to the posterior belly of the digastric muscle. Once these branches are given off, the nerve turns laterally to enter the posterior aspect of the parotid gland. Approximately 8.56 to 10.20 mm from the stylomastoid foramen, the facial nerve divides at the *pes anserinus* into the superiorly directed temporofacial and inferiorly directed cervicofacial branches (7). The nerve finally terminates into five branches: temporal, zygomatic, buccal, marginal mandibular, and cervical branches. The number of branches immediately after the *pes anserinus* and the number of terminal branches are variable dependent on the individual patient. The main trunk bifurcates into two branches at the pes anserinus in 86.7% and into three branches in 13.3%. The branching

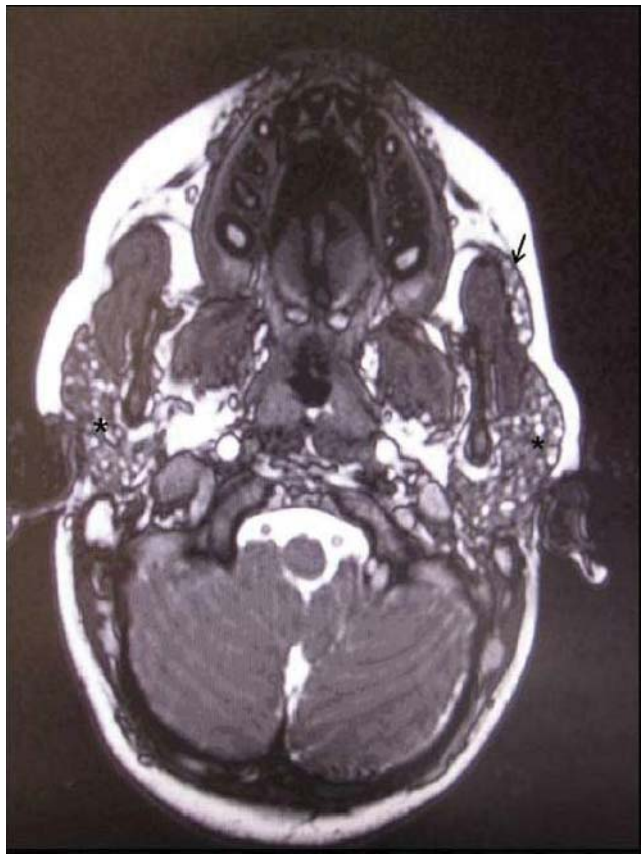

Figure 47.5 Axial MRI scan showing accessory left parotid lobe. (*Black arrow* points to left accessory parotid lobe; *asterisk* denote right and left parotid glands.)

pattern of the facial nerve is variable, and communicating or internerve branches are frequently present. Numerous variation patterns have been published. The buccal branch is the most variable and communicates with the zygomatic branch in 62% of cases and the marginal mandibular nerve in nearly 35% (8).

During parotidectomy, the localization of the facial nerve is critical. When the normal parotid anatomy is distorted as with a tumor, there are several constant relationships that will aid in finding the facial nerve. The tragal pointer is a projection of conchal cartilage that points toward the main trunk of the facial nerve. The facial nerve lies less than 1 cm medial and inferior to the tragal pointer (5). The nerve can also be found approximately 6 to 8 mm deep to the tympanomastoid suture line at the stylomastoid foramen. The styloid process is another constant landmark and the facial nerve lies on the posterolateral aspect of the styloid process near its base. The facial nerve is also located superior, posterior and deep to the cephalic portion of the posterior belly of the digastric muscle. After the nerve is identified at the stylomastoid foramen, anterograde dissection is required to continue surgical extirpation of the parotid glands. The surgical exposure of the nerve at this stage can be restricted and consequently care must be taken to avoid traction injury to the nerve at this juncture. Once the main divisions of the nerve are exposed, the plane of surgical dissection becomes more obtuse along the direction of the branches of the nerve (Fig. 47.6). Retrograde dissection of the buccal branch and temporal branch can be used to localize the main trunk. The buccal branch usually runs parallel to the parotid duct. The temporal branch can be roughly located along a line extending from the attachment of the ear lobule anterosuperior to a point 1.5 cm above the lateral aspect of the eyebrow (9). If the facial nerve cannot be identified using the above landmarks, a mastoidectomy may be performed and the facial nerve may be located in the mastoid (vertical) segment and thus may be traced to the stylomastoid foramen.

The *great auricular nerve* (C2, 3), a branch of the cervical plexus passes around the posterior border of the sternocleidomastoid muscle, ascends diagonally across

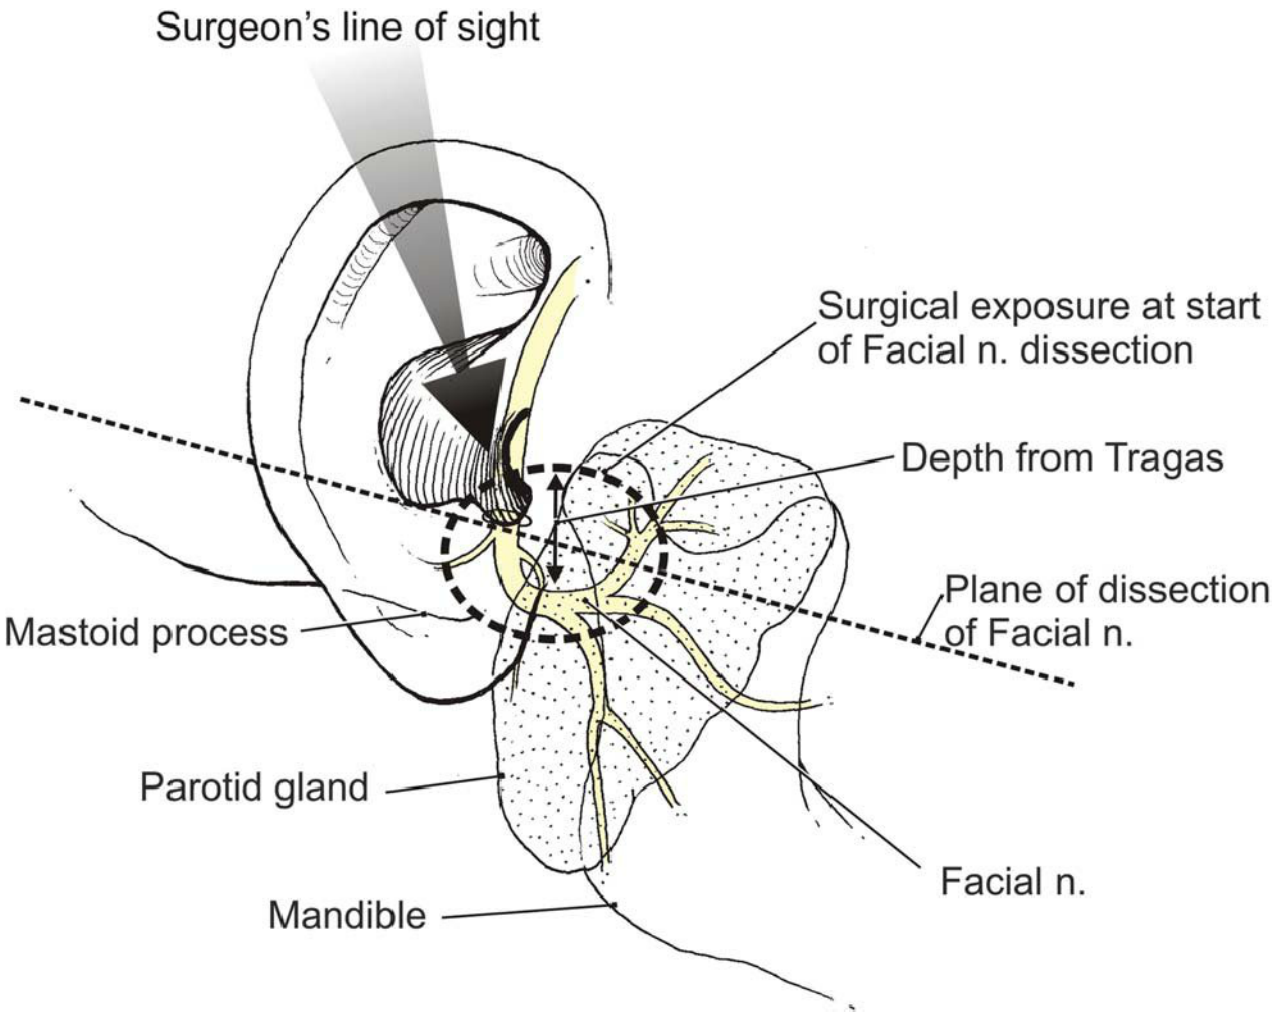

Figure 47.6 Illustrations depicting the depth of nerve at its point of entry into the parotid gland and surgical planes of dissection as compared to surgeon's line of sight.

the sternocleidomastoid muscle onto the parotid gland. It supplies sensation to the skin over the parotid gland, the posterior aspect if the auricle, and an area of skin from the angle of the mandible to the mastoid process. The nerve divides into an anterior and posterior division. This nerve is often damaged or intentionally sacrificed during parotidectomy causing numbness over the earlobe and skin over the parotid gland. Meticulous intraglandular dissection of the nerve can allow the nerve to be preserved if the location of the tumor permits such a dissection (10). Alternatively, in the author's experience, in most cases the posterior division of the nerve can be preserved avoiding complete anesthesia over the distribution of the nerve.

The ***auriculotemporal nerve*** is a branch of the mandibular division of the trigeminal nerve (V3). This nerve exits the skull base via foramen ovale, turns and runs anterior to the external auditory canal, and parallels the superficial temporal vessels. Its functions include supplying sensation to the scalp and carrying postganglionic parasympathetic fibers from the otic ganglion to the parotid gland. The auriculotemporal nerve and the facial nerve are intimately associated as communications between the auriculotemporal nerve and the facial nerve were observed in 93.3% of patients in one study (8).

The salivary glands receive their secretomotor innervation from the parasympathetic and sympathetic nervous systems. The parotid gland receives its parasympathetic stimulation by the glossopharyngeal nerve. The preganglionic parasympathetic fibers originate in the inferior salivatory nucleus, join the glossopharyngeal nerve, course through the lesser superficial petrosal nerve, and then travel through the foramen ovale to synapse in the otic ganglion. The postganglionic fibers then join the auriculotemporal nerve and thus are projected to the parotid tissue. The sympathetic stimulation is by the superior cervical ganglion. Sympathetic fibers begin in the thoracic spinal cord and synapse in the superior cervical ganglion. The postganglionic fibers form a plexus and travel on the external carotid artery to the parotid gland.

The parotid gland's unique lymphatic system is secondary to the fact that development of the capsule around the parotid gland occurs after the development of lymphatic system. Consequently, lymphatic structures are found within the parotid gland. There are periparotid as well as intraparotid lymph nodes; the periparotid lymph nodes are the most numerous and are found between the capsule and parotid gland while the intraparotid lymph nodes are located deep within the parotid gland. Both the periparotid and intraparotid lymph nodes drain the forehead, lateral temporal, frontal, and periorbital regions to include the scalp, pinna, external auditory canal, parotid gland, and lacrimal gland (11). Intraparotid nodes also drain the posterior nasopharynx, and soft palate. These two systems then drain into the superficial and deep cervical lymph nodes. Of clinical relevance, due to its lymphatic anatomy and patterns of drainage, a superficial parotidectomy if often considered in the clinical staging or management of cutaneous malignancies located in these anatomic subsites.

Submandibular Gland Anatomy

The paired submandibular glands are the second largest salivary glands and are located inferior to the floor of mouth. Each submandibular gland weighs approximately 15 g. Each submandibular gland is located within the submandibular triangle of the neck, which is bound by the mandible, posterior belly of the digastric muscle, and anterior belly of the digastric muscle (Fig. 47.7). Each submandibular gland forms a "C" shape around the posterior margin of the mylohyoid muscle, which divides the gland into a superficial and deep lobe (Fig. 47.8). The superficial lobe is above the mylohyoid muscle in the lateral sublingual

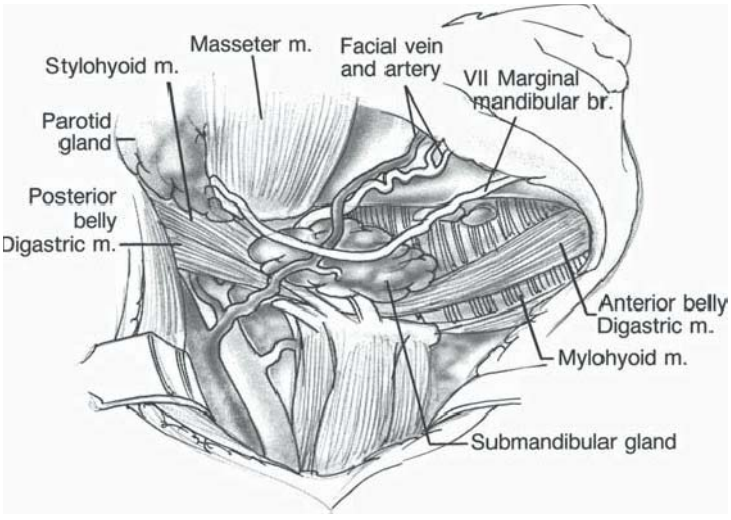

Figure 47.7 The submandibular triangle. Note the relationship of the marginal mandibular nerve to the mandible and facial vessels.

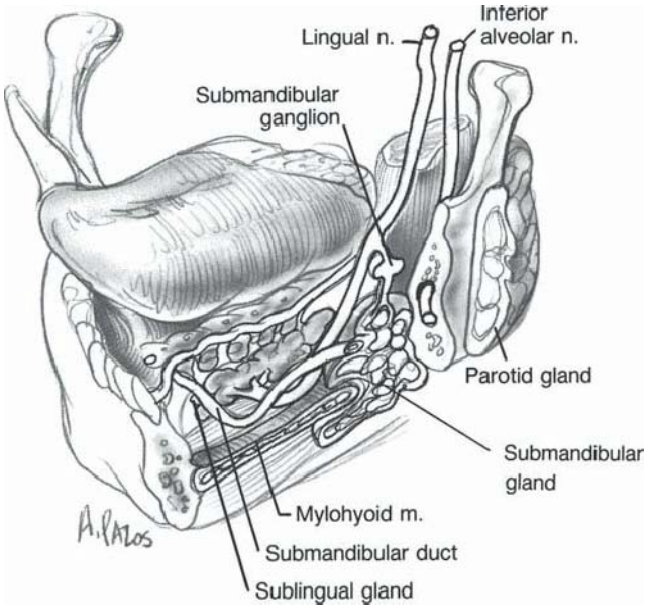

Figure 47.8 The superficial and deep lobes of submandibular gland are separated by the mylohyoid muscle. The sublingual gland has multiple ducts that open along the plica of the floor of the mouth.

space while deep lobe constitutes the majority of the gland and is located inferior to the mylohyoid. The capsule around the gland is derived from the superficial layer of the deep cervical fascia, as in the case of the parotid gland. Histologically, the submandibular gland contains both serous and mucous cells with serous cells predominating.

The submandibular duct (Wharton duct) is approximately 5 cm in length with a mean diameter between 0.5 and 1.5 mm (3). It begins on the medial aspect of the submandibular gland and passes superior to the hypoglossal nerve and inferior to the lingual nerve. It travels forward between the mylohyoid and hyoglossus muscles then onto the genioglossus muscle and opens into the oral cavity lateral to the lingual frenulum. The narrowest portion of the duct is at the ostium in the floor of the mouth near the papilla (3). From the perspective of the newer endoscopic salivary ductal procedures or sialendoscopy, the submandibular duct papilla is more difficult to access. The salivary duct may have multiple openings on the papilla or the opening may be located either at the apex of the papilla or on either side of it. Consequently, identification of the location of the papilla is often the rate-limiting step for sialendoscopy procedures. Once identified and dilated, the submandibular duct provides a more direct path for navigation of the endoscopes than the parotid duct.

The arterial blood supply to the submandibular gland is from the external carotid artery via the facial artery, which branches off of the external carotid artery in the carotid triangle above the lingual artery. It travels obliquely beneath the digastric and stylohyoid muscle and arches to enter a groove on the posterior surface of the submandibular gland. The artery then runs superior and anterior. Once it reaches the superior aspect of the gland, it curves superiorly over the body of the mandible at the anteroinferior angle of the masseter muscle to supply the face. The venous drainage is by the anterior facial vein. The anterior facial vein travels superficial to the submandibular gland. This vein lies deep to the marginal mandibular nerve. The Hayes-Martin maneuver is often used during submandibular gland excision to protect the marginal mandibular nerve by ligating the anterior facial vein 2 to 3 cm inferior to the mandible and elevating the vein superiorly off the gland thus protecting the marginal mandibular nerve in the elevated fascia (12).

The sympathetic innervation to the submandibular gland is through the superior cervical ganglion with postganglionic fibers that travel along the lingual artery to the gland. The parasympathetic innervation begins in the superior salivatory nucleus in the pons. The fibers join the facial nerve via the nervous intermedius within the cerebellar pontine angle or internal auditory canal and then exit the facial nerve along the chorda tympani. The chorda tympani exits the skull base via the petrotympanic fissure and then joins the lingual branch of the mandibular division of the trigeminal nerve in the infratemporal fossa. The preganglionic fibers synapse in the submandibular ganglion then reach the gland directly from the submandibular ganglion.

In contrast to the parotid gland, the capsule of the submandibular gland is developed prior to the formation of the lymphatic system; therefore, there are no intraglandular lymph nodes. The submandibular gland drains to the deep cervical and jugular chain lymph nodes.

Sublingual Gland Anatomy

The sublingual gland is the smallest of the three major salivary glands. The sublingual gland is an almond-shaped gland located anterior to the submandibular gland just below the floor of mouth mucosa in the sublingual space. The sublingual space is a potential space between the mylohyoid muscle and the geniohyoid and genioglossus muscles. It is medial to the mandible. This space also contains the lingual artery and nerve, hypoglossal nerve, glossopharyngeal nerve, and Wharton duct. In contrast to the parotid and submandibular glands, there is no capsule surrounding the gland. Histologically, the sublingual gland is composed of primarily mucous secreting cells.

Unlike the parotid and submandibular gland, the sublingual gland often has no associated major duct but rather drains via 8 to 20 small ducts (ducts of Rivinus) into the oral cavity. These ducts exit the superior aspect of the gland and drain along the sublingual fold. Occasionally, some of the ducts join together to form one major sublingual duct (Bartholin duct), which joins the submandibular duct.

The arterial blood supply to the sublingual gland is via the submental branch of the facial artery and the sublingual

branch of the lingual artery, both branches of the external carotid artery. The venous drainage is via the corresponding veins. The lymphatic drainage of the sublingual gland is to the submandibular lymph nodes.

The sublingual gland's sympathetic innervation is through the superior cervical ganglion with postganglionic fibers traveling along the lingual artery. The parasympathetic innervation is the same as with the submandibular gland, with preganglionic fibers traveling via the chorda tympani to join the lingual nerve and synapse in the submandibular ganglion. The postganglionic fibers then innervate the sublingual gland via branches of the lingual nerve.

Minor Salivary Gland Anatomy

There are approximately 600 to 1,000 minor salivary glands located mainly in the buccal, labial, palatal, and lingual regions. There can also be minor salivary gland tissue on the superior pole of the tonsil (Weber gland), tonsillar pillars, base of tongue (von Ebner gland), paranasal sinuses, larynx, trachea, and bronchi. Histologically, the minor salivary glands are composed of serous, mucous, or mixed cells. In contrast to the parotid and submandibular gland, each salivary unit has its own duct as opposed to a branching network of drainage.

The arterial blood supply, venous drainage, and lymphatic drainage correspond to the region the minor salivary gland is located. The majority of the minor salivary glands receive parasympathetic innervation from postganglionic fibers from the submandibular ganglion. However, the minor salivary glands of the palate receive parasympathetic innervation from the palatine nerves, supplied by the sphenopalatine ganglion.

PHYSIOLOGY OF THE SALIVARY GLAND

Microstructure of Salivary Glands

The basic secretory unit of the salivary gland consists of the acinus, myoepithelial cells, and ductal system. The acinar cells determine the type of secretion produced. The acini are divided into three types: serous cells (spherical and protein secreting), mucous cells (tubular and mucin secreting), or mixed cells (13). The acini are responsible for producing the primary secretion. The primary secretion has an electrolyte composition and osmolality similar to that of plasma. The serous cells produce secretory granules with amylase, whereas mucous cell granules contain mucin (13,14). As previously stated, the parotid gland contains purely serous cells (forming a thin watery saliva); the submandibular gland contains mixed cells but mainly serous cells; the sublingual gland contains mostly mucous cells (forming a thick, viscous mucin-rich saliva); and minor salivary glands have either serous, mucous, or mixed cells. Myoepithelial cells surround the acinar and proximal duct cells. They are contractile cells instrumental in moving secretory products toward the excretory duct (13,14).

As the saliva moves distally, the ductal system alters the composition of the saliva creating the ductal secretion. The first sets of ducts are the intercalated ducts, which lead from the acini and possess a carbonic anhydrase activity. In serous secreting and mixed glands, they secrete bicarbonate and absorb chloride from the acinar product (13). The next ductal cells are the striated duct cells, which are involved in the reabsorption of sodium from the primary secretion and the secretion of potassium and bicarbonate into the secretion. More sodium is resorbed than potassium is secreted causing the secretion to become more hypotonic (13,14). The excretory ducts are the final ducts in the secretory unit and connect to the oral cavity. These cells continue the process of sodium resorption and potassium secretion (14).

Basal cells of the intercalated duct and excretory duct cells are capable of giving rise to fully differentiated ductal epithelial cells. This is a significant feature with respect to the bicellular theory of tumorigenesis, which states that all tumors either arise from intercalated duct stem cells (pleomorphic adenoma, Warthin tumor, oncocytoma, acinic cell carcinoma, and adenoid cystic carcinoma) or excretory duct stem cells (squamous cell carcinoma and mucoepidermoid carcinoma). The bicellular theory has been somewhat abandoned in favor of multicellular theory of tumorigenesis, which states that salivary gland tumors arise from the differentiated cells of the salivary unit (15).

The final result of the secretory unit system is the production of a hypotonic solution, the degree of which is determined by the transport time. The hypotonicity of saliva allows the taste buds to perceive different tastes without being masked by normal plasma sodium levels (14). In general saliva is composed of 99.5% water in addition to proteins, glycoproteins, and electrolytes. The normal pH of saliva is 6 to 7 (14).

Salivary Gland Function

The function of saliva can be organized into five categories: lubrication and protection, buffering action and clearance, maintaining tooth integrity, antibacterial activity, and taste and digestion (14). The saliva produced from the salivary glands creates a seromucous coating. This coating helps to lubricate and protect the oral tissues and act as a barrier to irritants. Irritants include proteolytic and hydrolytic enzymes in plaque, carcinogens from tobacco use and exogenous chemicals, and extreme dryness from mouth breathing (16). The best lubricating component of saliva is the mucin. Its properties include low solubility, high viscosity, high elasticity, and strong adhesiveness, which allow the saliva to act as a good lubricant and biofilm barrier (17).

The second function is that saliva produces a buffering action. This can occur because saliva contains bicarbonate,

phosphate, urea and amphoteric proteins and enzymes. The bicarbonate is the most important component of the buffering system. It diffuses into dental plaque and caries, and neutralizes the acids. All of the substances together act to buffer ingested chemical and maintain an oral pH of 6 to 7 during stimulated high flow rates (14).

The maintenance of tooth integrity is the third function, in that it facilitates the demineralization and remineralization process. The demineralization process occurs when acids diffuse through the plaque to the actual tooth and dissolve the mineral in the tooth. These minerals then diffuse out of the tooth structure and into the saliva. Remineralization is the process of replacing lost minerals by the supersaturation with calcium and phosphate, which are found in saliva. Fluoride helps the remineralization process by forming a fluorapatite-like coating causing the tooth structure to be more resistant to dental caries (14).

Saliva contains immunologic and nonimmunologic agents for the protection of teeth and mucosal surfaces. The immunologic agents are secretory IgA, IgG, and IgM. The nonimmunologic agents include selected proteins, mucin, peptides, and enzymes. Secretory IgA is produced by plasma cells in connective tissues and then travel to the major and minor salivary glands where they are excreted through the duct with saliva. IgA is an antibody against bacterial antigens; it neutralizes viruses and promotes the aggregation of bacteria to prevent the attachment of bacteria to host tissue. The nonimmunologic agents are all products of acinar cells; they help protect the dentition from physical, chemical, and microbial insults. Lactoferrin is a nonimmunologic agent produced by the intercalated cells, which binds ferric iron in the saliva. Ferric iron is a nutritional source for bacteria. The lactoferrin essentially depletes the iron content in the saliva, thus starving the bacteria. Lysozymes are produced in the basal cells of striated ducts in the parotid gland, destroy and inhibit bacterial growth by causing cell lysis. Other proteins such as glycoproteins, statherins, agglutinins, histidine-rich proteins work to cause bacterial aggregation or clumping. The aggregation process prevents the ability of the bacteria, fungus, and viruses from attaching and colonizing the oral cavity tissues (14).

The final function of saliva is to enhance taste and begin digestion. As previously stated, saliva is a hypotonic solution in its final state, which enhances the tasting capacity of salty foods and nutrients. The hypotonic saliva contains proteins and gustin, which bind to zinc and enhance taste. Saliva also plays a role in the beginning stages of digestion as it contains amylase, which is produced in the parotid gland and assists in the breakdown of starch (14).

Secretion of Saliva

The secretion of saliva is controlled by a salivary center in the medulla; however, there are many specific stimuli that trigger the secretion including: physical (the act of chewing), gustatory (sweet is the least stimulating and acid is the most stimulating), and olfactory (poor stimulus). Other factors that can affect the secretion of saliva include medications (sedatives, antipsychotics, antidepressants, and diuretics), systemic conditions (autoimmune diseases, granulomatous diseases, cystic fibrosis, diabetes, eating disorders), or any condition affecting the salivary gland itself (16).

Salivary glands are innervated by both parasympathetic and sympathetic nerve fibers. Both systems use different neurotransmitters to produce the desired effect. The parasympathetic nervous system uses acetylcholine as its neurotransmitter. While acetylcholine can bind to a nicotinic or a muscarinic receptor, it is the muscarinic receptor that is involved in salivary gland stimulation. When the parasympathetic stimulation is predominant, the result is predominantly watery saliva. The sympathetic nervous system uses norepinephrine as its neurotransmitter and with all synapses being adrenergic. When the sympathetic stimulation is predominant, the result is a scant viscous saliva with increased concentrations of protein, organic solutes, and inorganic solutes (14).

A common complication after parotidectomy is gustatory sweating (Frey syndrome). In the normal patient the auriculotemporal branch of the trigeminal nerve carries sympathetic fibers to the sweat glands of the scalp and parasympathetics to the parotid gland. Frey syndrome occurs from aberrant reinnervation of the cholinergic sympathetic sweat glands with postganglionic parasympathetic fibers that have been exposed following parotidectomy. While the phenomenon of Frey syndrome is common (up to 80%) based on potassium iodide testing of postoperative patients, the degree that patients are actually symptomatic is quite variable (18). Clinically significant Frey syndrome is confirmed based on a patient history of problematic sweating while eating. Treatment consists of application of an anticholinergic topical ointment such as scopolamine, injection of botulinum toxin (18), or surgical transection of nerve fibers with or without placement of intervening grafts or adipose tissue.

Salivary Flow Rates

Salivary flow rates vary per individual and may also vary if stimulated or not stimulated by the autonomic nervous system. The normal flow for unstimulated saliva is anything above 0.1 mL/min and the minimum flow for stimulated saliva is 0.2 mL/min (14). The maximum stimulated flow rate is 7 mL/min (17). Stimulated saliva contributes approximately 80% to 90% of the average daily saliva production (17).

The average daily flow of saliva varies between 1.0 and 1.5 L. The different salivary glands each contribute a portion of the unstimulated saliva: 20% from the parotid gland, 65% from the submandibular gland, 8% from

the sublingual gland, and less than 10% from the minor salivary glands. When the glands are stimulated to produce saliva, the parotid gland contributes more than 50% of the total salivary secretions (14).

Hypersalivation, or ptyalism, can be secondary to either overproduction of saliva or oversecretion, which surpasses swallowing. This can be treated with botulinum toxin injections into the salivary glands (18), bilateral parotid duct rerouting with or without bilateral submandibular gland excision, or bilateral tympanic neurectomies. Salivary gland hypofunction is defined as salivary flow less than 0.1 mL/min or a 50% reduction below basal rates (14). This most commonly affects the elderly and is usually secondary to medication use or systemic disease.

IMAGING

Salivary gland imaging has evolved over the past years from plain films and sialograms to now an almost complete shift to computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound. CT scan is the modality of choice for patients with suspected acute or subacute inflammatory disease based on the history and physical, sialoliths, or salivary gland masses (Fig. 47.9). MRI is also a useful imaging tool in the work-up of a salivary gland mass. It is used to determine perineural, meningeal, or skull base invasion. Sialography is still useful and is reserved for the evaluation of chronic sialadenitis unrelated to sialolithiasis (19).

Ultrasound is a highly sensitive means to evaluate the major salivary glands. As a result of the technologic advances in ultrasound and the superficial nature of the salivary glands, the majority of the major salivary glands are accessible by ultrasound. On ultrasound all salivary glands are homogenous echogenic organs (20). While ultrasound is a useful tool in salivary gland evaluation, it is limited in its assessment of the deep lobe of the parotid gland due to shadowing by the mandible and the minor salivary glands due to their location in the floor of the mouth; therefore any abnormalities in these regions should be assessed with CT or MRI (21). Salivary gland imaging is discussed further in Chapter 48.

Figure 47.9 Axial CT scan showing a large sialolith in hilum of the left submandibular gland.

SIALENDOSCOPY

Sialendoscopy is a relatively new procedure that allows for the endoscopic intraluminal visualization of major salivary glands and offers a mechanism to diagnose and treat both inflammatory and obstructive pathology related to the ductal system. The most common indications for sialendoscopy include sialolithiasis (52%) followed by salivary gland swelling (6%). The overall success rate for endoscopic stone removal is 74% (22). The size of the stones removed ranged from 0.2 to 1.2 cm (23). Major complications are rare with sialendoscopy. Injury to the facial nerve has not been reported during sialendoscopy (22). Sialendoscopy is further discussed in Chapter 48.

HIGHLIGHTS

- Main function of the salivary glands is the production of saliva for lubrication and protection, buffering action and clearance of food, maintenance of tooth integrity, antibacterial activity, taste and digestion.
- Embryologically, all derived from outpouchings or oral ectoderm into the surrounding mesenchyme.
- Histologically, the parotid gland contains purely serous secreting acinar cells, the submandibular gland contains both serous and mucous secreting cells with predominately serous cells, and the sublingual gland is composed of primarily mucous secreting cells.
- The parotid duct enters the oral cavity at the level of the second maxillary molar.
- The facial nerve divides the parotid gland into superficial and deep lobes and terminates into five branches.
- The parotid gland receives parasympathetic innervation from the glossopharyngeal nerve via the auriculotemporal nerve and sympathetic innervation from the superior cervical ganglion.
- The submandibular duct enters the oral cavity in the floor of mouth lateral to the lingual frenulum.
- The submandibular gland and sublingual glands receive parasympathetic innervation from the superior salivatory nucleus and facial nerve via the lingual nerve and sympathetic innervation from the superior cervical ganglion.
- The basic secretory unit of the salivary gland consists of the acinus, myoepithelial cells, and ductal system.
- In general, saliva is composed of 99.5% water, in addition to proteins, glycoproteins, and electrolytes. The normal pH of saliva is 6 to 7.
- The average daily flow of saliva varies between 1.0 and 1.5 L.
- Salivary gland imaging has evolved from plain films and sialograms to now an almost complete shift to CT, MRI, and ultrasound.
- Sialendoscopy is a relatively new procedure that allows for the endoscopic intraluminal visualization of major salivary glands and offers a mechanism to diagnose and treat both inflammatory and obstructive pathology related to the ductal system.

48 Nonneoplastic Diseases of the Salivary Glands

Rohan R. Walvekar *Matthew A. Bowen*

Nonneoplastic disorders of the salivary gland encompass a wide range of disease processes that can affect the salivary glandular and the ductal system. These can be acute or chronic in their presentation and can also be broadly classified into inflammatory and noninflammatory disorders. Nonneoplastic disease processes affect both the major and minor salivary glands; however, they occur more commonly in the major salivary glands. Classification of the disease process is of importance. Treatment can be targeted toward a more generalized disease process affecting the entire gland (e.g., antibiotics in acute suppurative sialadenitis) or a locally directed treatment aimed at improving salivary flow and function (e.g., stone removal for an obstructed salivary gland). A history and physical examination allows differentiation of lesions or disease processes into their appropriate classification. Additional laboratory studies, special tests, imaging studies, and rarely a pathologic analysis via a diagnostic biopsy may be required to make a specific diagnosis. Extensive testing is rarely necessary to classify nonneoplastic disorders of the salivary gland. This chapter provides an overview of a variety of common nonneoplastic disease processes and also introduces the emerging field of sialendoscopy and its impact on the management of nonneoplastic salivary gland diseases (SGDs).

ACUTE INFLAMMATORY LESIONS

Acute Suppurative Sialadenitis

Acute sialadenitis is a bacterial infection of the salivary glands. High bacterial loads in the oral cavity provide opportunity for infection of the salivary glands. Normal salivary flow is protective against retrograde colonization and overgrowth of bacteria in the salivary ducts and parenchyma. Saliva has antimicrobial properties due to the presence of lysosomes, IgA antibodies, and sialic acid. These proteins are more concentrated in the submandibular, sublingual, and minor salivary glands as compared to the less viscous saliva in the parotid gland. Acute sialadenitis was first reported in 1828. It gained increased attention when President Garfield died from acute parotitis following abdominal surgery in 1881. The current incidence of acute sialadenitis has been reported at 0.02% of hospital admissions (1), with the parotid gland being most commonly affected. Thirty to forty percent of these episodes can occur in the postoperative patient. The disease occurs with the highest incidence after gastrointestinal procedures between postoperative day 3 and 7.

Salivary stasis, reduced flow, and obstruction can be precipitating events for acute sialadenitis. Dry mouth is seen with increasing age affecting up to 30% of patients over the age of 65 years. This could be attributed to a disease process but can also be subsequent to prescribed medications. Eighty percent of prescribed medications cause some degree of xerostomia and more than 400 medications can cause some degree of salivary gland dysfunction. Consequently, it is not surprising acute sialadenitis most frequently occurs in sixth or seventh decade of life. However, all age groups can be affected. A decrease in saliva production can be caused by multiple medical conditions and drug therapies, increasing the risk for acute suppurative sialadenitis. Examples include diuretic therapy for hypertension, osmotic diuresis from diabetes mellitus, and postsurgical fluid shift, especially after gastrointestinal procedures. Debilitated individuals who rely on caregivers for hydration and oral hygiene are also at risk for acute suppurative sialadenitis (Table 48.1). Antisialogogue medications and physical obstruction of salivary flow due to sialolithiasis or salivary duct stricture result in salivary stasis and can cause acute sialadenitis.

TABLE 48.1 SYSTEMIC AND EXOGENOUS SOURCES OF SALIVARY DYSFUNCTION

Alzheimer Disease	Scleroderma
Cystic fibrosis	SS
Diabetes	Dehydration
HIV/AIDS	Radiation therapy
Systemic lupus erythematosus	Various medications
Parkinson disease	Chemotherapy
Rheumatoid arthritis	
Sarcoidosis	

The classical presentation of acute suppurative sialadenitis is the sudden onset of diffuse enlargement of the involved gland with associated induration and tenderness (Fig. 48.1). A detailed history may reveal underlying risk factors or etiology. The gland should be palpated when possible. Bimanual palpation is more effective for the submandibular gland. Palpation may often reveal obstructing salivary stones. Palpation and massage of the gland may result in the expression of purulent exudate from the papilla of the involved gland. The unaffected glands should be palpated while the papillae are visualized to observe for expression and consistency of normal saliva. The purulent exudate should be cultured for aerobic and anaerobic bacteria, and a specimen for Gram staining.

Historically, *Staphylococcus aureus* has been attributed as the causative microbe in up to 90% of cases of suppurative sialadenitis. Other aerobic organisms implicated include *Streptococcus pneumoniae*, *Escherichia coli*, and *Haemophilus influenzae*. More recent microbiology studies have revealed that while *S. aureus* remains the most common bacteria; anaerobic, gram-negative, and polymicrobial infections are not uncommon (2,3). The most common anaerobic organisms are *Bacteroides melaninogenicus* and *Streptococcus micros*. In one study, anaerobic bacteria were isolated in 64% of cases, and β-lactamase-producing organisms were isolated from 51% of cases (3). Histologic examination shows glandular destruction with abscess formation. Ductal wall erosion is seen with associated penetration of glandular parenchyma.

Figure 48.1 Acute suppurative parotitis affecting the left parotid gland.

Initial treatment consists of antibiotics, warm compresses, gland massage, and sialogogues. Aerobic and anaerobic cultures are obtained to direct antimicrobial therapy. Empiric treatment with penicillinase-resistant antistaphylococcal antibiotic should be initiated while awaiting cultures. Efforts should be made to correct causative risk factors or comorbidities, such as uncontrolled diabetes, which can compromise treatment response. Oral or parenteral hydration should be given as appropriate. Computed tomography (CT) or ultrasound imaging is useful if an abscess or regional spread of infection is suspected. Sialography is contraindicated. Similarly, sialendoscopy, a relatively new diagnostic and therapeutic technique, is also contraindicated in this setting (4). Imaging can detect obstruction due to sialolithiasis or salivary strictures that can be addressed once the active infection has subsided.

In the event of abscess formation, incision and drainage is indicated and can be performed using a modified Blair incision to expose the parotid capsule. A hemostat can then be used to spread in the direction of the facial nerve fibers to enter the abscess cavity. Management of the abscess cavity follows standard recommendations that include packing or placement of a drain based on each individual case scenario. CT-guided or ultrasonography-guided needle aspiration may also be an option that can obviate open surgery. Treatment initiation usually results in rapid improvement within 24 to 48 hours. If the patient does not respond to therapy, antibiotic resistance, immune status, and abscess formation should be considered. Mortality rates up to 20% have been reported in the literature.

Mumps

The most common acute viral infection of the salivary glands is mumps. Prior to the release of the mumps vaccine in 1967, the incidence of mumps in the United States was as high as 300,000 cases per year and the most common cause of parotid swelling. This dramatically decreased to 266 reported cases in 2001 (5). Subsequently, the demographics of mumps shifted from being a disease of childhood to most commonly affecting young adults. Several outbreaks in the United States and other vaccinated countries have been reported in recent years (6–8). Prodromal symptoms include fever, malaise, myalgia, and anorexia.

The onset of parotitis usually occurs within 24 hours but may follow up to a week later. Parotitis is generally bilateral, but may be unilateral. Other salivary glands, such as the submandibular gland and sublingual gland, are less frequently involved and are almost never solely involved. Other manifestations include orchitis, aseptic meningitis, pancreatitis, and myocarditis. Sensorineural hearing loss is a rare complication. Diagnosis is made by confirmation of antibodies to the mumps S and V antigens. Diagnosis can also be made by isolating the virus from the cerebrospinal fluid (CSF) during the first 3 days of clinical symptoms for patients presenting with aseptic meningitis. Virus is also present in the saliva for approximately 1 week starting 2 to 3 days before onset of parotitis. Viral cultures of urine will also be possible for the first 2 weeks of illness (9–11). PCR or viral cultures can also be used to detect the virus. Therapy is symptom based. Chronic obstructive sialadenitis may develop many years after the acute episode of mumps.

Other Viral Diseases

Other viruses have been implicated in acute viral parotitis, including cytomegalovirus, Coxsackie A and B, cytopathic human orphan virus, echoviruses, influenza A, and lymphocytic choriomeningitis virus (12). Treatment of all viral infection is symptomatic. Added antibacterial therapy is indicated in the presence of superimposed infections.

HIV

Several salivary gland manifestations may occur in patients with human immunodeficiency virus (HIV). Diffuse gradual enlargement of the salivary glands may be seen and has been termed HIV-associated SGD (HIV-SGD). HIV-SGD may be encountered at any time in the HIV disease process, and may be the presenting symptom. The parotid gland is most commonly affected. Xerostomia can be present, mimicking Sjögren syndrome (SS). Other salivary gland manifestations of HIV include Kaposi sarcoma and lymphoma. While non–HIV-related lymphoepithelial (LE) cysts also occur, a significantly increased incidence of parotid LE cysts has occurred since the emergence of HIV. LE cysts histopathologically resemble branchial cleft cysts with an epithelial-lined cyst within a lymphoid stroma. Dave et al. (13) propose a classification system for lymphocytic parotid gland enlargement in HIV-positive pediatric patients: (a) parotid gland lymphadenopathy, (b) benign LE lesion, and (c) benign LE cysts. Treatment consists of observation and antiretroviral therapy. Needle aspiration can offer temporary symptomatic relief for large cysts, but recurrence is expected. For severe symptomatic cases, or for cosmetic reasons, sclerotherapy is a reasonable option (13). Sclerotherapy agents used include alcohol (14), doxycycline (15), and sodium morrhuate (16). Surgery or radiation therapy should be reserved for resistant cases (13).

GRANULOMATOUS INFECTIONS OF THE SALIVARY GLANDS

Tuberculosis of the Salivary Glands

Although cervicofacial involvement is the most common extrapulmonary manifestation of *Mycobacterium tuberculosis* infection (17), salivary gland involvement by far is rare. Older children and adults are most commonly affected. Parotid involvement is most common with primary *M. tuberculosis* infection, while in disseminated pulmonary infections, the submandibular gland is more commonly involved. Most cases of primary tuberculosis of the salivary gland are believed to arise from a focus of infection in the tonsil or teeth. The presentation is that of an enlarging firm parotid mass that is identical to a neoplasm on imaging (18). Clinical presentation may mimic acute inflammatory sialadenitis and diagnosis requires positive acid-fast salivary stain and purified protein derivative (PPD) test. However, PPD test is unreliable because of increasing incidence of nontuberculous mycobacterial (NTM) infections that give a negative PPD test. Fine needle aspiration can reveal caseous necrosis in some cases. PCR of fine needle aspirate is highly sensitive (18), but may not be easily obtained. After the diagnosis is made, treatment is the same as for any tuberculosis infection. In resistant cases, excision may be necessary and will be curative.

NTM are more common than *M. tuberculosis* in cervicofacial mycobacterial infections. Salivary gland involvement is still rare relative to involvement of cervical lymph nodes. *Mycobacterium kansasii*, *Mycobacterium scrofulaceum*, and *Mycobacterium avium* are the most commonly encountered NTM. These organisms are common in soil, water, and food, and are carried by domestic and wild animals. NTM infection is most commonly encountered in children younger than 5 years old. The typical presentation is tender induration in the region of the salivary gland that fails antibiotic therapy. The overlying skin develops thinning and adherence to the infected gland, with a characteristic violaceous hue. Abscess formation is common. Fine needle aspiration biopsy carries a risk of fistula formation, but is useful for microscopic evaluation for acid-fast bacilli in the aspirate. Culturing NTM takes weeks and is frequently negative, but useful if positive. Antibiotic treatment with clarithromycin or other antibiotics can be attempted, but often results in several weeks to months of treatment, during which the patient remains symptomatic and fistulization or repeated abscess formation must be managed. Therefore, complete gland excision of the affected gland is advocated as the definitive treatment (i.e., parotidectomy with facial nerve preservation).

Cat-Scratch Disease

Cat-scratch disease is caused by the gram-negative bacillus *Bartonella henselae*. A local infection at the scratch site is followed 1 to 2 weeks later by lymphadenopathy in the

draining lymph nodes. Parotid or submandibular lymph nodes may be involved. Lymph node enlargement progresses over 1 to 2 weeks and can persist for 2 to 3 months. Abscess formation may occur. Observation is usually sufficient with reassurance that the lymphadenopathy will spontaneously resolve. If the patient is highly symptomatic, antibiotics can be prescribed. Rifampin, erythromycin, gentamycin, azithromycin, and ciprofloxacin are all therapeutic options (19). Actinomycosis may also involve the salivary glands. Long-term penicillin therapy is combined with incision and drainage and excision of necrotic tissue for symptom control.

Sarcoidosis

Sarcoidosis is a granulomatous disorder with many systemic manifestations encompassing every organ system. Parotid gland involvement has been reported in 6% to 30% of patients with sarcoidosis (20–22). One notable presentation is that of uveoparotid fever (Heerfordt syndrome), which is characterized by uveitis, parotid enlargement, and facial paralysis, and has been reported to affect 0.3% of patients with sarcoidosis (23). Parotid swelling can last months to years and eventually resolves spontaneously. Submandibular, sublingual as well as minor salivary gland involvement may also occur. Biopsy of the minor salivary glands may establish diagnosis. Corticosteroids are effective, especially in the acute phase and for the management of facial paralysis. Uveitis can lead to glaucoma.

Sjögren's Syndrome

Sjögren's Syndrome (SS) is an autoimmune disorder with symptoms including xerostomia, dry eyes, and salivary gland enlargement (Fig. 48.2). SS is common and underdiagnosed. In the United States, approximately 1 million people have an established diagnosis, with an estimated 2 to 4 million people being affected. The male:female ratio is 9:1. SS affects people of all ages, but is typically diagnosed between the fourth and sixth decades. Primary SS affects the exocrine glands alone. In secondary SS, there is a coincidence of another autoimmune disorder, such as rheumatoid arthritis or systemic lupus erythematosus. The pathophysiology is poorly understood, but leads to B and T cell–mediated damage to exocrine glands. Non–organ-specific autoantibodies are present in approximately 60% of cases (24). These include rheumatoid factor (RF), antinuclear antibodies, and antibodies to the small RNA–protein complexes Ro/SS-A and La/SS-B. The histopathologic hallmark of SS is focal dense lymphocytic infiltration with little or no surrounding edema or fibrosis. CD4+ T cells predominate, with B cells accounting for approximately 20% of cells. Infiltration begins by surrounding glandular ducts and expanding to replace acinar epithelial cells. Acinar loss leads to decreased glandular function (25). A wide range of systemic and other organ-specific manifestations are possible. Fatigue and arthritis are common. Interstitial pneumonitis, rash or dry skin, achlorhydria, hepatosplenomegaly, genital dryness, myositis, and pancreatitis may be encountered. SS patients have been found to have a 44 times higher relative risk of developing lymphoma, which may present early or late in the disease. Predictors of lymphoma development include persistent enlargement of the parotid glands, splenomegaly, lymphadenopathy, palpable purpura, leg ulcers, low C4 level, mixed monoclonal cryoglobulinemia, and cross-reactive idiotypes of monoclonal RFs (26). Although the most prominent ocular symptom of the disease is dry eye, this is not a frequent presenting symptom. On the contrary, dry mouth (xerostomia) is a more common presenting complaint (27). Dry mouth is a debilitating feature of the disease and affects overall quality of life of these patients. Examination often denotes a dry oral mucosa with minimal expression of saliva when the parotid or submandibular glands are massaged. Placement of a tongue blade in the oral cavity causes it to adhere to the buccal mucosa confirming xerostomia.

Figure 48.2 SS in patient with acquired immunodeficiency syndrome-related complex.

Diagnostic criteria have been established (European-American Consensus Group Modification of the European Community Criteria for Sjögren's Syndrome) based on the presence of four of the following six criteria: symptoms of dry eye, signs of dry eye (abnormal results of Schirmer test), symptoms of dry mouth, signs of abnormal salivary glandular function, minor salivary gland biopsy focus score of greater than 1, and presence of SS-A or SS-B antibodies (28). Sensitivity and specificity range from 85.1% to 93.5% and 93.3% to 94.0%, respectively. Imaging such as CT or magnetic resonance (MRI) of the parotid gland can demonstrate speckled calcification that is often encountered in patients with SS having parotid involvement (Fig. 48.3).

Treatment for SS involves symptomatic treatment for xerostomia and prevention of ocular or dental damage. Salivary production can be improved by stimulation of

Figure 48.3 CT of a patient with SS showing stippled calcification.

existing salivary flow. This can be done by use of sugarless or sour candies, fruit slices such as peaches or nectarines. Citrus flavored sugarless tablets ("Salivasure," Scandinavian Health and Beauty Products, Perkasie, PA) are available. Malic acid in the tablets and maltose lozenges also stimulate salivary sections and reduce symptoms of oral dryness (29). Pilocarpine, a muscarinic–cholinergic agonist acting predominantly on M3 receptors, is a systemic sialogogue that may be prescribed and does provide symptom relief. However, side effects including sweating, flushing, and increased urination are common and can be dose-limiting. Cevimeline is a derivative of acetylcholine with a higher affinity for M1 and M3 receptors on the salivary glands (30,31) and has been shown to be of benefit in a double-blinded placebo controlled randomized study that studied the drug randomly in 197 patients with primary and secondary SS (32).

Oral secretions can be replaced by encouraging the patient to take frequent sips of water. Artificial saliva preparations that contain methyl cellulose provide more viscosity and lubrication than water. Fluoride treatments can be used to reduce dental caries. In addition, patients should be counseled to take meticulous care of dentition with frequent (at least once every 6 months) visits to the dentist for cleaning and plaque control (33). Novel therapeutic options such as sialendoscopy with irrigation of the salivary ductal system with or without instillation of steroids has also been shown to demonstrate benefit in terms of improvement of salivary gland discomfort, reduced incidence of salivary gland swelling, and improved salivation (34). The authors' personal experience in this area suggests a potential in the future for a combined therapeutic options that would involve salivary endoscopy with irrigation with or without steroid injections in conjunction with medical therapy to optimize and individualize treatment protocols.

Chronic Sialadenitis

Chronic sialadenitis is characterized by recurrent inflammation and pain in the major salivary glands. Precipitating events include the triad of stasis, obstruction, and reduced salivary flow rate. Sialolithiasis, salivary duct stricture, external duct compression, systemic disease (e.g., SS), or states (e.g., dehydration) may be causative. As seen with acute suppurative sialadenitis, the parotid gland is more commonly involved. Repeated glandular infection results in permanent damage to the salivary gland characterized by sialectasia, ductal ectasia, and progressive acinar destruction combined with a lymphocytic infiltrate. Symptoms are often exacerbated by eating. The structural changes with chronic repeated infections result in reduced function. Xerostomia develops in up to 80% of patients as the salivary glands become progressively damaged. Chronic inflammation damages the gland, with findings of ductal ectasia, acinar destruction, and a lymphocytic infiltrate of the parenchyma.

Patients with chronic sialadenitis present with a history of recurrent painful swelling of the affected salivary gland(s) that is often aggravated by eating. Physical examination confirms asymmetric, firm, and occasionally tender glands. The glands can also be atrophic and hard in consistency that can be either diffuse or discrete. In the latter case, imaging and needle biopsy may be required to rule out a coincidental neoplasm. Examination of the oral cavity must be performed to assess xerostomia, quality and consistency of the saliva, patency of the duct opening at the papilla, and to perform bimanual palpation of the glands. Examination may often reveal a calculus that may be palpable in the floor of the mouth or over the masseter muscle. Ultrasonography is a valuable adjunct to physical examination and can help detect salivary stones that are not palpable clinically, as well as neoplastic process and strictures.

Gland massage during exam typically reveals decreased salivary output. The consistency of saliva may also vary and can be more tenacious as compared to a normal water-like consistency of saliva. Changes in saliva occur as a result of the chronic inflammatory process. During acute episodes, sodium and chloride values approach those in the serum; glucose is elevated while phosphate levels decrease. Levels of plasma derived IgA, IgG, IgM, albumin, and transferrin are increased, as well as myeloperoxidase, lactoferrin, and lysozyme, which are derived from inflammatory infiltrate or the acini. The pattern of immunoglobulins in the saliva shifts from IgA-predominance (normal for saliva) to IgG-predominance. After the acute episodes have resolved, the increased levels of sodium and proteins in the saliva remain in patients with chronic sialadenitis. However, these levels normalize in patients with noninflammatory enlargements.

The diagnostic workup should include imaging with a CT with and without intravenous contrast to evaluate for calculi or neoplasms within the gland. Sialography may be useful to detect ductal abnormalities such as ectasia or strictures. More recently, several authors have described specialized MRI protocols to view the salivary gland ducts, termed MRI sialography, which may prove useful as the technique is developed (35–37). Workup for SS or indolent mycobacterial infections should be considered.

After excluding treatable causes, initial treatment for chronic sialadenitis includes sialogogues, hydration, massage, and antibiotics during acute exacerbations. When conservative management is insufficient, several procedures have potential to decrease symptomatic burden. However, results are inconsistent, which can lead to frustration for the patient and physician. Treatment options include papillary dilation (with or without sialodochoplasty), steroid injection into the duct, dilation of ductal strictures, ductal ligation to promote gland atrophy, gland irradiation, and surgical gland extirpation. Sialendoscopy has been gaining increasing attention as a diagnostic and therapeutic tool, which may spare gland removal (38).

Chronic recurrent parotitis from several causes can eventually lead to the development of benign LE lesion. This lesion belongs in the spectrum of diseases characterized by a lymphoplasmacytic infiltrate combined with acinar atrophy and ductal metaplasia. Lymphoid follicles surround epithelial nest giving rise to the development of the so-called epimyoepithelial island. The LE lesion generally affects one gland, most commonly the parotid gland and there is a female preponderance (60% to 80%) (Fig. 48.4). This first presents as an asymptomatic enlargement unless there is an associated infection. In the absence of symptoms or complications, no treatment is necessary. Intermittent infections should be managed like episodes of acute sialadenitis. Recurrent or chronic infections with drainage and pain as well as cosmetic deformity may necessitate surgical removal.

Figure 48.4 Sialogram of patient with benign LE lesion.

Juvenile Recurrent Parotitis

Sialadenitis can also result in progression to juvenile recurrent parotitis (JRP) or recurrent parotitis of childhood that have similar consequences in terms of salivary gland damage. JRP is a well-recognized salivary gland disorder and is the second most common salivary disease in children. The clinical presentation of JRP involves recurrent, nonobstructive, nonsuppurative swelling of either one or both of the parotid glands (39). The condition usually affects children from infancy to age 12 years. Most children will stop having further episodes after puberty, but in some cases this phenomenon can continue into adulthood. In either case, acute flare ups require intense treatment with antibiotics, analgesic, and hospital admissions. In the authors' personal experience, the unpredictability of the condition and need for repeated treatment and hospital admission creates a huge burden on the family and also impacts quality of life of the patients.

JRP is idiopathic. Many possible theories have been proposed to explain this condition including a congenital malformation of the Stenson duct, genetic aberrations, viral or bacterial infections, allergic, and autoimmune origins (39,40). Diagnosis of JRP is based on the clinical presentation and exclusion of other potential etiologies (Fig. 48.5). The treatment for JRP is similar to acute suppurative sialadenitis (41). Superficial parotidectomy is contraindicated since the disease in most cases is self-remitting. Due to its inflammatory nature, surgery carries a higher risk of facial paralysis. Some minor procedures have been investigated for treatment of JRP such as duct ligation or tympanic neurectomy without promising results (42). In 1986, Galili and Marmary (43) reported improvement of JRP with the use of sialography. These traditional treatment options have found to have limited effectiveness or carry

Figure 48.5 MRI sialography showing multiple dilatations bilateral parotid glandular system in patient with JRP (A, anterior; R, right; L, left; *asterisk* denote parotid glands).

a high morbidity associated with them. Interventional sialendoscopy with duct dilation, irrigation of the glandular system, instillation of steroid and stent placement, if necessary, have been shown to have therapeutic benefit and provides long-term symptom relief (39,44,45).

Sialolithiasis

Salivary stones are composed of various ratios of organic and inorganic substances. The inorganic substances are mainly calcium carbonate and calcium phosphate. The organic components include glycoproteins, mucopolysaccharides, and cellular debris. The formation of the sialolith is thought to occur around an inorganic nidus (38). Salivary calculi most commonly present in the submandibular gland (80%), followed by the parotid gland (20%) and sublingual gland (1%). Minor salivary calculi are uncommon, with a predilection for the upper lip and buccal mucosa (46). In 75% of calculi involving the major glands, only a single calculus is found. Multiple gland involvement occurs in approximately 3%, and there is a slight male preponderance, with most occurring in middle age. Calculi commonly occur in patients with chronic sialadenitis but are otherwise only infrequently associated with other diseases. Gout is the only systemic disease known to cause salivary gland calculi. Despite their similar chemical makeup, 90% of parotid calculi are radiolucent with standard facial x-rays (Fig. 48.6). Sialography is essentially 100% effective in making the diagnosis as essentially all are detectable with CT. Stones less than 2 mm in size may be missed by imaging (Fig. 48.7). Ultrasonography is an excellent tool for imaging of salivary stones (Fig. 48.8). It is useful both for diagnosis and for guidance intraoperatively. Ultrasonography for SGD is not widely used in the United States whereas in Europe, it is widely utilized. It is relatively inexpensive, repeatable, dynamic, versatile as it can be used to guide surgery, and accurate in trained hands; it also provides real-time images. MRI is not an optimal tool to detect calculi. However, MRI sialography is a new modification of MRI that allows delineation of the ductal system and consequently stones with high definition. Virtual MRI endoscopy is another innovation that allows three-dimensional reconstructions to provide a virtual endoscopic image of the salivary ductal system (37).

A theoretical prerequisite for calculus formation is the presence of a nidus of material allowing the precipitation of salts, almost certainly coupled with salivary stasis.

Figure 48.7 CT showing parotid calculus.

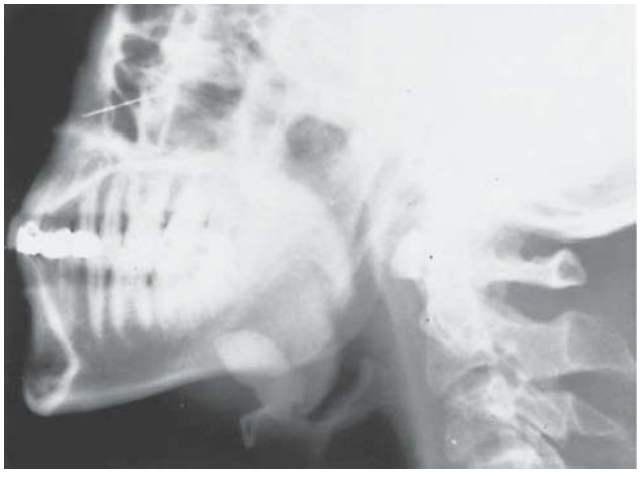

Figure 48.6 Plain radiograph showing large submandibular calculus.

Figure 48.8 Ultrasonography pictures showing a large submandibular salivary stone appearing as a hyperechoic casting a hypoechoic shadow. (*Black arrow* points to salivary stone.)

The submandibular duct is believed to be more susceptible to calculus formation because its saliva is more alkaline and has a higher concentration of calcium and phosphate and higher mucus content. Furthermore, the duct is longer and has an antigravity flow. Submandibular calculi usually arise within the duct, whereas those in the parotid are at the hilum or within the parenchyma.

Most patients present with a history of recurrent swelling and pain in the involved glands, often associated with eating. Calculi can present as acute suppurative sialadenitis. However, there are many patients with stones that do not result in significant infection for many years and are detected incidentally on imaging or physical examination. Consequently, acute suppurative sialadenitis with repeated episodes of obstruction and swelling is not a requirement for diagnosis. The calculus may be palpable in the involved duct, and the gland may be diffusely enlarged and mildly tender. Massage of the gland demonstrates decreased flow of cloudy or mucopurulent saliva. Complications of sialolithiasis include acute suppurative sialadenitis, ductal ectasia, and stricture.

Treatment depends on the location, size, and shape of the calculus. Traditional options include conservative therapy with sialogogues, gland massage, and hydration to facilitate spontaneous passage of the calculus. This is usually successful for extremely small stones, that is, 2 mm or less. Transoral stone removal or salivary gland excision is usually required for patients with recurrent symptoms. Newer treatment options include extracorporeal or intraductal shockwave lithotripsy, interventional sialendoscopy (discussed in the next section), or combined hybrid techniques using endoscopic/transoral or endoscopic/external approaches for removal of submandibular and parotid stones, respectively.

Sialendoscopy

Sialendoscopy involves the passage of miniature endoscopes into the salivary ducts. Saline is irrigated through the tip of the endoscope to distend the ductal walls and promote visualization. Sialendoscopy allows diagnosis of salivary gland pathology and treatment of sialolithiasis, ductal pathology, and inflammatory SGDs. The endoscopic anatomy of the salivary glands was described by Katz in 1990, including the genu of Stenson duct at the masseter (47). Various endoscopes have been used, ranging in size from 0.8 to 1.6 mm (Fig. 48.9) (48). Sialendoscopes typically have at least one port for irrigation, with larger endoscopes incorporating a second channel for instrumentation. Interventional capabilities utilizing sialendoscopes include endoscopic stone removal with forceps and wire baskets, laser fragmentation of stones, balloon dilation for stenosis, and instillation of medication for therapy (4,38,49,50). Current indications for sialendoscopy can be stratified into mechanical and nonmechanical interventions. Mechanical indications include those performed

Figure 48.9 Erlangen 1.6 mm "all-in-one" interventional sialendoscope with a distant camera head and light source attachment. Two ports: water drops on the hub of the scope indicating the irrigation port. The middle port is the 0.8 mm interventional channel.

with the goal of relieving an obstruction to salivary flow such as endoscopic management of salivary stones and strictures (Fig. 48.10). In addition, sialendoscopy can be both diagnostic and therapeutic for inflammatory disorders such as radioiodine-induced sialadenitis, JRP, and autoimmune-related sialadenitis. For these disease processes, irrigation of the duct with or without instillation of medication seems to help improve symptoms in 50% to 100% of cases with single interventions (39,49,51–53). The procedure is minimally invasive, low-risk, repeatable, and can often be performed in the office setting or as an outpatient procedure. Consequently, sialendoscopy provides a minimally invasive option for the management of nonneoplastic

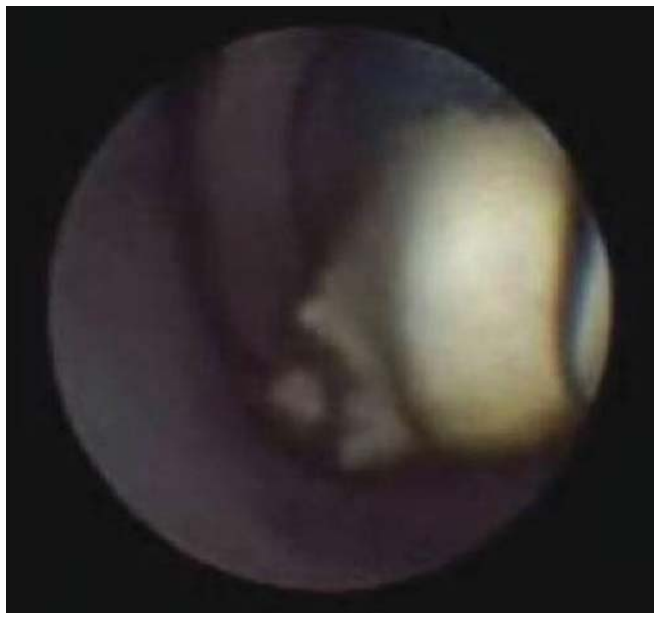

Figure 48.10 Figure illustrating endoscopic stone removal with wire basket.

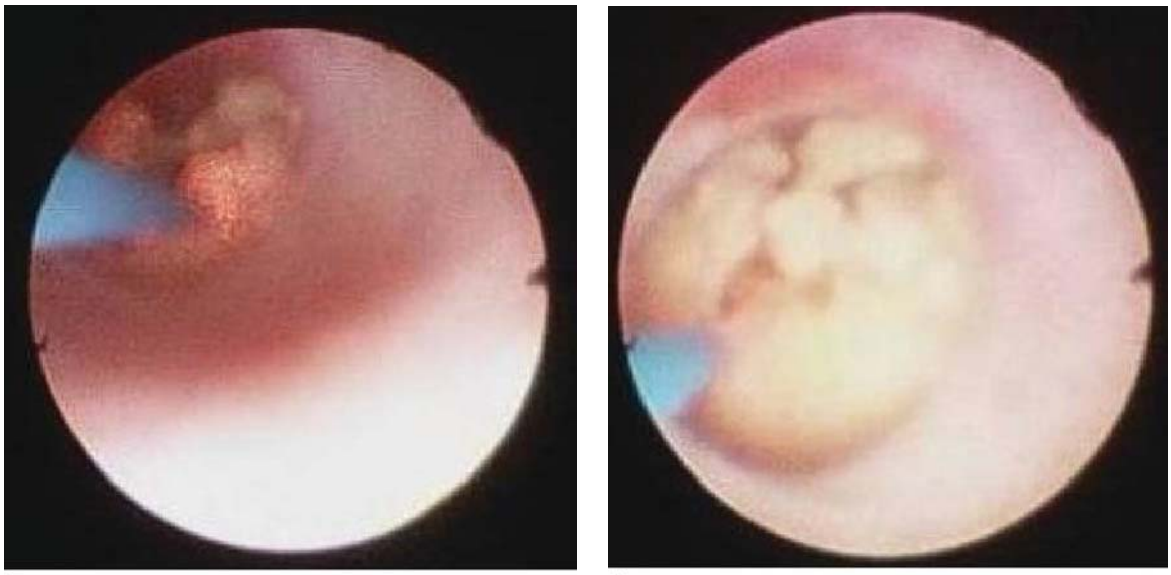

Figure 48.11 Laser fulguration of large hilar submandibular stone with holmium laser **(A)**. Submandibular stone being broken into smaller fragments amenable to removal **(B)**.

diseases of the salivary glands with the possibility of gland preservation.

One of the major impacts sialendoscopy has made on the therapy of SRDS is in the management of salivary stones. Marchal (38) has provided an algorithm for the management of salivary stones. Stones less than 4 mm for the submandibular gland and 3 mm for the parotid gland can often be managed with complete endoscopic removal. For larger stones up to 5 or 6 mm, laser lithotripsy and endoscopic stone removal can be performed (Fig. 48.11). For larger stones, hybrid techniques that involve a transoral incision or an external approach with the use of sialendoscopy to guide dissection site permit stone removal with gland preservation (54,55). Walvekar et al. (56) recently described a novel approach utilizing the da Vinci robotic system for management of large hilar-glandular submandibular stones using a combined approach technique. Ultrasonography can also be a useful adjunct to sialendoscopy to permit preoperative and intraoperative stone identification and removal (57).

Cystic Lesions

Most true cysts of salivary tissue occur in the parotid gland, where they account for 2% to 5% of all parotid lesions. Cysts may be acquired or congenital. A type of congenital cyst is the dermoid cyst, which consists of keratinizing squamous epithelium with associated skin appendages, and is treated by complete removal with preservation of the facial nerve. A congenital ductal cyst, generally manifested in infancy, requires sialography for diagnosis but no therapy unless repeated infections occur (58). First branchial cleft cysts account for less than 1% of all branchial cleft anomalies. They often present within the parotid gland and are classified as type 1 and 2 cysts. Type 1 cysts are duplications of the external auditory canal and are derived from ectoderm. Type 2 is an ectodermal and mesodermal lesion arising from the first and second arches (surrounding the first branchial cleft) (59). Regardless of the type and location of the cyst, the tract of the cyst is intimately associated with the facial nerve. Furthermore, frequent prior infections may obscure the true nature of the lesion, with many patients having repeated incision and drainage before the correct diagnosis is made. Excision during a quiescent period with preservation of the facial nerve is curative. Facial nerve anatomy may be anomalous in these cases; consequently, intraoperative facial nerve monitoring is useful.

Acquired cysts may be associated with neoplasms, benign LE lesions, trauma, parotitis, calculi, duct obstruction, mucus extravasation, and HIV infection (60). The neoplasms most frequently associated with cysts are pleomorphic adenoma, adenoid cystic carcinoma, mucoepidermoid carcinoma, and Warthin tumor. Nonneoplastic cysts that are asymptomatic do not need to be treated, while those that become repeatedly infected should be excised.

Mucoceles (mucous extravasation phenomenon) and mucous retention cysts almost invariably involve the minor salivary glands, most commonly on the lips, buccal mucosa, and ventral portion of the tongue. Mucous cysts are true cysts with epithelia lining and result from duct obstruction. Mucoceles, however, do not possess an epithelial lining and are not true cysts but represent mucus extravasation into the surrounding soft tissues. If required, treatment of both is by marsupialization or excision.

The ranula is an extravasation mucocele that arises from the sublingual gland, either from a ruptured main salivary duct or from ruptured acini following obstruction (61). It presents as a cystic swelling in the floor mouth superficial to the mylohyoid muscle. A more advanced presentation of ranula is the plunging ranula that is an extension of the oral ranula into the neck along the deep lobe of the submandibular gland between the mylohyoid and hyoglossus muscles or through congenital dehiscence in the mylohyoid muscle (62,63). The therapeutic options for oral and plunging ranulas are aimed at either surgical excision of the lesion or attempts at inducing fibrosis and scarring that would eliminate the formation of the ranula (61,62,64). These interventions can range from simple incision, marsupialization with or without packing, excision of the ranula with or without the sublingual gland, laser vaporization, and the use of sclerosing agent OK-432 (61,63). Excision of the ranula with the associated sublingual gland is associated with the best outcomes with lowest recurrence rates (61,62,64,65). Usually, this can be accomplished via a transoral route. Transoral resection can be achieved with routine surgical techniques. A transoral robot-assisted approach has been described for the management of simultaneous bilateral floor of mouth ranula (66).

RADIATION INJURY

It has been estimated that radiation therapy for head and neck cancer causes radiation-induced xerostomia in 30,000 to 50,000 individuals in the United States annually (67). Xerostomia occurs when the salivary glands are exposed to radiation doses above 20 to 30 Gy (68). When radiated, heavy metal ions present in the granules of serous cells catalyze lipid peroxidation in the glandular tissue (69). This results in enzymatic spillage and cell lysis. The parotid glands are more susceptible to injury (70). Sullivan et al. evaluated the histology of radiated human submandibular glands and found that both serous and mucinous acinar cells are equally destroyed by high doses of radiation, whereas previous animal models have suggested that serous acini are more susceptible to radiation injury (69,71,72). Zymogen granules have been implicated as a mechanism for the higher susceptibility of acinar cells to radiation, compared to mucinous acini (71,72). Acute inflammatory reaction causes a purulent exudate within the ducts and the parenchyma. The acute inflammatory reaction subsides without treatment provided that irradiation is stopped. Continued irradiation leads to complete destruction of the serous acini and subsequent atrophy in the gland. Radiation-induced thyroid neoplasms are well documented, and there is similar evidence that salivary and parathyroid tumors are also induced. Both pleomorphic adenomas and malignant neoplasms are increased in incidence (73,74).

Radioactive Iodine-Induced Sialadenitis

Sialadenitis is the most common complication of I-131 treatment for well-differentiated thyroid malignancy, with a reported incidence of 10% to 60% (52,75). The sodium–potassium–chloride transporter in salivary tissue concentrates I-131 to levels that are 30 to 40 times higher than plasma levels, which is sufficient to cause glandular damage (76). In patients with radioactive iodine (RAI)-induced sialadenitis, the parotid glands are affected more frequently than the submandibular glands with an approximate ratio of 9:1 (52,77). Caglar et al. (77) used Tc-99m pertechnetate salivary gland scintigraphy to assess salivary function in patients with RAI-induced sialadenitis and control patients, and found that the development of RAI-induced sialadenitis is dose dependent. Preventative measures have been shown to be effective at reducing the likelihood of developing RAI-induced sialadenitis. For patients with persistent symptoms, sialendoscopy and irrigation (with or without steroid instillation) has found to provide symptom relief in majority of patients. Typical findings at the time of endoscopy include ductal stenosis, presence of cellular debris and mucous plugs as well as the absence of vascular marking on the mucosa of the salivary duct with a generalized blanching suggestive of chronic inflammation (52,53).

Trauma

Penetrating injuries to the parotid glands may involve the duct or facial nerve. Any penetrating injury posterior to the anterior border of the masseter muscle should be suspected of causing a ductal injury. Inspection of the wound directly often allows adequate assessment of the duct. If the duct cannot be identified, a probe may be passed transorally and located in the wound. This should confirm the status of the duct. If the duct has been transected, optimal treatment is end-to-end anastomosis over a polyurethane catheter or salivary duct stent with 6-0 or finer sutures (Fig. 48.12). The catheter is then sutured in place to the buccal mucosa, to be removed in 2 weeks. If the proximal end of the duct cannot be readily identified, compression of the gland often produces enough saliva from the cut end to allow its identification. Alternately, if the primary duct is long enough, it may be sutured directly into the oral cavity through a puncture wound. If this is not possible, the duct may be ligated or a new duct may be created from buccal mucosa. In all these situations, except ligation, repeated dilation with lacrimal probes may be necessary to achieve a satisfactory final result. The Marchal dilator system used for sialendoscopy can be used as well for duct probing. Interventional sialendoscopy to check integrity of ductal repair via endoluminal irrigation of saline can be helpful.

Laceration of the parenchyma can usually be managed conservatively. Closing the parenchyma and the capsule with a few interrupted sutures generally suffices. If a salivary cutaneous fistula develops, healing can generally be ensured by repeated aspiration and a pressure dressing. Resolution may take 1 to 2 weeks to allow for the traumatized ductal system to reopen. Persistence of a fistula strongly suggests duct obstruction rather than parenchymal injury alone (78). In this setting, sialography or MR

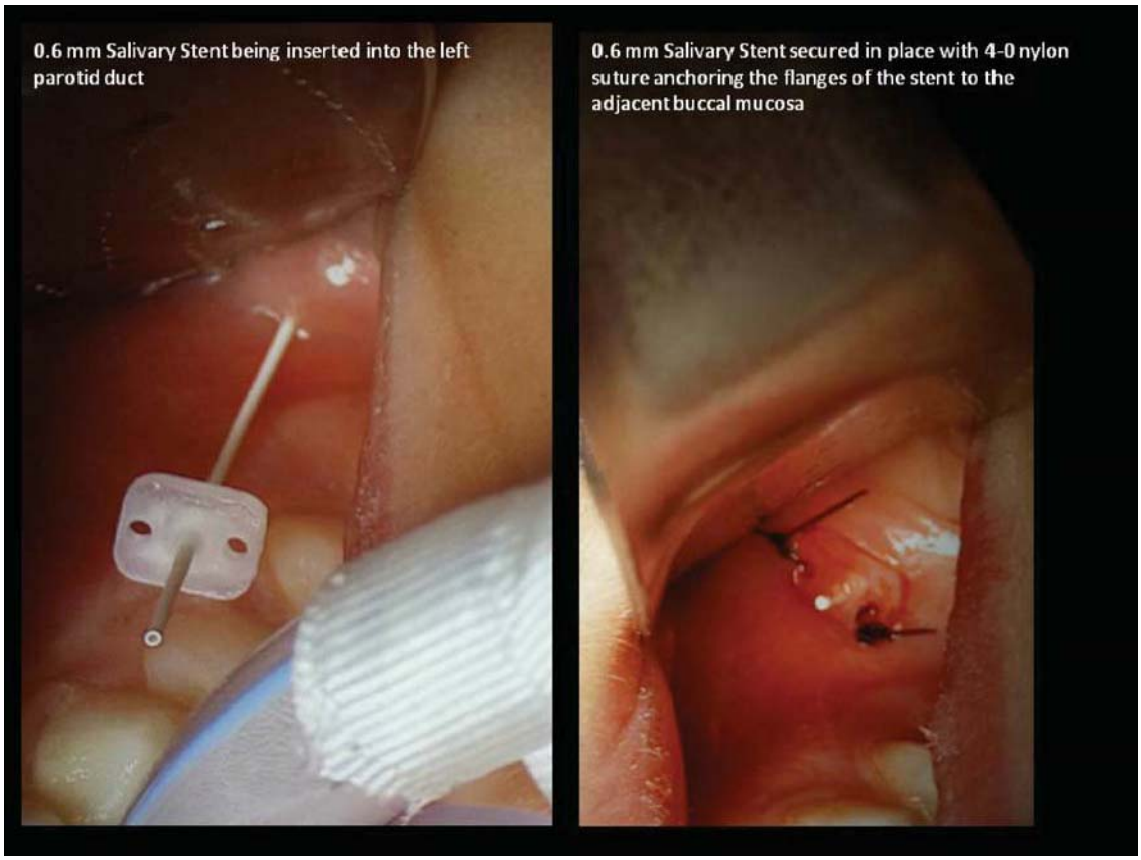

Figure 48.12 Salivary stent 0.6 mm (Hood Laboratories, Pembroke, MA).

sialography should be performed. If duct obstruction is found, repair should be performed, if possible. If conservative treatment fails, excision of the gland is curative as is administration of radiation of sufficient dose to destroy the gland. The latter is probably ill-advised except in extraordinary circumstances. Injection of botulinum toxin has been shown to be effective in case of refractory salivary fistula (79–81).

Injury to the facial nerve may also occur from penetration wound. A thorough evaluation of facial nerve function should be performed on any patient suffering a penetrating injury to the face. If the patient cannot perform volitional testing, a nerve stimulator may be used. If the wound is anterior to a vertical line from the lateral canthus to the mental foramen, repair is probably unnecessary (even with clear dysfunction) because recovery is likely.

Injuries posterior to this line should be repaired immediately. Whereas delayed repair has some possible theoretic advantages, these advantages are overshadowed by the importance of being able to find both ends of the nerve and the ability to do so through the open wound itself. Additionally, some believe that delayed repair does not really have advantages. Repair must be meticulous and with magnification.

Blunt trauma may also injure the gland with resultant concussion, edema, or hemorrhage. These usually resolve without treatment, although temporary duct obstruction may occur. A large hematoma should be drained before it becomes organized because subsequent fibrosis and scarring may lead to duct obstruction and to a cosmetic deformity.

The submandibular and sublingual glands are managed in a similar manner to that of the parotid gland, but ductal injuries here are much less common because of the protection afforded by the mandible.

Sialadenosis

Sialadenosis is a nonspecific term used to describe a noninflammatory nonneoplastic enlargement of a salivary gland, usually the parotid. In most cases, the mechanism is unknown, but there are many associations. The salivary gland enlargement is generally asymptomatic. Bilateral parotid gland swelling is common in obesity secondary to fatty hypertrophy. However, a complete endocrinologic and metabolic workup should be performed before this diagnosis can be made. This is important because obesity is frequently associated with other disorders such as diabetes mellitus, hypertension, hyperlipidemia, and menopause.

Malnutrition is also commonly associated with sialadenosis. This can occur in the form of pellagra, cirrhosis, diabetes mellitus, beriberi, anorexia nervosa, and bulimia. Sialadenosis has been reported in kwashiorkor and

hypovitaminosis A. In these conditions, the enlargement is secondary to hypertrophy.

Parotid swelling is intimately associated with alcoholic cirrhosis. It is so rare in nonalcoholic cirrhosis that it can be used as a differential diagnostic feature, occurring in 30% to 80% of cases of alcoholic cirrhosis. Evidence suggests that this enlargement is based on protein deficiency, and histologic changes are similar to those in general malnutrition.

Any disease that interferes with the absorption of nutrients may also lead to parotid gland hypertrophy. Reported diseases include celiac disease, bacillary dysentery, carcinoma of the esophagus, Chagas disease, and ancylostomiasis. Sialadenosis may also occur in uremia, hypothyroidism, myxedema, testicular or ovarian atrophy, pregnancy, lactation, and chronic relapsing pancreatitis.

The prognosis is generally good if the underlying disease can be corrected. In this setting, the parotid glands generally return to normal.

OTHER DISORDERS

Pneumoparotitis may occur with any episode of increased intrabuccal pressure. It has been reported in glass blowers and after intubation and endoscopy. Cheilitis glandularis is an uncommon disease manifested by enlargement of the labial salivary glands, which then secrete a clear, thick, sticky mucus (82). The glandular hypertrophy may occur to such a degree that eversion of the lower lip occurs, in which case vermilionectomy is usually curative. In Kussmaul disease (sialodochitis fibrinosa), a mucous plug causes obstruction in a collecting duct. This commonly occurs in a dehydrated patient and is manifested by recurrent swelling with associated pain. The appearance of a mucous plug at the duct orifice is diagnostic. Treatment consists of gentle massage and sialogogues to extrude the plug in addition to rehydration when appropriate. A number of drugs may cause salivary gland enlargement as a side effect. These include isoproterenol, ethambutol, phenbutazone, phenothiazine, iodine compounds, and heavy metals.

Necrotizing sialometaplasia is a disease of cryptogenic origin, although some cases appear to occur as a reaction to injury. It is generally manifested as a mucosal ulceration most commonly found in the hard palate, but it may occur in any salivary tissue. There is a male preponderance. Necrotizing sialometaplasia may be mistaken histologically for squamous cell or mucoepidermoid carcinoma, hence the importance of verifying the correct diagnosis. Mucosal ulceration with pseudoepitheliomatous hyperplasia, ischemic lobular necrosis, and dissolution of acinar walls with a release of mucous occur. This causes a subsequent inflammatory granulation tissue response combined with squamous metaplasia of the acini and ducts. The lesion is self-healing and requires no treatment. Clinical correlation with history of duration of illness, risk factors of head and neck cancer and clinical presentation as well as progression are key to identifying these conditions that mimic head and neck cancer but clearly have a more favorable prognosis. If the clinical presentation does not correlate with the history extreme care must be taken to assure the correct diagnosis prior to undertaking a major resection. If the diagnosis is in doubt, a repeat biopsy should be performed (83).

A disease that may be a variant has recently been described. It has been termed "subacute necrotizing sialadenitis." The lesion presents as a painful, nonulcerated, erythematous swelling of the posterior hard palate. Histologically, most of the acinar cells are lost, and there is atrophy or necrosis of the ductal cells. The lesion is self-healing in 2 to 4 weeks.

Aberrant salivary gland tissue may occur in a variety of locations. It is particularly common within lymph nodes in the parotid area. It has also been reported to occur in the mandible, lower neck, hypopharynx, middle ear, sternoclavicular joint, thyroglossal duct, and pituitary gland. In the mandible, the tissue may be on the surface or in a central location. If on the surface, the lesion appears to be merely ectopic submandibular tissue and is always benign. Central lesions are uncommon and even less common in the maxilla. When these tissues become neoplastic, the type of tumor may be a mucoepidermoid carcinoma, adenoid cystic carcinoma, or adenocarcinoma, in that order (84).

Finally, parotid gland enlargement may occur in patients with HIV infection. It usually occurs as a symmetric diffuse enlargement of both parotid glands. This clinical presentation in a young person should raise suspicion of HIV infection. Table 48.2 summarizes diagnosis and management of SGDs.

COMPLICATIONS

Complications of nonneoplastic SGD usually stem from the underlying condition or etiology that causes salivary gland involvement. For example, viral diseases affecting the salivary glands rarely lead to a complication related to the salivary glands, but may cause serious injury, either temporary or permanent, to other organ systems. Certain conditions, however, have the capability of causing direct consequences. For example, patients with acute sialadenitis may progress to abscess formation that in some cases may lead to life-threatening upper airway edema due to spread of infection into deep neck spaces.

The long-term consequences of chronic SGDs include xerostomia and the development of benign LE lesions. Xerostomia can lead to severe dental caries, dysphagia, odynophagia, hoarseness, and reduced quality of life. Benign LE lesions are associated with the development of lymphoma, pseudolymphoma, and anaplastic carcinoma. Sarcoidosis may be associated with facial paralysis and with severe systemic illness (Heerfordt syndrome). Sialolithiasis can be asymptomatic but can cause recurrent salivary gland swelling and obstruction of salivary flow leading to acute

TABLE 48.2 DIAGNOSIS AND MANAGEMENT—DISEASES OF THE SALIVARY GLANDS

Disease	Features	Management
Viral	Acute onset; associated symptoms	Symptomatic
Acute suppurative sialadenitis	Acute onset; postoperative or debilitated patient; purulent saliva from duct; diffusely swollen and painful gland	Hydration: massage: antistaphylococcal antibiotic
Chronic sialadenitis	Painful recurrent swelling; decreased saliva production	Sialogogues; massage; antibiotics for acute exacerbations
Tuberculosis	Painless swelling, often with drainage	Long-term antibiotics
Sarcoidosis	Usually asymptomatic swelling	Symptomatic
SS	Painless swelling of multiple salivary glands; may be associated with another autoimmune disease	Symptomatic
Sialolithiasis	Painful swelling, usually associated with eating	Removal of calculus
First branchial cleft cyst	Repeated acute suppurative swelling	Excision, usually with parotidectomy
Penetrating injury	Obvious defect with appropriate history	Careful evaluation; repair
Sialadenosis	Asymptomatic swelling	Workup to find underlying cause

suppurative sialadenitis. As described above, this in turn may lead to the development of more severe neck infection and to septicemia. The same may occur with first branchial cleft cysts. Penetrating injuries may lead to the development of salivary cutaneous fistula or to partial or total facial paralysis.

Finally, since many patients with nonneoplastic salivary gland disorders are now being managed in a minimally invasive fashion with sialendoscopy and hybrid approaches, it is important to be aware of some of the complications associated with these procedures. Extravasation of fluid into the floor of mouth and cheek can lead to swelling and edema. In some cases, this can cause airway compromise. Salivary duct tears are also reported. In case of minor tears, conservative management with antibiotics and anti-inflammatory medication is satisfactory. In the event of a major duct avulsion, salvage gland resection is often required. Residual stones, scarred papilla of the gland, ductal stenosis, and ranula formation are procedure-related complications that can also present as acute suppurative sialadenitis and must be borne in mind. Major bleeding, infection, and facial nerve damage are uncommon (34,54).

HIGHLIGHTS

- The majority of nonneoplastic disorders of the salivary gland can be categorized based on clinical history and physical examination.
- Classification of the SGD process helps direct treatment and prognostication.
- Diagnosis of autoimmune and granulomatous conditions often requires special laboratory tests and salivary gland biopsy to detect underlying disease process.
- Ultrasonography is an excellent imaging tool that is under utilized and can provide cost-effective dynamic feedback to the surgeon.
- The possibility of underlying neoplastic disorders must be considered while treating nonneoplastic disease processes.
- Patients with salivary gland cysts should undergo a complete work up to determine the cause and direct therapy.
- Salivary gland surgery, especially parotidectomy, must be recommended with caution in patients with inflammatory diseases given the high probability of postoperative facial nerve paresis.
- The diagnosis of sialadenosis requires further investigation to identify an underlying cause.
- Necrotizing sialometaplasia mimics carcinoma; clinical presentation must be correlated with history. Biopsy must be obtained prior to planning major surgical resection.
- Newer minimally invasive surgical, medical, and diagnostic options such as botulinum toxin injection, ultrasonography, and sialendoscopy should be considered to complement traditional treatment algorithms.

49 Outcomes, Effectiveness, and Quality of Life: Measuring Clinical Effectiveness

Maureen Hannley

HEALTH STATUS ASSESSMENT

Within the last 25 years, the measurement of health-related quality of life (HRQOL), medical- and patient outcomes, and clinical effectiveness has moved beyond its origins in health care research to find wider application across specialties and practice settings. Our society has grown and changed, and with it the need to allocate health service resources rationally across diverse health programs has steadily grown as well, prompting the evolution of new health policy decisions in both the public and private sectors. To assist in formulating those new decisions, caregivers, health care institutions, and even drug and device manufacturers have been called upon to develop and apply measures of the broad effects of illness states on patients' lives, the effectiveness of intervention options, and their outcomes. Granted, some general instruments have been in use in the United States for 30 years or more, and millions of such questionnaires have been distributed. However, changes in delivery systems, advances in technology, new issues in health care payment systems, and a shift in patient management to include more chronic care and care of the aged have increased the importance of patient participation in assessment of their health care using contemporary health status assessment instruments.

In the past, simple biomedical indicators of change in health status, such as morbidity and avoidable mortality, survival rates, adverse reactions, complications, symptom relief, pain, and physical and biochemical markers of recovery, were the standard metrics of treatment outcome. Although it took an act of Congress and subsequent changes in research funding by the National Institutes of Health (NIH) (Patient Outcomes Research Act of 1989, S. 702), changes in health policy and allocation of health care resources have gradually moved to define health outcomes of intervention in the broadest sense, specifically those focused on the impact of the condition and its treatment on the patient's emotional and physical functioning and lifestyle. At the center of this trend is the theme that a definition of health can no longer be limited to the absence of disease as measured by the traditional quantifiable criteria, but must also define the impact of disease and disease intervention on overall quality of life (QOL) and satisfaction with care (1,2).

THE "QUALITY OF LIFE"

"Quality of life is a vague and ethereal entity, something that many people talk about, but which nobody knows very clearly what to do about" (3).

A paradox of measuring "quality of life"—a widely-recognized concept in the social and health sciences—is that it has no standard, uniformly accepted definition. While there is general agreement among experts that QOL is subjective and highly individual, its criteria and indicators reflect a similarly wide range of perspectives. These range from the lyrical—"the perceived discrepancy between what is and what might have been"—to the pragmatic—"evaluation of (personal) well-being with physical symptoms, sexual function, work performance, emotional status, etc." (4). A multitude of operational definitions exist that reflect philosophical, psychological, sociologic, economic, or biologic perspectives, but the inescapable conclusion is that the perception and achievement of QOL is personal, unique, and dependent on one's own preferences, circumstances, values, and priorities in life. This has important implications that are explored in a later section.

HRQOL research was first conducted in cancer treatment settings where the balance between quality and duration of life was a pivotal issue in decisions to use new drugs or combinations of drugs of either partial or unknown efficacy but with very serious side effects (5). Since then, QOL has become an important goal of treatment and marker of success in health interventions of all kinds. By definition, HRQOL is more focused than general QOL and thus

lends itself more readily to criteria for measurement, at least from a functional perspective, related to the ability to perform activities of daily living (ADL) and fulfill role functions adequately. Moreover, sophisticated health technology and treatments have expanded the life span, meaning that more people live—and live longer—with chronic health conditions. Thus, HRQOL includes perceptions of physical, emotional, and social well-being, before, during, and after treatment and the impact of those factors on the ability to lead a satisfying life.

However, it is a double-sided concept, incorporating positive as well as negative aspects of well-being and life, and is multidimensional, encompassing social, psychological, and physical health (1). Although not routinely explored, a thorough profile of HRQOL would also include some assessment of the patient's satisfaction with treatment (especially as it relates to the symptoms of greatest personal concern), and prospects for future well-being. In today's environment of crushing health care costs, issues related to concerns about economic stability might well be included. To be useful, HRQOL must be a personal construct and it must be dynamic for, as health changes for the better or the worse, perspectives on life, roles, relationships, and experiences change. But poor health or the presence of disease is not invariably associated with poor HRQOL; rather, it can be shaped by factors such as coping, expectancy, and adaptation (6) and studies have shown repeatedly that doctors' and patients' assessment of outcome do not always coincide. It is important to understand as well that although health is usually an important component of overall QOL, health status is neither a predictor nor a determinant of QOL: each can vary independently, even paradoxically.

In the most idealistic sense, the goal of medical or surgical treatment is to extend life and to optimize the patient's health-related quality of that life, however he or she might define it. This is not a new concept. What *is* relatively new is the interest in formalizing its definition and measurement, and in using it as the unifying theme for assessing the burden of disease, the efficacy or effectiveness of treatment for that disease, and the individual outcome of treatment on the patient.

If HRQOL includes perception of physical, emotional, and social well-being and the impact of those factors on the ability to lead a satisfying life, many of the diseases and disorders treated in otolaryngology—head and neck surgery have an undeniable impact. Who would debate the pleasure of being able to smell a beautiful flower or the bouquet of a fine wine? Allergic or nonallergic rhinosinusitis can deprive patients of this sensation and impose other uncomfortable symptoms such as nasal congestion, fatigue, and pain. Evidence of hearing loss appears on an audiogram but does not reveal how it affects the ability to enjoy music, participate in a conversation in a crowded restaurant, or listen to a child's whispered secrets. Loss of these elements of QOL can result in depression, anxiety, and withdrawal. The list continues: voice and the ability to speak, to sing, to tell the world who we are; sleep-disordered breathing; the gastroesophageal reflux disorders; the loss of facial symmetry and expression; and the cruel spectrum of head and neck cancers, some of the most visually obvious and functionally disabling cancers of all. The biomedical intervention outcomes for these conditions and others have been documented and reported; a few clinical trials have been completed, enough so that meta-analyses are becoming possible. But if ever there were multitudes of reasons to make measurement of HRQOL and patient-related outcomes a part of the clinical picture, otolaryngology—head and neck surgery has them!

WHY MEASURE HEALTH-RELATED QUALITY OF LIFE AND FUNCTIONAL STATUS?

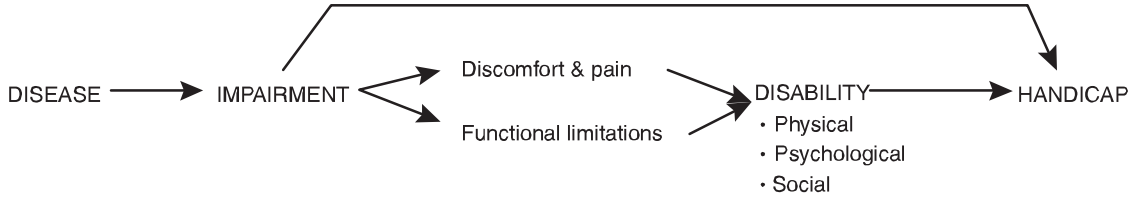
Given that compassionate patient care of the highest quality is the goal of every health care provider, there is a need to understand the process from the perspective of the patient. While clinical outcomes are certainly important—indeed, would be considered the primary outcome in medical and surgical interventions—they are not always related to how the patient feels about the disease, its impact, the intervention, and *its* impact. Those are issues that may influence not only patient satisfaction, but the recovery process itself (7). The recent social imperative for individuals to take more responsibility for their personal health through prevention, healthy living, and self-education has made awareness of HRQOL a fact of life: most people are not familiar with the traditional biomedical markers of health and disease, but they do consider health an essential part of QOL. And quite simply, patients like to talk about themselves—they *like* to be asked that most basic of questions: "How do you feel?" Thus, including both clinical and patient-based outcome allows health care quality to be measured in a meaningful way for both clinicians and patients.

Apart from the humanistic issues related to increasing awareness of the patient's experience of health, disease, and treatment, there is a growing number of circumstances in which such measurements will play a key role: First, decisions about allocation of resources from third-party payers, managed care, and government agencies are increasingly requiring evidence of the effectiveness of health care interventions in the broadest sense—euphemistically termed "outcomes-adjusted reimbursement." That is, data will be expected on whether the treatment leads to a life worth living, by providing a more patient-oriented baseline against which the medical effects of the intervention can be evaluated (1,8). For example, two or more drugs may have comparable medical effectiveness against the same condition but produce very different HRQOL results; this could prove to be a significant factor for both the patient and the provider in the decision-making process.

Second, the US Food and Drug Administration (FDA) now encourages drug and pharmaceutical manufacturers to develop and use patient-reported outcome measures (PROMs) to support labeling claims, especially those

that are "best known or best evaluated from a patient perspective" as a part of the approval process for new drugs and devices (9). While evidence of this nature could be an asset to prescribing physicians when counseling patients in the United States, in Europe it is used to determine availability and pricing of medications. It is not unreasonable to anticipate that such a practice will become more widespread here as patient-reported HRQOL data become more influential in health policy and reimbursement decisions.

Another way in which HRQOL data can be used, and which has been somewhat sensationalized, is to assist in determining quality-adjusted life years (QALYs), an approach which has become one of the key considerations in allocation and reimbursement decision processes. A QALY is the arithmetic product of life expectancy and quality of the remaining years. A QALY places a weight on time in different health states: a year of perfect health is worth 1 and a year of less than perfect health is worth less than 1. Death is considered to be equivalent to 0. QALYs can be used to compare the extent of benefits gained in a broader sense from a variety of interventions when compared to their costs, side effects, and survival time (10). Only a small number of HRQOL measures are used for this application and it remains a subject of considerable controversy when used in the context of governmental control of health care benefit allocation.



Fourth, health technology assessments (HTAs) are used in many European countries to determine the benefits or added value of new technologies for the purpose of reimbursement and pricing decisions and/or the establishment of clinical guidelines. In the United States, HTA is carried out through the Agency for Healthcare Research and Quality. The recent interest in comparative effectiveness research has prompted US expert advisors to call for the HTA process to include not only clinical and biomedical outcomes, but also "… important measures of effectiveness such as patient-reported outcomes, including health related quality of life, patient satisfaction, activities of daily living, and work productivity as relevant to the various USA stakeholders" (11). A large NIH project, the Patient Reported Outcomes Measurement Information Service (PROMIS) offers tools that can be used as primary or secondary endpoints for clinical studies of treatment effectiveness in a wide variety of chronic diseases and in the general population.

Finally, contract research organizations use patient-reported HRQOL instruments routinely as a part of their protocols when conducting large-scale clinical trials and field studies for drug and device manufacturers, in preparation for submitting new drug applications to the FDA.

FUNCTIONAL STATUS

The conceptual framework for measuring multidimensional functional health status is related to the World Health Organization (WHO) classification of impairment, disability, and handicap, and seeks to address the functional and psychosocial outcomes of diseases, disorders, and conditions (2). Although "impairment," "disability," and "handicap" are interrelated concepts, they are not interchangeable. Their relationship is shown in Figure 49.1. An *impairment* is a problem in body structure or function, which can manifest itself as a functional limitation, for example, difficulty in hearing and/or discomfort and pain. Impairment describes the biologic status: loss of a body part, dysfunction secondary to trauma, disease, malformation, etc. If severe enough, the impairment can also—but does not invariably—result in a *handicap*, which prevents the individual from carrying out life roles. Functional limitations or discomfort and pain produced by an impairment can lead to a *disability*—restriction in performing all or some of the ADL due to physical, psychological, and/or social issues, including such problems as fear, embarrassment, feelings of isolation, or loss of independence. This can be seen with disorders such as Ménière disease and head and neck cancer. While restriction in performing ADL can be measured objectively, the patient's QOL experience is subjective, affected by how he or she feels about those restrictions. Awareness of how the patient feels about his or her impairment can give useful insights into its life impact, leading to some therapeutic enablement strategies (12). Disabilities can also lead to handicap (although use of the word "handicap" has fallen into disfavor, imparting some negative psychosocial connotations) (10).

These broad definitions of biologic states and their associated physical, mental, and social consequences set the stage for the structure common to the tools we use to measure health status, including physical health, mental health, social health, role function, and overall well-being. Most can be characterized in terms of the range and focus of the information they collect. Although there are several

Allen PF. Assessment of oral health related quality of life. 2003. Health & QOL Outcomes 1:40

Figure 49.1 Relationship of impairment, disability, and handicap. (From Allen PF. Assessment of oral health related quality of life. *Health Qual Life Outcomes* 2003;1:40, with permission.)

ways in which to group the hundreds of available PROMs and HRQOL measures, for this discussion, we consider the instruments in the broadest sense: *generic*, *symptom-specific*, and *disease-specific*. While these three categories of health status and QOL instruments each have their own properties, advantages, and disadvantages (see Table 49.2), they have an additional important property in common. Because the goal is to learn the impact of disease and interventions on the patient's HRQOL and functional status, they are designated patient-reported outcome measures (PROMs). As officially defined by the US FDA, a PROM is "… an instrument of any aspect of a patient's health status that comes directly from the patient (i.e., without interpretation by a physician or anyone else)" (13). A PRO can describe health status, disability, handicap, a functional outcome, or a factor contributing to QOL in a standardized measure; these data provide a useful supplement to the medical assessment. In a very real sense then, the patient becomes the clinician's partner in achieving balanced insights into clinical effectiveness.

TYPES OF HEALTH-RELATED QUALITY OF LIFE MEASURES

Generic HRQOL instruments are designed to be applicable across a broad range of diseases, disorders, and conditions. Similarly, they can be used with different groups of patients and to assess the impact of a range of different interventions, making them valuable for comparative effectiveness studies. Both general QOL and HRQOL can be addressed with generic instruments. Some of the most widely used generic scales are the Medical Outcomes Survey SF-36 (MOS SF-36); the Glasgow Benefit Inventory (GBI); and the World Health Organization Quality of Life Assessment Inventory (WHOQOL-BREF). Just as a number of factors contribute to overall QOL, HRQOL instruments are designed to measure those perceptions by separate questions organized into *domains*, with the goal of parsing out individual influences on the overall quality score. Over the years, consensus has been established that HRQOL is a multidimensional concept, divided for measurement into three core domains: physical, social, and psychological. It is important, however, to distinguish between *functional* scales and HRQOL scales. In the physical domain, perception of normal or disrupted function such as mobility, pain, and sensory function are evaluated. In the social domain, questions are centered on items such as ADL, interactions with family and friends, and responsibilities in and out of the home. The psychological domain would involve emotional and mental functioning, including mood, distress, memory, self-image, special concerns, etc. While these three domains are fundamental, some instruments contain other domains, such as vitality, spirituality, sexuality/intimacy, financial concerns, and role function. Each domain is comprised of a series of questions that are scored separately and/or contribute to an aggregate score. An overall global HRQOL will yield an estimate of the patient's subjective evaluation of his or her own health; this may be different than simply the sum of the domain scores (14). A brief list of some of the more commonly used generic HRQOL instruments is presented in Table 49.1.

Although generic instruments have been in widespread use longer than any other type and thus have very stable psychometric properties and reliability, they often lack the sensitivity to evaluate subtle changes or mild disease, lack relevant subdomains, or fail to demonstrate health impact of certain conditions such as rhinosinusitis or mild to moderate hearing impairment. Disease-specific or possibly symptom-specific instruments might be a better choice to overcome these shortcomings.

Disease-specific scales are designed to assess specific diagnostic or patient populations; they are not generalizable to other patient populations in the same way that generic instruments are. Disease-specific scales have the goal of detecting the impairments associated with specific diseases or conditions, and/or to be responsive to clinically significant changes related to interventions or the natural history of the disease. They will frequently include scales both for evaluating functional impairment and for evaluating HRQOL. In contrast to the generic instruments, they have the advantage of containing statements and domains that are relevant only to the clinical condition in question. Because they are designed to assess HRQOL in investigative groups or patient populations, they are likely to be more reactive to treatment-related changes than are the generic instruments. Disease-specific instruments should always have a means of establishing the severity of the condition to allow accurate interpretation of the results, assessment of change, and case-mix adjustment when evaluating group data. Disease-specific scales may be structured with subdomains or they may have a single focus; selection of one instrument over another will be guided by the user's clinical or research goals.

As the term denotes, *symptom-specific instruments* are designed to focus exclusively on symptoms produced by a particular disease or condition (there is some debate as to whether these are actually HRQOL scales) and thus are extremely well suited to measure intervention-related changes. They have the additional advantage of being brief, reducing the patient burden considerably, and minimizing interference with clinical routine. The five-question Nasal Obstruction Symptom Evaluation (NOSE) Scale is a case in point (15).

If generic instruments lack the sensitivity of disease- and symptom-specific instruments to subtle life impact and treatment-related changes, the more specific instruments have the disadvantage of being so focused that they fail to evaluate problems in other life domains that may interact with the condition of interest, yielding a score that does not take into account the impact of the disease on the individual's global QOL—or whether other life factors exacerbate the impact of the disease. It is important to be sensitive to how seriously the condition under study affects specific functions or aspects of a patient's life. This is especially true of the emotional and social domains. For example, deafness or hearing loss may be associated with feelings of depression or isolation; vertigo with loss of control; voice disorders with embarrassment, reduced self-image, and diminished participation in group interactions. However, disease- and symptom-specific scales have a substantial advantage: with further questioning by the clinician they allow the patient to identify those items that are of greatest significance to him or her, or with the relative importance of relief that treatment could bring, perhaps improving satisfaction with care (16). Several validated scales have been developed to measure individual problems, severity, and expectations of relief, but inter-test consistency has been found suboptimal even in the same patients (17). The way in which questions are structured in each domain could influence the patient's decision of how to rank the items. A summary of the three types of HRQOL instruments' advantages and disadvantages appears in Table 49.2.

TABLE 49.2 COMPARISON OF GENERIC, SYMPTOM-SPECIFIC, AND DISEASE-SPECIFIC HEALTH MEASURES

	Example	Advantages	Disadvantages
Generic	SIP	Comparisons can be made between populations with different problems Psychometric properties are known Can capture a wide range of dysfunction in different areas not specific to disease Better for resource allocation, as it addresses "whole person"	Not sensitive to subtle changes in specific conditions Discriminant validity and responsiveness may be poor May be too long to be practical for patient and for scoring/analysis
Symptom-specific	NOSE	Focus on specific symptom(s) in order to measure change	Misses impact on whole organism that may have prognostic value for intervention
Disease-specific	Head and Neck Quality of Life (HNQOL) Scale	More likely to detect subtle changes Greater responsiveness to disease-specific interventions Contain domains and statements related uniquely to condition of interest	Cannot compare with general population May have lesser sensitivity to impact of comorbidity May not capture items or issues of greatest concern to patient

CHOOSING HEALTH STATUS ASSESSMENT INSTRUMENTS IN PRACTICE

Literally thousands of HRQOL instruments of every description have been published in all categories and are available to users. The Patient Reported Outcomes and Quality of Life database (PROQOLID: http://www.proqolid.org) includes 654 instruments, 500 of which are condition-specific. The database can be searched alphabetically, by condition, or by specialty (the otolaryngology listings are rather sparse). The Online Guide to Quality-of-Life Assessments (OLGA: http://olga-qol.com) is said to include thousands of PRO instruments in its database.

Most experts agree that choosing one generic and one disease- or symptom-specific questionnaire is the best strategy for achieving a well-rounded and precise picture of a patient's HRQOL and functional status. The most important factor to keep in mind is the goal of using a health status assessment instrument. Different instruments will be used for different goals, even if they are used with the same condition. For example, if the purpose of administering the HRQOL instrument is to compare the impact of a selected intervention in two or more patient populations that fall within the same general category (e.g., auditory disorders, voice disorders), a broader scale (e.g., Hearing Handicap Index, Voice Handicap Index) would be appropriate. If the aim is to determine whether a specific treatment improves symptoms, a short, symptom-specific index would be sufficient. For more serious, perhaps life-threatening illnesses, use of a measure of depression (e.g., the Beck Depression Inventory [BDI]) and/or anxiety (e.g., State/Trait Anxiety Index) may be appropriate.

Some general properties should be considered in the selection process. These would fall into three main categories: (a) Is (the instrument) relevant? (b) Is it practical? (c) Is it methodologically sound?

Relevance is the extent to which the content of the instrument is applicable to the condition or the patient under study. If it was validated on individuals under the age of 50 years, it may have limited value for a geriatric patient; an allergic rhinitis questionnaire may not be the best choice for evaluation of a patient with chronic rhinosinusitis (CRS). Obviously, if the problem is a relatively straightforward disease or symptom, an instrument with a broad array of life domains related to mobility, ADL, role fulfillment, etc., would be irrelevant to the clinical goal. Patient-reported instruments that have the greatest relevance to the patient/group being studied will yield the highest quality data. Examine the instrument carefully before administration to assure that it is the most relevant choice, with content and format appropriate for the goals of the clinical or research application. Care must be taken also when administering the instruments to populations with unique cultural values, such as immigrants from other parts of the world who have not yet become completely acculturated, and those whose lifestyle is shaped by ethnic, religious, or sexual orientation (18). Most of the major HRQOL instruments now have been translated into other languages and validated; Spanish versions of the instruments are useful additions to practices where significant numbers of the patient population are Hispanic.

Earlier in this chapter, reference was made to the fact that there is no generally accepted definition or criteria for "quality of life," a quite idiosyncratic construct—yet, hundreds of instruments have been developed to measure it. Many of these existing measures of QOL fail to take into account the individuality of one's own unique criteria by imposing standardized models of QOL and domains selected by the instrument developers. The question arises then: Do they simply describe QOL as health professionals and society believe it to be for people who are ill, something that may have little relevance to the patients who respond to the questions? (19). Undoubtedly, there are a number of universal factors that contribute to QOL, but they would probably be accorded different weights in different societies and cultures; and, QOL being the dynamic construct that it is, would change with time and social and health status. The most important and relevant contributors to an individual's QOL at a given moment in time, however, may not be captured by a standardized QOL questionnaire. Moreover, if the factors being measured with a standard questionnaire do not coincide with those that are important to the patient, it is unlikely that intervention will produce evidence of change since the instrument is not measuring what is important to the patient (19). Irrelevant questionnaire content can also succeed in alienating the patient, making him feel his issues are of no consequence and perhaps weakening adherence to treatment. There are several individualized QOL scales available, but they are far from ideal: they are not validated, cannot be used across patients to compare results, may be complex to interpret and analyze, and patients may not be completely forthcoming about their more personal feelings and priorities.

PROMs and HRQOL measures will not be added to a busy clinical practice if they are not practical. Of foremost consideration is the length of the instrument: it must be straightforward and not so long that it delays the patient's appointment, or creates an undue burden on the patient, especially the very ill patient, requiring no more than about 10 minutes to complete, if possible (14). In addition, unreasonably lengthy questionnaires may be only partially completed and their usefulness thus undermined. They should be easy to understand, and be self-administered, requiring few instructions or clarification from support staff. The instrument should be easy to score and to interpret with norms provided, ideally so that it can be completed by a nurse or other personnel with minimal training. All of these factors should minimize the cost of adding this procedure to the practice: the form can be mailed to the patient in advance of the appointment (risky, since many

will forget to bring it to their appointment), completed in the waiting room, or in the examining room.

A PRO instrument is of value only if it is well-designed and methodologically sound. A well-designed PROM is capable of assessing patients across a broad spectrum of disease severity; conversely, a poorly designed instrument may misrepresent the impact of the disease and treatment or fail to identify significant intervention outcomes, especially those associated with very mild or very severe disease. Whatever the instrument or battery of instruments selected, PROM of HRQOL and health status should have four essential properties: reliability, validity, sensitivity, and responsiveness. Of these, validity and reliability are the fundamental properties and the most crucial.

Reliability is an important attribute for a test measure. It is a measure of the reproducibility of the results—or that it will give the same results in different situations (e.g., different situations, different days). Reproducibility, of course, is the cornerstone of the scientific method. Reliability provides significant information for either research or clinical purposes in that it indicates how much of the variability in the measures that might be caused by different situations is caused by variability among patients (20). So the reliability is the efficiency with which a test can differentiate among patients on some given features. Some other valuable aspects of reliability are its *test–retest reliability*: the correlation between performance on two separate occasions; and *interobserver reliability*: the degree of agreement in test results when administered by two different observers (20). The latter attribute would, of course, not be of concern for PROMs.

Validity is the extent to which an instrument measures what it claims to measure. This is also known as *face validity*. Related to face validity is the *content validity*: does the scale tap all contents, behaviors, and elements of the feature to be measured? Another aspect of validity is *criterion validity*, or the extent to which the measure correlates with a "gold standard." This is somewhat problematic because there is no gold standard for HRQOL as such; but if the measure is compared to another generally accepted measure of the same construct, a correlation coefficient between the two scores will enable assessment of the criterion validity. A frequently used, but rarely defined measure is the *construct validity* of the attribute under study, used when there is no other measure of the same attribute for comparison. It refers to the extent to which the instrument succeeds in operationalizing the theoretical relationship between the attribute of interest and other related attributes (20).

The *responsiveness* of an instrument is an important attribute for it is this property that indicates the extent to which changes in values correlate with true changes in status. This is highly significant when obtaining intervention-related change scores. The responsiveness of a HRQOL scale is largely dependent on patients' initial health status. For example, a patient's health may be so poor that further deterioration will go undetected since he or she already reported the lowest score ("floor effect"). The importance of magnitude of change depends on baseline status and must be compared to an independent criterion for interpretation (21). Closely related to responsiveness is *sensitivity*, the amount of change an instrument is able to detect.

APPLICATIONS IN OTOLARYNGOLOGY—HEAD AND NECK SURGERY

Given the number of subspecialty practice areas within otolaryngology—head and neck surgery, it should not be surprising that there is a similarly broad range of disease-specific QOL and functional outcome measures related to these areas. A list of a variety of useful instruments (which is by no means comprehensive) is presented in Table 49.3. Many have been developed and validated by otolaryngologists; others by audiologists, speech—language pathologists, physical therapists, nurses, sociologists, health science researchers, and other physicians such as plastic surgeons, allergists, pulmonologists, pediatricians, neurologists, gastroenterologists, and oncologists. These tools represent the full range of health status measurement formats: while most are PROs, they may measure functional status, HRQOL, self-perceived well-being, symptom status, overall QOL, satisfaction with care, or a combination of two or more of these. They may be multidimensional, with questions in several domains or a very brief disease-specific functional index. Several indices of general comorbidity have been included in the list, reflecting the role of comorbidity in head and neck cancer, rhinosinusitis, gastroesophageal reflux disease (GERD), and sleep-disordered breathing. A significant number have been translated into other languages, and validation processes have been repeated to assure the instruments' cross-cultural and cross-linguistic validity. The international availability of HRQOL and functional outcome measures should have the benefit of encouraging international collaborative clinical research efforts, constructing databases, and facilitating meta-analyses.

The use of health status and HRQOL instruments has supported the clinical value of a variety of procedures and addressed controversies with data. Clearly, the index disease for which both functional status and HRQOL measures are appropriate is head and neck cancer, with its impact on speech, swallowing, breathing, taste, and often appearance. Not surprisingly, reports on HRQOL describe high rates of depression and anxiety in these patients, varying somewhat with the cancer site and stage, treatment modality, and patient variables such as age, gender, support system, and comorbidity. These associations are uniform across domestic and international papers and instruments used—the most common being the EORTC—HN35, the University of Washington quality of life instrument (UW-QOL-R), and the Functional Assessment of Cancer Therapy (FACT-HN). Testing specifically for depression can guide the clinician to consideration of a referral for psychosocial counseling or, as one paper suggests, distinguish medical and treatment

TABLE 49.3 DISEASE-SPECIFIC HRQOL AND FUNCTIONAL OUTCOMES INSTRUMENTS

ALLERGY

Allergic Rhinitis
Allergy outcome survey (AOS)
Caregiver treatment satisfaction questionnaire for allergic rhinitis (CGTSQ-AR)
Nocturnal rhinoconjunctivitis quality of life questionnaire (NRQLQ)
Patient benefit index for allergic rhinitis (PBI-AR)
Pediatric allergic disease quality of life questionnaire (PADQLQ)
Pediatric rhinoconjunctivitis quality-of-Life questionnaire (PRQLQ)
Rhinitis symptom utility index (RSUI)
Rhinoconjunctivitis quality of life questionnaire (RQLQ)

RHINOLOGY

Nasal Obstruction
Nasal health survey (NHS)
NOSE scale
Nasolacrimal duct obstruction symptom score (NLDO-SS)

Rhinosinusitis
Chronic sinusitis survey (CSS)
Rhinitis symptom utility index (RSI)
Rhinosinusitis disability index (RDI)
Rhinosinusitis QOL survey (Rhino-QOL)
Sinonasal assessment questionnaire (SNAQ-II)
Sinonasal outcomes test (SNOT-16; SNOT-20, SNOT-22)

Olfaction
U. Penn. smell identification test (UPSIT)

OTOLOGY/NEUROTOLOGY

Otitis Media
Chronic ear survey (CES)
Chronic otitis media (COM-5)
Otitis media clinical severity index (OM-CSI)
Otitis media diary (OMD)
Otitis media functional status questionnaire (OM-FSQ)
Otitis media outcomes (OMO-22)
Otitis media survey (OM7-27)
Otitis media-6 (OM-6)
Parents' questionnaire on consequences of OM on family life (PARENT-QOL)

Ménière Disease
Ménière disease outcomes questionnaire (MDOQ)
Ménière disease patient-oriented symptom-severity scale (MD-POSI)

Hearing Impairment
Effectiveness of auditory rehabilitation (EAR)
Hearing disability handicap scale (HDHS)
Hearing evaluation and auditory evaluation (HEAR-14)
Hearing handicap inventory for adults (HHI-A)
Hearing handicap inventory for the elderly (HHI-E)
Hearing satisfaction scale (HSS)
Single sided deafness questionnaire
Youth quality of life instrument-Deaf and hard of hearing module (YQOL-DHH)

Tinnitus
Tinnitus annoyance index (TAI)
Tinnitus handicap inventory (THI)
Tinnitus questionnaire
Tinnitus reaction questionnaire
Tinnitus severity questionnaire (TSQ)

Vertigo/Dizziness
Activity balance confidence questionnaire (ABCQ)
Dizziness handicap inventory (DHI)
Dizziness patient-oriented severity index (D-POSI)
European evaluation of vertigo questionnaire
UCLA dizziness questionnaire (UCLA-DQ)
Vertigo handicap questionnaire (VHI)
Vertigo symptom scale (VSS)
Vertigo, dizziness, imbalance questionnaire (VDI)
Vestibular activities of daily living (VADL)

Vestibular Schwannoma
Penn acoustic neuroma quality of life scale (PANQOL)

Facial Paralysis
Facial clinimetric evaluation scale (FaCE)
Facial disability index (FDI)

Cochlear Implants
Nijmegan cochlear implant questionnaire
Speech intelligibility ratings
Speech perception categories

Hearing Aids
Abbreviated profile of hearing aid benefit
Glasgow hearing aid benefit profile (GHABP)

LARYNGOLOGY

Voice Disorders
Consensus auditory-perceptual evaluation of voice (CAPE-V)
Pediatric voice handicap index (pVHI)
Pediatric voice-related quality of life (PVRQOL)
Singing voice handicap index (SVHI)
Voice function outcome measure (VFOM)
Voice handicap index 10 (VHI-10)
Voice outcome survey (VOS)
Voice-related quality of life (VRQOL)
Voice symptom scale (VSS)

HEAD AND NECK

GERD/EERD
Gastroesophageal reflux disease health-related quality of life (GERD HR-QL) scale
Gastroesophageal reflux disease quality of life (GERD-QOL) scale
Gastrointestinal symptom rating scale
GERD symptom frequency questionnaire (GSFQ)
Pediatric gastroesophageal reflux disease symptom and quality of life questionnaire (PGSQ)
Pharyngeal reflux symptom questionnaire
Quality of life in reflux and dyspepsia (QOL-RAD)
Quality of life questionnaire in gastroesophageal reflux (Reflux-qual)
Reflux disease questionnaire (RDQ)
Reflux questionnaire (ReQuest)
Reflux symptom index (RSI)
Supraesophageal reflux questionnaire

Adenotonsillitis
Pediatric throat disorders outcome test (PTDOT)
Tonsil and adenoid health status instrument (TAHSI)

Sleep-disordered Breathing
Empirical sleepiness scale
Epworth sleepiness scale (ESS)
Functional outcomes of sleep questionnaire (FOSQ)
Obstructive sleep apnea-18 (OSA-18)
Obstructive sleep apnea patient-oriented symptom severity scale (OSA-POSI)
Obstructive sleep disorders-6 (OSD-6)
Pittsburgh sleep quality index (PSQI)
Sleep apnea quality of life index (SAQLI)
Sleep disorders questionnaire (SDQ)
Snore outcomes survey
Symptoms of nocturnal obstruction and related events (SNORE)

Head and Neck Cancer
Distress inventory for cancer (DIC)
Dysphagia handicap index
EORTC QOL (HN-35)
Functional assessment of cancer therapy (FACT-HN)
Halitosis associated quality of life (HAQOL)
Head and neck oncology outcome assessment
Head and neck quality of life (HNQOL) scale

TABLE 49.3 DISEASE-SPECIFIC HRQOL AND FUNCTIONAL OUTCOMES INSTRUMENTS *(Continued)*

Mayo Clinic postlaryngectomy questionnaire (MCPQ)
MD Anderson dysphagia inventory (MDADI)
Neck dissection impairment index (NDII)
Parotidectomy outcome inventory (POI-8)
Quality of life radiation therapy instrument (QOL-RTI)
Speech handicap index (SHI)
University of Washington quality of life instrument (rev) (UW-QOL-R)
Washington University head and neck comorbidity index (WUHNCI)
Xerostomia specific questionnaire

Anterior Skull Base Surgery
Anterior skull base surgery QOL

FACIAL PLASTIC SURGERY
Blepharoplasty outcomes evaluation
Cleft evaluation profile
Derriford appearance scale
Facelift outcomes evaluation
Facial appearance sorting test (FAST)
Facial injectables, longevity, late and early reactions and satisfaction questionnaire (FILLERS Q)
Facial lines outcomes questionnaire
Facial lines treatment satisfaction questionnaire
Midface dysfunction scale
Observer-rated facial disfigurement 9 point Likert scale
Lip reanimation outcomes questionnaire
Observer scar assessment scale
Obturator functioning scale
Patient-rated facial disfigurement analogue scale
Rhinoplasty outcomes evaluation
Skin rejuvenation outcomes evaluation

COMORBIDITIES
Adult comorbidity evaluation 27 (ACE 27)
Charlson comorbidity index (CI)
Cumulative illness rating scale (CIRS)
Index of coexistent disease (ICED)
Klabunde index
Modified Kaplan-Feinstein index
World Health Organization international classification of functioning, disability, and health (ICF)

side effects from true depression (22). The impact of comorbidity on functional outcomes, QOL, and prognosis for disease-specific survival is widely acknowledged as well. Recognition of this strong association has led to recommendations for integration of tumor-specific staging systems with comorbidity in order to develop better instruments for prognostication (23). As previously discussed, it is important to solicit patients' input to assessment of their status. If asked to prioritize the importance of their functional impairments, for example, patients with oral or oropharyngeal cancer in one study identified speech, chewing, and swallowing function as being more important than all other domain scores (24). Traditional functional assessments continue to be a part of the management process: speech, swallowing, hearing, balance, quality of sleep, and facial movement. More validated functional scales have been developed, with the capacity to quantify the level of function, that are responsive to change, and can be analyzed in the context of both clinical status and impact on HRQOL. Used with generic QOL scales, these measures can form a battery that paints a broader picture of the disease and intervention impact on the patient as a person.

Functional assessments and HRQOL studies have been used to great advantage in other areas of otolaryngology—head and neck surgery. A series of systematic reviews has demonstrated rather conclusively that endoscopic sinus surgery is effective in relieving the symptoms of CRS, notably nasal obstruction, postnasal discharge, facial pain, bodily pain, and fatigue, while improving the HRQOL in several domains (25–27). Headache and hyposmia are less affected. While these findings may not be news for many clinicians, they take the results out of the realm of personal experience and into the desired area of evidence-based management when accompanied by consensus-based management guidelines (28) and provide a solid foundation for patient counseling.

The American Academy of Otolaryngology—Head and Neck Surgery Foundation (AAO—HNSF) has sponsored a series of practice-based patient outcomes and HRQOL studies on a range of topics: nasal obstruction (Nasal Obstruction and Septoplasty Effectiveness study [NOSE]), obstructive sleep apnea (Studying Life Effects and Effectiveness of Palatopharyngoplasty study [SLEEP]), tonsillectomy in children and adults (TO TREAT), rhinosinusitis, and tympanostomy tubes. All showed improvement in symptoms and QOL, adding to the evidence base for effectiveness of common otolaryngology procedures. PROMs and HRQOL measures have yielded equally valuable information about otitis media, Ménière disease, vestibular schwannoma, and spasmodic dysphonia, which contribute to greater understanding of disease impact and clinical decisions to some extent.

However, a theme of health status, effectiveness, and HRQOL studies in rhinosinusitis, as well as a number of other otolaryngic diseases and disorders, is that symptom outcome is studied inconsistently in many studies, even if there is a consensus-based standard to guide such studies (28,29). Thus, the credibility of some of the clinical research literature is weakened by being under-powered, lacking consistent inter-study operational definitions, failing to consider all variables or symptoms related to a disease entity, including inappropriately heterogeneous groups, and marred by a lack of replicability. The Cochrane Database of Systematic Reviews (http://www2.cochrane.org/reviews) provides an exceptionally high-quality series of regularly updated systematic reviews of the effects of health care. Frequently, the conclusion of the review is that

there is insufficient evidence of adequate quality to support claims of effectiveness of an intervention, contrary to what may be the "conventional wisdom." The data are often subjected to meta-analysis to increase the power of the findings of numerous studies that would be too small to produce reliable results individually. Finally, benefits and potential harms of interventions are identified, as well as conditions in which they should be used. One valuable feature of the reviews is that they identify the type of studies needed to demonstrate effectiveness; recommendations may include study design, types of patients to be included, variables, etc. The Cochrane Database could be considered the definitive source for evidence-based information about health care effectiveness, and for planning studies in this area.

FEEDBACK, EFFECTIVENESS, AND QUALITY OF PRACTICE

The ultimate test of whether incorporating HRQOL measures into clinical practice is productive, valuable, or even necessary lies in two questions: (a) did use of the measures increase patient satisfaction? and (b) did they improve health outcomes? (30). As previous discussion has illustrated, there is a growing body of literature documenting symptom and QOL improvement following treatment. While the health status or HRQOL scale used in the study is routinely identified, and domain scores may be summarized, mention is rarely made of whether the questionnaire results were discussed with the patient, whether they improve doctor–patient communication, or whether they influence the clinical decision process.

The application and analysis of *functional outcome measures* are well established, both for clinical research and for clinical use. They are reported regularly in the literature as structured studies and as observational series, as provider-reported outcome and as PROs. Objective medical criteria for successful outcomes are satisfied: audiometric thresholds improve, apnea/hypopnea indices decrease, and number of episodes of rhinosinusitis is reduced. Patient-reported functional outcomes are improved: they can hear better in more conditions, they can sleep through the night and no longer have daytime sleepiness, and they can breathe better and are not bothered by post-nasal drip. Those functional outcomes could be anticipated on the basis of the medical outcomes, obtained informally from the patient, or quantified by means of a validated questionnaire; the latter will allow comparisons across patients with attention to patient- and medical variables and measurement of intervention-related change. Patient satisfaction is good—not as a result of the health measure, but as a result of the successful intervention. Health care outcomes could be improved by the use of formal functional outcomes instruments to improve patient selection criteria for a given intervention approach with analysis of group data. If the study is concerned with a novel intervention, however, the provider- and patient-reported functional outcome measures become more significant and have the potential to improve health care in the sense of providing more options for management of specific diseases or conditions.

One issue should be considered more closely, however: what to do *with*, and *about*, available HRQOL information as an entity. There is little uncertainty about following up on functional impairment of swallowing, breathing, or speaking; inclusion of referral for psychiatric or psychosocial support is a less consistent feature of action plans. With short-term management, for example, septoplasty, tympanostomy tubes, tonsillectomy, the utility of HRQOL information is as a useful supplement to medical- and patient-reported functional outcome data. For long-term or chronic disease management, the potential contribution of HRQOL information is greater.

In the hierarchy of cancer treatment objectives, disease control is the primary issue, and preserving or restoring function would be a key consideration as well, with patient-reported HRQOL occupying an unspecified position in many health care environments. Although patients report that they are in favor of completing QOL questionnaires in clinic and that it assists in describing their health problems to their doctors, its importance is not rated as highly by clinicians (31). Murphy et al. (32) notes appropriately that in order for QOL measurements to have meaning to clinicians, they should be linked with clinical benchmarks and that both generic and head and neck cancer-specific measures should be included in the assessment battery to provide a comprehensive assessment of global health and tumor-specific issues. These authors concluded by expressing some reservations about whether the routine use of QOL measures in the clinical setting is beneficial to patients, suggesting that methodologic issues need further study and refinement.

The use of HRQOL information in the clinical setting is far from limited. Used appropriately, it can serve as a screening tool, a monitoring tool, as a method of promoting patient-centered care, in assisting the decision-making process, as a method of facilitating communication among multidisciplinary teams, and as a means of monitoring the quality of patient care (33). HRQOL measures also have short-term clinical application to supplement medical- and patient-reported functional outcomes for documentation of intervention effectiveness. Evidence from randomized clinical trials has demonstrated that the use of patient-reported HRQOL information is valuable in improving discussion and detection of HRQOL problems but has less impact on how clinicians manage patient problems or on subsequent patient outcomes. This may be related to the introduction of a new component into the clinical machine that has no established place in how patients and clinicians communicate with each other or how clinical decisions are made.

In addition to the lack of a traditional place in the clinical routine, other barriers to adoption of HRQOL information in clinical care may exist. First, the time constraints of

busy clinicians, particularly surgeons, do not give them the opportunity for extended consultations with their patients. Second, while clinicians are comfortable discussing physical functioning and symptoms with their patients, they may be less comfortable discussing emotional functioning and daily living activities, even if both topics derive from the same QOL questionnaire. Third, clinicians may not view the information from the patient as being sufficiently important to warrant a change to the treatment plan, although at least one European study reported that QOL was considered as essential as survival for head and neck cancer patients by many of the 500 otolaryngologists surveyed (30,34). Head and neck cancer patients are a highly symptomatic and complex group with multiple QOL issues that merit consideration. There is evidence that nurse specialists can provide more holistic care for such patients and make an important contribution through discussion and follow-up of their HRQOL issues (35). This may be considered an attractive feature of a management plan for caregivers and patients alike.

SUMMARY AND CONCLUSIONS

During the 20th century, average life expectancy in the United States increased more than 30 years, much of it due to advances in health care (36). Expectations for a healthier life at older ages have increased and with them the perspective of health as a positive contributor to the QOL, not simply an absence of disease. Patient-reported QOL and functional outcome assessments as supplements to the more traditional clinical indicators are becoming more common and represent a paradigm shift in measuring the health outcome of clinical interventions. This approach defines a more patient-led baseline against which intervention effectiveness can be assessed, imposing fundamental and positive changes on health care delivery, policy, research, and economics.

HIGHLIGHTS

- The concept of general QOL is highly individual, with no set definition or criteria. It is subject to change with age and circumstances. HRQOL includes perceptions of physical, emotional, and social well-being, before, during, and after treatment and the impact of those factors on the ability to lead a satisfying life. To be useful, HRQOL must be a personal construct and it must be dynamic for, as health changes for the better or the worse, perspectives on life, roles, relationships, and experiences change. Although health is usually an important component of overall QOL, health status is neither a predictor nor a determinant of QOL.
- The conceptual framework for measuring multidimensional functional health status is related to the WHO classification of impairment, disability, and handicap, and seeks to address the functional and psychosocial outcomes of diseases, disorders, and conditions. Functional outcomes and HRQOL can be assessed using PROMs.
- PROMs fall into three categories: generic, disease-specific, and symptom-specific. *Generic HRQOL instruments* are designed to be applicable across a broad range of diseases, disorders, and conditions. They can be used with different groups of patients and to assess the impact of a range of different interventions, making them valuable for comparative effectiveness studies. *Disease-specific scales* are designed to assess specific diagnostic or patient populations; they have the goal of detecting the impairments associated with specific diseases or conditions, and/or to be responsive to clinically significant changes related to interventions or the natural history of the disease. *Symptom-specific instruments* are designed to focus exclusively on symptoms produced by a particular disease or condition and thus are extremely well suited to measure intervention-related changes.
- Functional outcome and HRQOL instruments must be methodologically sound for confident clinical and research use. They must be validated and shown to have adequate reliability, validity, responsiveness, and sensitivity. *Reliability* is a measure of the reproducibility of the results; *validity* is the extent to which an instrument measures what it claims to measure; *responsiveness* indicates the extent to which changes in values correlate with true changes in status; *sensitivity* is the amount of change in status that the instrument is able to detect.
- The potential of HRQOL and functional outcome measures to increase satisfaction with care and improve health outcomes must be demonstrated before they will be accepted as routine components of the health care delivery system. Although functional outcomes measurements will be easier to implement, HRQOL measures are valuable tools, especially in the care of patients with chronic diseases or those requiring long-term care. HRQOL measures can serve as a screening tool, a monitoring tool, as a method of promoting patient-centered care, in assisting the decision-making process, as a method of facilitating communication among multidisciplinary teams, and as a means of monitoring the quality of patient care; nurse-specialists can be invaluable partners in identifying and discussing HRQOL problems with patients.

50 Taste

Natasha Mirza

The goal of the chemosensory system is the detection and discrimination of foods and the initiation and sustenance of ingestion. This system is present in both vertebrates and invertebrates and well developed even in a newborn infant. It is estimated that more than 2 million Americans have some kind of chemosensory disorder (1). What is proven so far has been that a loss or alteration of taste affects nutritional intake and leads to multiple nutrition-related medical problems (2). For this reason, it is important to understand the mechanism of taste and to identify some of the effects of taste dysfunction and the means of reducing them. This chapter briefly reviews the anatomy and physiology of taste including taste transduction; clinical evaluation of the taste system; the impact of aging, medications, and other disease states; and discusses some of the methods to help decrease some of the harmful effects of taste loss on both nutrition and quality of life.

DEVELOPMENT OF THE TASTE SYSTEM

Morphologic evidence shows that there is a functional taste system present *in utero*. Even premature infants respond pleasurably to sucrose and glucose. The hedonic system of pleasantness is also well developed in infants (3). The acceptance of sweet and rejection of bitter seem to be hardwired while the effect associated with odors depends much more on experience.

ANATOMY OF THE TASTE SYSTEM

In mammals, taste buds are located throughout the oral cavity, in the pharynx, the laryngeal epiglottis, and at the entrance of the esophagus. Taste buds on the dorsal lingual epithelium are the most numerous (total number of taste buds, all classes, approximately 4,600 per tongue). Here, taste buds are contained within three major classes of papillae, the fungiform, foliate, and circumvallate, while the filiform papillae are nongustatory. Fungiform papillae are most densely distributed on the tip and sides of the tongue. These papillae generally contain one to several taste buds per papilla (4). They are innervated by the chorda tympani branch of the facial (VII cranial) nerve and appear as red spots on the tongue because they are richly supplied with blood vessels. The total number of fungiform papillae per human tongue is around 200. The foliate papillae are situated on the edge of the tongue slightly anterior of the circumvallate line. They are predominantly sensitive to sour tastes and are innervated by the glossopharyngeal (IX cranial) nerve and average five foliate papillae per side of the tongue with approximately 120 taste buds per foliate papillae. Circumvallate papillae are sunken papillae, with a trough separating them from the surrounding wall. The taste buds are in tiers within the trough of the papillae. They are situated on the surface of the circumvallate line and form an inverted V on the posterior of the tongue. They confer a sour/bitter sensitivity to the posterior one-third of the tongue. They are innervated by the glossopharyngeal (IX cranial) nerve. There are 3 to 13 circumvallate papillae per tongue with about 250 taste buds per papillae. The filiform papillae are mechanical and nongustatory. In addition, there are 2,500 taste buds on the epiglottis, soft palate, and laryngeal and oral pharynx.

In mammals, taste buds are aggregations of 30 to 100 individual elongated "neuroepithelial" cells (50 μm in height, 30 to 70 μm in width) (5). At the apex of the taste bud, microvillar processes protrude through a small opening, the taste pore (4 to 10 μm in diameter) into the oral milieu. Just below the taste bud apex, taste cells are joined by tight junctional complexes. Taste cells are bipolar cells, which connect to the epithelial surface of the oral cavity via dendritic processes and to a nerve axon at the base which invades the bud and ramifies extensively, with each fiber

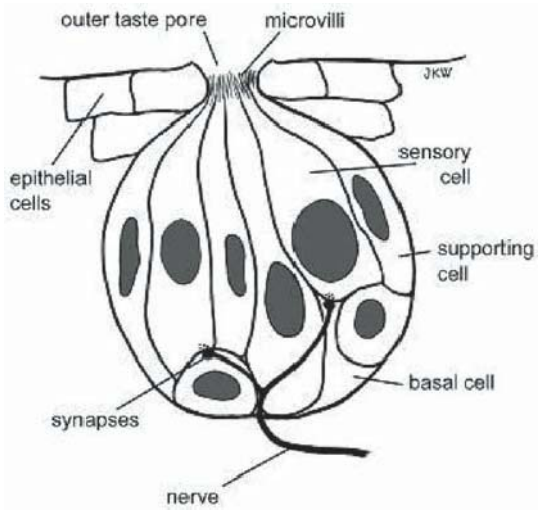

Figure 50.1 Anatomy of a taste bud. (From Geriatric Otolaryngology, eds. Eibling and Calhoun, 2006, Published by Taylor and Francis group.)

typically synapsing with multiple receptor cells within the taste bud (Fig. 50.1). There are at least three different types of taste cells although the function of these cells overlaps. The lifespan of a mammalian taste cell is approximately 10 days. As a cell ages, a nerve terminal detaches, finds a developing cell, and forms a new synapse. The new cell has to be of the same taste specificity as the old dying cell; in other words, taste receptor cells act as surface markers to guide nerve fibers to the right cellular target. Cells in each taste bud contain the sensory receptor cells, supporting cells, and basal cells that differentiate into new receptor cells. A single taste bud is all that is needed to provide sensation for all the four tastes so that even the decrease in number of lingual papillae does not necessarily lead to a significant loss of taste.

TASTE TRANSDUCTION

It is important to understand some of the basic science that is involved in taste transduction to understand the effects of pathologic conditions on this mechanism (6). Stimuli entering the mouth first interact with sites on the microvilli within the taste pore. Salts and sour acidic stimuli use ion channels while sweet and bitter substances react with protein compounds. Taste receptors trigger transduction cascades, which then activate synapses and cause the excitation of nerve fibers. A signal is produced, which is then carried to the brain, relaying information on the identity and intensity of the gustatory stimulus. Receptor proteins are located on the apical surface of cells and from there the stimulus enters the cell either via an ion channel as it does for the salty and sour tastes or via second messenger systems like cyclic AMP for bitter and sweet. Once the stimulant enters the cell there is a change in the internal electrical state of the cell, which leads to the secretion of a neurotransmitter and activation of a nerve fiber.

Each taste serves a specific purpose in the maintenance of health of an individual. Salt taste guides the intake of sodium chloride and thus the salt–water homeostasis. Sour helps with the recognition of complex foods. At low concentrations, it is pleasant but once it reaches high concentrations it becomes an unpleasant taste and leads to avoidance. It guides acid–base regulation and is sensitive to extracellular pH changes. The sweet receptor is a classical proteinaceous molecule analogous to an olfactory receptor. It responds to soluble carbohydrates in the oral cavity and regulates caloric intake, nutrition, and energy balance. It uses a second messenger like cAMP to activate a cyclic nucleotide cascade. Sweet taste has a strong hedonic effect and is well developed in infants. Bitter taste like sour is bearable and even to some extent pleasant in low concentrations but is repulsive when strong. Bitter receptors belong to the second messenger system of G proteins. They set off a G-protein–coupled receptor (GPCR)-mediated signal that leads to dual signaling of cAMP and cGMP within the cell. Bitter taste serves as a warning system designed by nature to protect against the ingestion of harmful compounds. Even newborn infants are seen to respond to bitter compounds, like quinine, with distaste (7). Umami as a taste was discovered about 100 years ago and is somewhat similar to sweet taste. It is derived from L-glutamate and is the taste present in Monosodium glutamate (MSG), chicken broth, meat extracts, and aging cheese. Umami receptors act much the same way as bitter and sweet receptors (they involve GPCRs), but not much is known about their specific function. It is thought that the amino acid L-glutamate binds to a type of GPCR known as a metabotropic glutamate receptor (mGluR4). This causes the G-protein complex to activate a secondary receptor, which ultimately leads to neurotransmitter release. The intermediate steps are not known. This taste helps guide the intake of peptides and proteins.

INNERVATION OF THE TONGUE

Taste receptor cells do not have an axon. Information is relayed onto terminals of sensory fibers by transmitters. These fibers arise from the ganglion cells of three cranial nerves. Over the anterior tongue the chorda tympani (a branch of the facial nerve) is sensory for taste and the lingual nerve, a branch of the trigeminal nerve serves general sensation. The chorda tympani "hitchhikes" along the lingual nerve travels through the middle ear and joins the facial nerve in the fallopian canal, then to the geniculate ganglion and terminates in the upper portion of the nucleus solitarius.

Over the posterior tongue, taste is conveyed via the glossopharyngeal (IX cranial) with some branches of the vagus providing additional taste sensation. In this region of the tongue, general sensation is also provided by the same two nerves. The IX nerve travels through the jugular foramen and terminating in the tractus solitarius

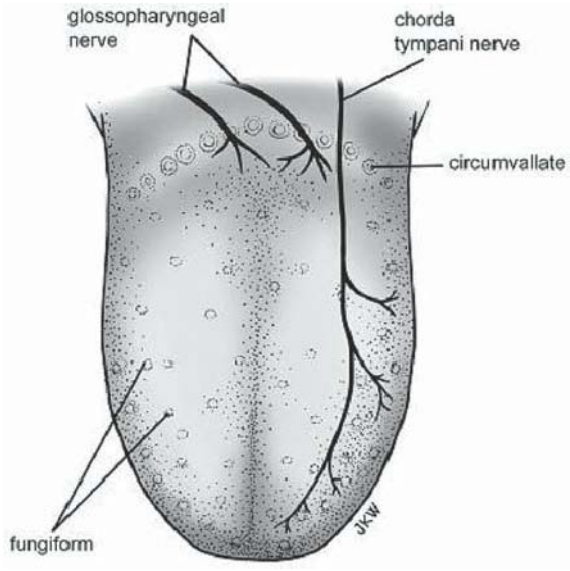

Figure 50.2 Innervation of the tongue. (From Geriatric Otolaryngology, eds. Eibling and Calhoun, 2006, Published by Taylor and Francis group.)

(gustatory nucleus). The trigeminal nerve is responsible for detecting the burning sensation caused by certain foods, for example, peppers. The superior laryngeal nerve, a branch of the vagus, innervates taste buds on the laryngeal surface of the epiglottis. Its role in taste is unknown (Fig. 50.2).

Central Pathways

Taste fibers from cranial nerves VII, IX, and X form part of the fasciculus solitarius and synapse centrally in the medulla (in a thin line of cells called the nucleus of the solitary tract). From there, the information is relayed to the somatosensory cortex for the conscious perception of taste and to the hypothalamus, amygdala, and insula, giving the so-called affective component of taste. This is responsible for the behavioral response, for example, aversion, gastric secretion, and feeding behavior. Nature has provided some of the compensation mechanisms that make taste very robust. These depend on the fact that there is inhibition among the central projections of the taste nerves. Taste nerves normally inhibit one another across the midline. Therefore, when a nerve is damaged there is a decrease in inhibitory impulses from that side, which in turn leads to an increase in responses from the opposite side. This disinhibition of the damaged nerve leads to an overall preservation of taste and total ageusia or loss of taste is very rare. On the other hand, the olfactory system depends on one nerve and is therefore more vulnerable to injury. It is also interesting to note that damage to taste releases inhibition on the trigeminal nerve and causes intensification of sensations like oral burning and oral touch and also makes certain foods, for example, fatty foods less palatable (8).

Genetic Variations

Phenylthiocarbamide and 6-n-propylthiouracil (PROP), chemically related compounds, are probes for genetic variation in bitter taste. Tasters and nontasters are identified based on the individual's ability to perceive PROP. The perceived intensity grades tasters into medium tasters (PROP is bitter) and supertasters (PROP is very bitter). Compared with supertasters, nontasters have fewer taste papillae on the anterior tongue (fungiform papillae) and experience less negative (e.g., bitterness) and more positive (e.g., sweetness) sensations from certain foods and beverages like alcohol.

Pain and other propriosensation are also more intense in these people and their thresholds for chili peppers and a fatty food is also more intense. According to some studies, the preference for and consumption of various (bitter-tasting) foods, recognized for their cancer-preventive properties, are also linked to an individual's PROP status (9,10). According to Bartoshuk, variations in oral sensation alter not only the intake of foods but also habits like smoking and alcohol consumption. She has found that for supertasters vegetable intake is lower leading to various pathologic states, for example, colon cancers. On the other hand, high-risk foods and habits tend to be less in supertasters as they generally do not like the taste of fatty foods, alcohol, or cigarette smoke (11).

TASTE TESTING AND BACKGROUND

Verification of taste loss is an important aspect of testing when a patient comes to the doctor complaining of taste loss. It is often found that the sense of taste maybe normal but the sense of smell is impaired leading to a loss of flavor. Flavor is a complete sensory experience arising from ingested stimulant molecules and involves taste, smell, texture, and temperature. Taste studies looked at two primary aspects of taste: acuity and intensity. Taste acuity measures two different parameters: (a) taste detection or threshold testing, which is a measure of the concentration at which a distinction can be made between a taste substance (tastant) and water, and (b) taste recognition, that is, which is sweet, sour, salty, or bitter. Taste intensity is a suprathreshold measure of taste qualities. Whole mouth testing is used to assess the individual's ability to detect, identify, and evaluate the intensity of different concentrations of the four taste substances. Spatial taste testing is used to assess different areas of the tongue to identify if there is localized impairment of taste.

The methods used in taste testing involve an evaluation of taste identification and taste intensity. For most individuals everyday taste-related experiences involve suprathreshold experiences. In the *whole-mouth taste testing*, five concentrations of sucrose, sodium chloride, citric acid, and caffeine are presented in a solution form. The subject sips, swishes, and expectorates it. The subject then

indicates whether the solution tasted sweet, salty, sour, or bitter and rates its intensity on a segmented visual analog scale (VAS) with the extremes labeled as very strong and very weak and with a background logarithmic gradation of shading.

The regional taste test described below is a well validated taste test used by the several chemosensory centers to assess gustatory dysfunction (12,13). It employs four suprathreshold stimulants: namely NaCl for salty, sucrose for sweet, acetic or citric acid for sour, and quinine sulfate or caffeine for bitter. A drop of the tastant (sweet, sour, salt, and bitter) is placed on the tongue with a micropipette and the subject is asked to identify the solution. These taste solutions are applied to four areas of the tongue: anterior right and left and posterior right and left. About 15 mL aliquots of single concentrations of sucrose (0.49 M), sodium chloride (0.31 M), citric acid (0.015 M), and caffeine (0.04 M) are presented in random order to selected regions of the tongue. Each taste solution is presented to each tongue region six times, in random order, for a total of 96 trials. This is a forced choice test in which patients are asked to identify solutions, with their tongue extended from their mouths, by pointing to a card labeled, "sweet," "sour," "bitter," and "salty." When a patient is unable to identify a solution, he or she is encouraged to guess. Patients are asked to rinse their mouths with distilled water between presentations. A total of 96 trials are employed (4 tastants × 6 trials × 4 tongue regions) and is generally administered over 45 minutes.

Threshold or intensity testing is much more difficult. Intensity testing involves a VAS, which is a 9-level scale of increasing shades of gray with the minimum at one end and maximum at the other. The problem with such testing is that the strength of a tastant is likely to vary across individuals, for example, the most intense sweet experienced by a supertaster is much more intense than the same concentration experienced by a nontaster.

Electrogustometry

Electrogustometry utilizes a weak electric stimulus to produce a sour taste when applied to taste receptors. It is useful to measure taste in specific loci of the anterior tongue. Its main disadvantage is the inability to measure specific tastes.

Videomicroscopy

This procedure was described by Miller and Reedy (14) in 1990. It is a noninvasive procedure designed to provide a 50- to 100-fold magnification to resolve the number and location of taste pores on the lingual papillae without destructive tissue preparation. Videomicroscopy (VM) allows the study of taste perception in terms of quantified taste receptor organs. Studies by Miller and Reedy have confirmed that taste pore staining is a valid method for counting taste buds. VM has the capability to successfully view, capture, and store high-resolution digital images. Fungi from papillae are approximately 0.1 to 1 mm in diameter and each taste pore has a diameter of 5 to 10 µm in fixed dehydrated tissues but is larger in living tissues. There are three to four taste pores per papilla. This method affords the advantage of being a nondestructive method allowing one to study dynamic changes in taste receptor populations over time. It also allows comparison of the anatomy with function in living subjects. The images obtained facilitate documentation, storage, and analysis of the papillae and pore images (Figs. 50.3 and 50.4).

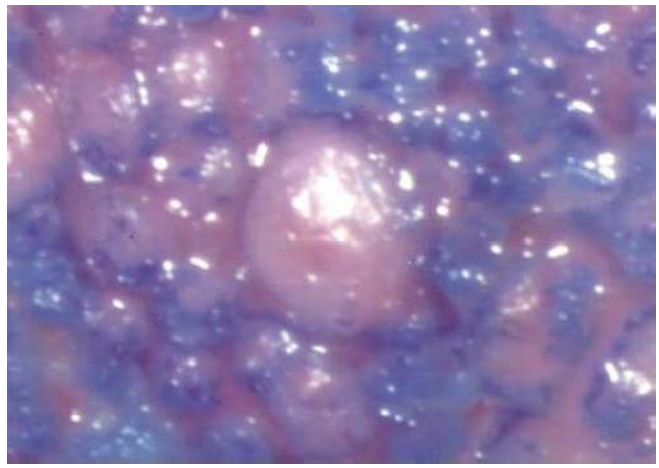

Figure 50.3 High power view of lingual fungiform papilla. *Arrow* shows taste pore. (From Laryngoscope. Lippincott Williams and Wilkins, 2008.) Mirza N, Machtay M, Devine P, Troxel A. Gustatory impairment in patients undergoing head and neck irradiation. Laryngoscope 2008; Jan 118(1):24–31.

TASTE ALTERING CONDITIONS

It is important to remember that when the taste system is damaged it may result in either a loss of taste or more often a distortion of taste or "phantom taste." Some of the conditions mentioned below are common causes of taste dysfunction and are discussed in greater detail here.

Aging

While age causes a decrement in all taste sensitivities, sweet taste in almost all studies reviewed seemed the most robust and survived the longest (15,16). Most studies have also found that males were much more vulnerable to the effects of aging compared with age-matched females both for taste thresholds and intensities. The relationship of the density of taste buds to taste sensitivity has demonstrated that NaCl threshold is inversely related to the number of fungiform papillae (more papillae = more sensitivity, lower threshold) (17,18). Arey et al. (19) found degenerative changes in taste receptors with a regression of gustatory papillae. Olfaction is more affected than taste and leads to a decrease in flavor overall.

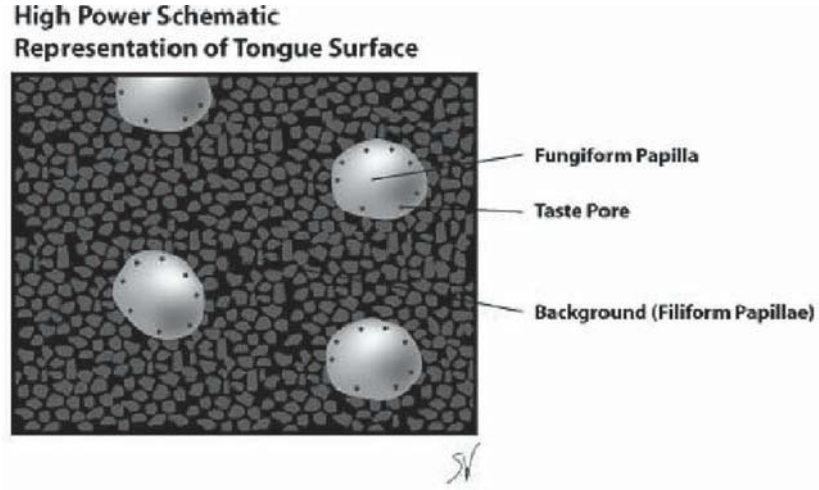

Figure 50.4 Schematic view of videomicroscopy. (From Laryngoscope. Lippincott Williams and Wilkins, 2008.) Mirza N, Machtay M, Devine P, Troxel A, Abboud SK, Doty RL. Gustatory Impairment in patients undergoing Head and Neck Irradiation. Laryngoscope. 2008. Jan 118(1): 24-31

Sucrose being the most robust of the tastes accounts for changes in eating habits of the elderly with a preference for cakes and pastries and hence deleterious health effects. However, there was no significant age-associated deterioration in somatic sensations such as touch and burning pain in the tongue, showing that aging affects taste perception and oral somatic sensations differently. Reasons for taste loss may also be related to decrease in the flow of saliva, which in turn leads to decreased taste receptor stimulation. Gingivitis and periodontal disease increase taste thresholds. In fact, several studies have shown a lowering of taste thresholds with an improvement in oral hygiene. Trials of antifungal troches and antibiotics have therefore been tried in an effort to improve oral health.

Systemic Diseases

Systemic diseases like diabetes, gastric disease, hypothyroidism, liver disease, chronic renal failure, Alzheimer and Parkinson disease affect taste. For example, uremia may introduce toxins into the blood stream leading to taste alterations and the problem improves with dialysis. Similarly, diabetics may develop neuropathies, which may affect the gustatory nerves and lead to abnormalities of taste. Perimenopausal women often complain of "the burning mouth syndrome," which is believed to be related to a lowering of the bitter taste threshold and a release of oral pain inhibition (20,21).

The use of systemic medications especially antihypertensive drugs and chemotherapeutic agents affect taste. Medications are suspected of introducing tastable substances into the blood and thereby altering taste thresholds; for example, chemotherapy drugs are well known to lower the bitter threshold and account for an aversion to certain foods like meats. Schiffman found that certain drugs can modify taste transduction or the turnover of cells and alter taste perception. The taking of more than one medication (so-called polypharmacy) is becoming more common and this compounds the problem with taste dysfunction.

Smoking affects taste especially the bitter sense. Hsu and Davis (22) found that smoking decreased gustatory sensitivity. Mirza et al. (23) performed a longitudinal study on the effects of radiation on the gustatory system and found that radiation adversely affected sour taste the most and also caused damage to the taste pores. Recovery took approximately 6 months.

Nerve Damage

This can occur from surgery involving pressure on the gustatory nerve, for example, during a tonsillectomy, middle ear surgery, or from a resection of the nerve involved with a tumor. Such losses are generally temporary as there is overlap in taste fibers and nerve damage leads to a release of inhibition of the contralateral nerves so everyday taste is generally not affected. Taste phantoms occur with some conditions like Bell palsy and acoustic neuromas. Generally, these phantoms last for about 6 months and then resolve spontaneously. Review of the literature suggests that possible indirect damage to the lingual branch of the glossopharyngeal nerve could be the cause of the taste disturbance after a tonsillectomy (24).

This symptom may be reversible within 2 years after tonsillectomy. Patients should be informed of the risk of postoperative taste disturbance after tonsillectomy as being one of the rare complications of this surgery.

Radiation and Chemotherapy

Taste dysfunction, which includes a partial loss (hypogeusia), complete loss (ageusia), and abnormal taste (dysgeusia), for example, a metallic taste, is a well-known complication of radiation and chemotherapy for head and neck cancer. This dysgeusia impacts both nutritional intake and the quality of life, with patients developing mouth sores and inflammation. Mirza et al. conducted a prospective, longitudinal study on newly diagnosed head and neck cancer patients and found that sour taste

was most affected after radiation and chemotherapy. The number of taste buds was also significantly decreased after radiation. While taste generally recovered after 6 months of therapeutic radiation, the number of taste buds did not return to the preradiation levels. Taste damage was independent of the decrease in saliva production although xerostomia has obvious deleterious effects on taste as well. Efforts to avert radiation injury are therefore needed and include dose sculpturing techniques to decrease radiation to nontarget tissues, altered fractionation schedules to decrease normal tissue injury, replenishment of stem cells through the administration of growth factors and the need for the development of mucosal protectants, along with the need to alter the diet of radiation patients (with food additives, flavorants, avoidance of very high-temperature foods), to decrease the impact of taste alterations in this population.

EFFECTS OF TASTE LOSS

What most individuals complain of is a loss of flavor and enjoyment of foods, which is most often related to the well-known loss of olfaction combined with some taste loss (25). The effect is a loss of appetite which puts the individual at higher risk for depression, anorexia, and weight loss. Institutionalized individuals, for example, often show an increase in taste thresholds, which may account for the poor intake and nutritional status of some of these people. Poor taste perception combined with olfactory loss puts the individual at risk for food poisoning from the ingestion of spoiled foods.

THERAPY FOR TASTE LOSS

No specific therapy or pharmacologic agents are available to reverse the loss of taste with aging and in general the prognosis is poor. Awareness of taste alteration and decrement is paramount in making sure individuals get a balanced diet and prevent health problems, which are secondary to a poor and unhealthy diet.

Flavor amplifiers have been developed to enhance the flavor by adding an extra ingredient to the food. Examples of these are seasoning salts, fruit juices, meat stocks, and gravy. MSG also helps as a flavor enhancer especially for protein-based dishes, for example, meat loaf, casserole, etc., because it adds a savory taste to these foods. Other food enhancers include vinegars, sun-dried tomatoes, herbs, and spices. Color enhancers make the food more appealing and enjoyable to people who have a poor appetite.

Anecdotal evidence also exists that lack of the trace elements can lead to decreases in metabolic functions. Chauhan et al. (26) has therefore suggested that zinc supplementation be tried to enhance taste along with vitamins A, B_{12}, and folic acid for the maintenance of taste bud integrity. For individuals suffering from oral pain, the use of capsaicin as a desensitizer of pain receptors and clonazepam as a gamma-aminobutyric acid agonist has been shown to help, for example, sufferers of the "burning mouth syndrome" (27).

CONCLUSION

Current research is geared toward the development of drugs containing taste ligands, which activate or inhibit taste receptor proteins. These, in turn, can then increase or decrease specific tastes (e.g., artificial sweeteners like saccharin and aspartame). Awareness of the loss or alteration of taste should be an important part of education for individuals suffering from a taste dysfunction so that a conscious effort is made toward the preparation of a nutritionally balanced diet. When an individual notices a loss of taste, a referral to a chemosensory center should be made where a multidisciplinary team approach can help with the elimination of the reversible causes of taste loss. Protectants of taste should be researched for and avoidance of drugs and harmful habits like smoking should be encouraged as they will help preserve the natural taste function. Keeping the sense of taste strong is essential for the enjoyment of life and for the survival of the human race as a whole.

HIGHLIGHTS

- Sensory cells in taste buds do not have axons. Rather, they process chemical signals and activate sensory neurons via synapses.
- Individual taste sensitivity is genetically determined and is highly variable.
- Taste sensitivity is quantifiable utilizing standardized testing.
- Taste is affected by many diseases such as diabetes, chronic renal failure, Parkinson, and Alzheimer.
- Some common medications affect taste, such as antihypertensives and chemotherapy drugs.
- Taste may be affected by interruption of the sensory neural pathways such as chorda tympani and lingual nerve.
- No specific treatment exists for taste dysfunction. Adjunctive measures such as food color and flavor enhancers (MSG, etc.) may benefit affected patients.

51 Stomatitis

Richard O. Wein *Miriam O'Leary*

This chapter covers the broad category of diagnoses that fall under the diagnosis of stomatitis. The term "stomatitis" indicates an inflammation and potential breakdown of the oral cavity mucosal surfaces and is typically symptomatic. The clinical presentation may extend to the oropharynx or the external perioral region. The etiologies are multiple and include treatment-related, infectious, immunologic, systemic, nutritional, and idiopathic causes.

The diagnoses that fall under this classification can be challenging to identify and require a detailed assessment of a patient's history of presentation and associated conditions. Additionally, these presentations are not solely seen in the adult population and some forms of stomatitis are unique to the pediatric population.

Given that many of these diagnoses are localized manifestations of systemic diseases, collaborative management of patients with our Dermatology, Infectious Disease, Oral Medicine, and/or Rheumatology colleagues is expected.

Interestingly, despite being encountered daily in general practice, the etiology of many of these oral lesions remains unclear. Many of the advocated treatment options vary dramatically within the medical literature and may only offer symptom control and not affect cure of the underlying diagnosis. As such, this chapter attempts to summarize some of the common perspectives relative to these diagnoses; however, for those seeking more detail on any one condition, the reader is encouraged to review the articles cited within the chapter's reference list.

CLINICAL ASSESSMENT

The clinical appearance of stomatitis is variable. Presentations can differ from simple localized to fulminant manifestations and may include components of mucosal erythema, hyperkeratosis, ulceration, pseudomembrane, and/or vesicle formation.

The rate of epithelial turnover in the oral cavity ranges from 3 to 7 days. As a result, this anatomic location is quick to demonstrate visible signs of a metabolic disturbance from a systemic condition or in relation to treatment (1).

Throughout this chapter, a theme should develop relative to the importance of a thorough history of presentation and the assessment for associated diagnoses. Some of the conditions that are discussed are diagnoses of exclusion, while others may represent the earliest presentation of a more significant systemic process.

Pertinent issues that should be addressed in the history include the circumstances and the time course surrounding the onset of symptoms, recent changes in medications, aggressiveness of oral hygiene and product use, palliating/provoking factors, quality of pain and any prodromal symptoms.

A full head and neck examination is necessary in these cases in an effort to assess for synchronous findings beyond the oral presentation. Dentures should be removed and assessed for quality of fit while asking the patient about the original date of manufacture in addition to visits for modification. In cases of buccal mucosal lesions, the relationship of the ipsilateral dentition and any amalgam that contacts the mucosa in a closed mouth position should be identified. Additionally, the quality of salivary production should be assessed.

Exudative lesions should be considered for gram stain and culture (with fungal cultures additionally requested). Tzanck smear and viral cultures should also be considered in patients with vesicular lesions.

Laboratory assay, in cases where a wide differential diagnosis continues to exist after history and physical examination, can include a complete blood count (CBC) with differential, erythrocyte sedimentation rate (ESR), antinuclear antibody (ANA), and cytoplasmic-antineutrophil cytoplasmic antibodies (c-ANCA) in addition to levels

for iron, ferritin, total iron-binding capacity, folate, thiamine (B1), riboflavin (B2), pyridoxine (B6), cobalamin (B12), zinc, and magnesium (2). In xerostomic patients, anti-SSA and anti-SSB can be drawn to assess for Sjogren disease.

Biopsy remains a powerful tool for establishing a definitive diagnosis in patients with stomatitis of unclear etiology. Patients with vesiculobullous lesions should have perilesional tissue sent for direct immunofluorescence (DIF) for deposition of IgG, IgA, and/or complement C3. Biopsy should be considered in patients with suspected recurrent aphthous stomatitis (RAS), oral lichen planus (OLP), or graft-versus-host disease (GVHD) to rule out oral squamous cell carcinoma because of the potential for similarity in appearance.

Patients with a history and findings highly suggestive of an inflammatory bowel condition, such as Crohn disease or ulcerative colitis (UC), should be considered candidates for colonoscopy.

ETIOLOGY

Our understanding of the etiology of treatment-related mucositis at the cellular level continues to evolve. Some aspects may be genetically predetermined and explain the heterogeneity of response between patients to different treatments.

Theories on the development of mucositis have traditionally stated that it was the result of direct damage to the basal epithelial cell layer leading to an impairment of the renewal capacity of the surface epithelium. The resultant clonogenic cell death would result in atrophy and consequent ulceration with the clinical presentation of mucositis.

Additional evidence has suggested that an acute microvascular injury resulting from endothelial apoptosis may play a more significant role in the etiology of mucositis than previously considered. Electron microscopy has demonstrated that endothelial and connective tissue damage precede epithelial changes in irradiated oral mucosa. This finding suggests that the development of treatment-related mucositis is not just an epithelial process.

Sonis et al. (3) describe the five phases of mucosal barrier injury as a result of chemotherapy and/or radiation therapy as:

1. Initiation with generation of reactive oxygen species
2. Up-regulation with generation of messengers including nuclear factor-κB
3. Signaling and amplification with proinflammatory cytokines including tumor necrosis factor-alpha (TNF-α)
4. Ulceration with inflammation with bacterial colonization and pain
5. Healing with epithelial proliferation and the return of local microbial flora

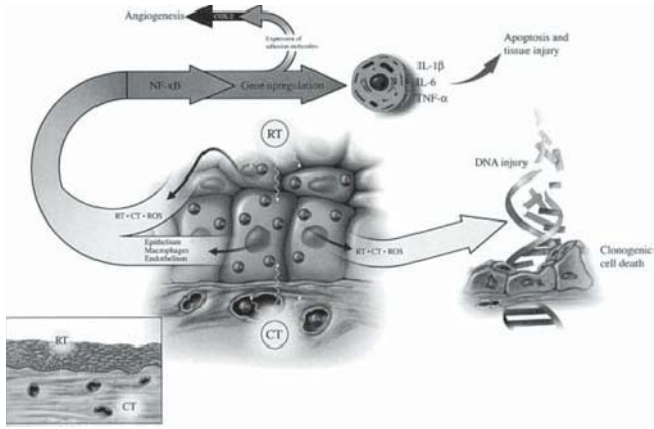

Diagram 51.1 Mucositis as a result of radiation therapy or chemotherapy occurs as a result the creation of reactive oxygen species (ROS) and the stimulation of transcription factors (such as nuclear factor-κB). Resultant double-stranded DNA breaks leads to clonogenic cell death. Up-regulation of TNF-α and the interleukins (IL-6 and IL-1β) leads to apoptosis of cells in the basal epithelium. Additional expression of factors, cyclooxygenase-2, stimulates reactive angiogenesis. (From Sonis ST, Elting LS, Keefe D, et al. Perspectives on cancer therapy-induced mucosal injury: pathogenesis, measurement, epidemiology, and consequences for patients. *Cancer* 2004;100(9 Suppl):1995–2005, with permission.)

TREATMENT-RELATED STOMATITIS

Stomatitis can occur as a result of multiple forms of therapy; however, it is most evident and has the greatest impact in the treatment of cancer. It is expected that with chemotherapy and radiation therapy some degree of stomatitis, also known as mucositis, development will be experienced. Strategies for prevention, assessment, and treatment of treatment-related mucositis have been well documented; however, variation in findings and recommendations exist.

Assessment tools typically categorize the severity of a presentation by assessing a patient's well-being, utilizing mouth and throat soreness (MTS) scores, and defining the patient's functional capacity. Oral function can be assessed through dietary capacity, the ability to eat in public, and overall speech quality. An example of a quality-of-life instrument used in this setting is The Oral Mucositis Weekly Questionnaire—Head and Neck Cancer. It has been shown to be a reliable and valid means for assessing the impact of mucositis on patients undergoing treatment (4).

Administration of 5-fluorouracil, with or without leucovorin, is associated with oral mucositis in as many as 40% of patients with grade 3 and 4 presentations occurring in 10% to 15% of patients (5). In a double-blind randomized study by Sorensen et al., patients undergoing chemotherapy with 5-fluorouracil and leucovorin received prophylactic chlorhexidine or cryotherapy in attempt to decrease treatment-associated mucositis. Prophylactic chlorhexidine (10 mL at 0.1% concentration) was utilized three times per day with 1-minute oral rinses. Cryotherapy was performed with crushed oral ice 10 minutes before and

35 minutes after administration of chemotherapy. The frequency and duration of oral mucositis were significantly improved with both treatment options. Combined use of cryotherapy and chlorhexidine were not examined during this study (6).

Another preventative treatment option, frequently reported in patients with hematologic malignancies, is palifermin. Palifermin is a recombinant human keratinocyte growth factor-1 (hKGF-1) that is considered to offer mucosal protection by inducing epithelial hyperplasia. Typical administration is in multiple pre- and posttreatment administrations of 60 μg/kg. Use of single-dose palifermin was studied in sarcoma patients receiving doxorubicin chemotherapy in a randomized, double-blind, placebo-controlled trial. Single-dose intravenous palifermin (180 μg/kg body weight), administered before each cycle, was noted to significantly reduce the incidence and severity of mucositis experienced. During the trial, the drug was well tolerated and majority of patients experienced thickening of oral mucosa and tongue. Biopsies of the affected areas noted increased levels of proliferative marker Ki-67 suggesting a palifermin-associated etiology (7).

The medications associated with treatment-associated mucositis are not limited to the conventional chemotherapeutic options but also include agents like hydroxyurea (8) and the newer targeted therapies such as imatinib mesylate (9), cetuximab, panitumumab, gefitinib, erlotinib, rapamycin, sorafenib tosylate, and lapatinib (10).

Mucositis associated with radiation therapy is a common finding that tends to be self-limited after the completion of treatment. Mucositis typically peaks between weeks 5 to 6 during treatment as assessed by MTS scores (11). Radiation-associated mucositis is worse in patients undergoing radiation with accelerated regimens (5). Grade 3 and 4 mucositis requiring gastrotomy tube placement is more significant with chemoradiation protocols (38%) than compared to radiation alone (18%). The risk of developing mucositis is the same for patients undergoing treatment of an oral cavity and oropharyngeal cancer as those treated for a laryngeal and hypopharyngeal cancer.

Prophylactic pilocarpine has been shown to decrease the incidence and severity of treatment-associated mucositis that is presumed through the up-regulation of salivary function during treatment (12). However in contrast, in a randomized phase III prospective trial of bethanechol, which has a similar ability to stimulate salivary function, prophylactic treatment did not prevent mucositis or candidiasis in head and neck cancer patients undergoing radiotherapy (13).

In 2004, the Multinational Association of Supportive Care in Cancer and the International Society for Oral Oncology (MASCC/ISOO) offered a consensus statement with recommendations on treatment-associated mucositis.

In the setting of radiation therapy, the MASCC/ISOO advocated the use of benzydamine, a nonsteroidal anti-inflammatory that inhibits TNF-α (not available in the United States), and did not support the use of chlorhexidine as a prophylactic for mucositis (5).

In patients treated with chemotherapy, the prophylactic use of acyclovir was not recommended. Cryotherapy was not advocated in the setting of treatment with 5-fluorouracil, with or without leucovorin. Additionally, the panel did not support the prophylactic use of pentoxifylline or low-level laser therapy in patients preparing for stem cell transplant (5).

Novel agents requiring additional evaluation include Gelclair, AES-14, and human keratinocyte growth factor-1 (hKGF-1) and hKGF-2. Gelclair, a mixture of polyvinylpyrrolidone, sodium hyaluronate, and glycyrrhetinic acid, has demonstrated improved pain scores during treatment yet clinical trial data were lacking. AES-14, a proprietary form of administering L-glutamine, demonstrated the capacity to decrease grade 2 or greater mucositis when compared to placebo. Repifermin (hKGF-2) was shown to reduce grade 2 to 4 mucositis in clinical trials, and head and neck cancer patients receiving palifermin (hKGF-1) experienced a lower incidence and shorter duration of mucositis when compared to placebo (5).

The Cochrane Collaboration reviewed 131 studies with over 10,000 randomized patients in assessing treatment options for the prevention of oral mucositis in patients receiving cancer treatment. Less than 10% of the studies were considered to have a low risk of bias associated with their performance. The therapies shown to offer some benefit compared to placebo included: aloe vera, amifostine, cryotherapy, granulocyte-colony stimulating factor, intravenous glutamine, honey, keratinocyte growth factor, polymyxin/amphotericin antibiotic paste, and sucralfate. The strength of the evidence was described as variable (14).

Graft-Versus-Host Disease

Acute GVHD is dependent upon type I cytokine-driven CD8 effectors, while chronic graft-versus-host disease (cGVHD) has traditionally been associated with type II CD4 T cells (15). The median onset of GVHD is 6 months after transplantation with oral manifestations seen in up to 80% of patients.

The clinical presentation includes xerostomia, oral ulceration, altered capacity for taste, and recurrent candidal infections (16) (Fig. 51.1A and B). The clinical appearance can mimic oral squamous carcinoma. Of note, patients who have undergone hematopoietic stem cell transplant are at increased risk of developing oral squamous cell carcinoma and should have regular surveillance exams with biopsy performed for suspicious lesions (17). Histologic findings of GVHD on biopsy include hydropic degeneration of the basal layer of the epithelium, intracellular edema, apoptotic bodies, fibrosis, and lymphocytic infiltrate in the submucosa (18).

The current therapy for cGVHD is nonspecific immunosuppression.

Figure 51.1 GVHD of the lateral **(A)** and dorsal **(B)** tongue in a patient with prior history of bone marrow transplant.

Contrary to conventional belief, Imanguli et al. believe that cGVHD is not a type II cytokine driven disorder. They advocate a model that oral cGVHD results from type I interferon (IFN)-driven proliferation and differentiation of Th1/Tc1 differentiated effectors. This concept was supported by the finding of T cells in cGVHD infiltrates expressing T-bet, a transcription factor critical for Th1/Tc1 polarization and the production of IFN-γ and granzyme B. With these new findings, the authors suggest that new treatment approaches for cGVHD should focus on affecting the IFN-mediated inflammatory axis (15).

Lichenoid Reactions

Lichenoid reactions of the oral cavity represent an immunologic response to a systemic or local stimulus. Reactions can present as a contact stomatitis, as seen in the buccal mucosa opposing a dental amalgam (Fig. 51.2), or may represent a drug reaction from the initiation of a common medication. An extensive number of oral medications have been associated with lichenoid drug reactions (Table 51.1). The most common agents responsible for oral lichenoid drug reactions are nonsteroidal anti-inflammatories, antihypertensives, and HIV antiretrovirals. Presentation of a lichenoid reaction can vary widely but typically occurs within 2 to 3 months after initiation of a medication (19).

In addition to dental amalgam, contact lichenoid stomatitis has been reported with cinnamon flavoring (as a result of cinnamic aldehyde) and other flavorings commonly found in mints and mouthwashes. A history of a recent change in the use of oral hygiene products or variation in the habitual use of a mint or gum brand may help elucidate this risk factor.

Figure 51.2 Lichenoid contact reaction from local amalgam.

TABLE 51.1 MEDICATIONS ASSOCIATED WITH ORAL LICHENOID DRUG REACTION

Tetracycline	Chloroquine
Carbamazepine	Quinine
Phenytoin	Quinidine
Valproic acid	Isoniazid
Chlorpropamide	Rifampin
Glipizide	Streptomycin
Insulin	Zidovudine
Tolbutamide	Imatinib
Bismuth	Dactinomycin
Amphotericin B	INF-α
Ketoconazole	Gold salts
Atenolol	Penicillamine
Enalapril	Aspirin
Hydrochlorothiazide	Ibuprofen
Methyldopa	Naproxen
Metoprolol	Benzodiazepines
Lithium	Tricyclic antidepressants
Indomethacin	Allopurinol

Adapted from Schlosser BJ. Lichen planus and lichenoid reactions of the oral mucosa. *Dermatol Ther* 2010;23(3):251–267.

Individuals with contact allergy to inorganic mercury amalgam present with an oral mucosal lesion within 1.0 cm of the suspected offending restoration, and they lack associated cutaneous lichen planus (CLP). Patch testing to inorganic mercury has been advocated for recalcitrant presentations and should be read on days 7, 10, and 14 in an effort to identify late reactions. In the setting of a positive patch test, subsequent improvement of oral lesions is highly likely with removal and replacement of the restoration. Contact lichenoid reactions are not unique to mercury and may also occur to gold and palladium (20,21).

INFECTIOUS

Candidiasis

Oral candidiasis is the most common form of fungal stomatitis. Approximately 30% to 60% of individuals carry candidal species as part of their normal oral flora (22,23). *Candida albicans* is the most common candidal species in the oral cavity and accounts for up to 80% of oral isolates.

Multiple local and systemic factors can lead to candidal overgrowth. Recurrent oral candidiasis is typically seen in patients with poorly controlled diabetes, HIV-positive patients (with decreased CD4 counts), at the extremes of age (premature and elderly), and in patients with xerostomia. Use of broad-spectrum antibiotics and topical or inhalational steroids can also predispose to candidal overgrowth (22–24).

The most recognized clinical presentation of *Candida* is readily diagnosed but other forms of oral candidal infection may be more difficult to identify. The category of erythematous candidiasis is actually the most common form of oral candidiasis and presentations under this subheading are varied. Erythematous candidiasis includes acute and chronic atrophic candidiasis, angular cheilitis, median rhomboid glossitis, and chronic multifocal candidiasis (22,23).

Multiple classifications are reported for oral candidal infections. Table 51.2 presents a system that delineates candidal infections into five categories (24).

Pseudomembranous candidiasis, also known as thrush, is common in immunocompromised populations and may be diagnosed in all age groups. White creamy plaques on an erythematous mucosal base may be seen throughout the oral cavity with various degrees of associated symptoms. Extension of thrush to involve the pharynx and esophagus may also occur and present with dysphagia and odynophagia (23,24).

Acute atrophic candidiasis is also known as "antibiotic sore mouth." It occurs as a result of use of broad-spectrum antibiotics. Patients complain of oral burning and present with an erythematous patches on the buccal mucosa or dorsal tongue with papillary atrophy noted on examination. Chronic atrophic candidiasis is seen with denture use and is discussed in greater detail below.

Chronic hyperplastic candidiasis, also known as candidal leukoplakia, is the least common form of oral candidal infection. It presents on the buccal mucosa as a superficial white lesion that is incapable of being wiped away from the underlying mucosa. If the lesion does not resolve with use of antifungal therapy, leukoplakia should be viewed as more likely representing the diagnosis and biopsy considered (23,24). Candidal-associated diagnoses include actinic cheilitis, median rhomboid glossitis, and linear gingival erythema.

Angular cheilitis, also know as perleche (Fig. 51.3), represents a combination of fungal (*C. albicans*) and bacterial (*Staphylococcus aureus*) infections. Pain and erythema with fissuring at oral commissure are noted. This finding is common in denture wearers and is the result of the loss of alveolar bone height over time with the pooling of secretions at the oral commissure. In young dentate patients, infection with HIV should be considered as a potential diagnosis in recurrent presentations (23,24).

Median rhomboid glossitis, also known as central papillary atrophy, presents at the midline dorsal oral tongue.

TABLE 51.2 CLASSIFICATIONS OF VARIOUS TYPES OF ORAL CANDIDIASIS

Pseudomembranous (exudative) candidiasis
(Exudative candidiasis)
Acute atrophic (erythematous) candidiasis
Median rhomboid glossitis
Oral candidiasis
Chronic atrophic candidiasis
(Denture stomatitis)
Chronic hyperplastic candidiasis
(Candidal leukoplakia)
Candida-associated diagnoses
Actinic cheilitis
Median rhomboid glossitis
Linear gingival erythema

Parentheses indicate additional names used to describe the above-listed entity.
Adapted from Sharon V, Fazel N. Oral candidiasis and angular cheilitis. *Dermatol Ther* 2010;23(3):230–242.

Figure 51.3 Angular cheilitis.

Figure 51.4 Median rhomboid glossitis in a patient with a history of Sjogren disease and immunosuppression.

The smooth or lobular demarcated region anterior to the circumvallate papillae is typically asymptomatic in presentation (Fig. 51.4). A mirrored palate lesion may be seen from direct contact with the tongue (23,24).

The diagnosis of chronic multifocal candidiasis, separate from the classification above, is assigned to those patients with more than one form of candidal infection (e.g., angular cheilitis and denture stomatitis) that is present for greater than 4 weeks with the lack of predisposing risk factors (immunosuppression, xerostomia, medications) for candidal infection (23).

The diagnosis of oral candidiasis can be established solely on clinical exam or may be augmented with the use of exfoliative cytology, culture, or biopsy. On smear, budding oval yeast forms with nonbranching septate pseudohyphae with blastocysts are noted. On biopsy specimens, fungal elements invading the parakeratin layer of the epithelium can be seen (Fig. 51.5) (23,24).

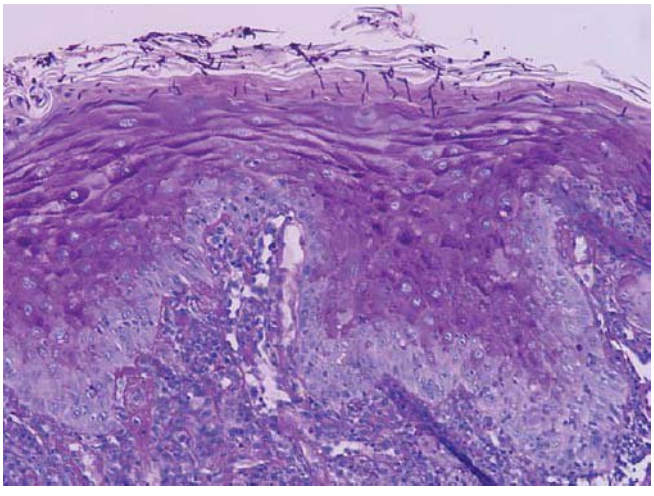

Figure 51.5 Periodic acid-Schiff staining of a biopsy specimen with candidal invasion of the parakeratin layer of epithelium.

A wide variety of topical and systemic treatment options are available. For the limited common forms of acute infection, topical agents are typically employed prior to use of to systemic antifungal agents. Topical therapies come in the form of lozenges (clotrimazole), tablets (miconazole), suspensions (nystatin and amphotericin B), and creams (ketoconazole). Oral agents typically include the azole class of antifungals (fluconazole, ketoconazole, and itraconazole) (23,24).

The length and type of treatment is dependent upon the presentation (acute vs. chronic), patient characteristics (immunocompromised), and response to the initiation of therapy. Although the length of treatment varies with respective medication, treatment for at least 2 to 3 weeks is common with most agents. Drug resistant forms of *Candida* may be seen in patients requiring longer courses of antifungal therapy. Oral agents are typically used in patients at recalcitrant presentations or when a significant risk of developing systemic infection exists (22–24).

Denture-Related

Denture-related stomatitis occurs in up to 70% of denture wearers and is highest in the elderly, women, smokers, and individuals with compromised immune function. Causes include includes poor hygiene and continual (night-time) denture use. Colonization with *C. albicans* and with the formation of resistant biofilms on the denture result in a presentation that is resistant to use of nystatin oral rinses. Culture of the denture can help confirm the diagnosis (24,25).

Denture stomatitis, also known as chronic atrophic candidiasis, has been described to have three subtypes of presentation that include:

Type I—localized inflammation
Type II—diffuse erythema involving the denture-bearing mucosa
Type III—papillary hyperplasia on mucosa (Fig. 51.6) (23,24).

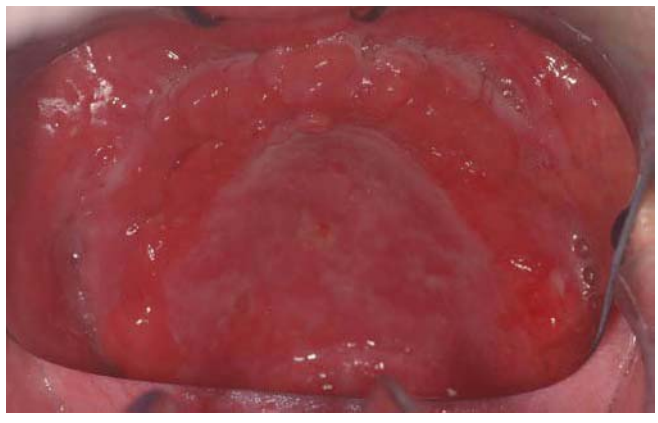

Figure 51.6 Erythema and papillary hyperplasia seen with denture stomatitis.

Poor fitting dentures exacerbate oral trauma through rough edges and inadequate contact spots and should be addressed with routine maintenance. The importance of sanitization with commercially available denture cleaners needs to be emphasized to address the formation of biofilms. Treatment with oral fluconazole or topical clotrimazole cream and nystatin (to the mouth and denture) may require 1 month of treatment for resolution (25).

Noncandidal Fungal Etiologies

Noncandidal etiologies of fungal infections of the oral cavity that can present as stomatitis include paracoccidioidomycosis, histoplasmosis, and mucormycosis.

Paracoccidioidomycosis is primarily seen in South America (Brazil, Colombia, and Venezuela) and is associated with smoking, poor nutrition, and alcohol abuse. It affects the mucous membranes, lymph nodes, lungs, and bones. Chronic presentations are more common than subacute and more likely to be associated with mucosal lesions. Painful oral cavity lesions are seen in about 60% of patients. The gingiva is the most commonly affected site with involvement also seen in the soft palate, lower lip, and tongue (26). The classical clinical presentation is a superficial ulcer with granular appearance and hemorrhagic points (Table 51.3). Treatment involves use of antibacterials (sulfamethoxazole) and antifungals (itraconazole and amphotericin B) and is dependent upon the clinical presentation (27).

Histoplasmosis is caused by the organism *Histoplasma capsulatum*. It is most commonly found in the Ohio and Mississippi River Valley regions of the United States and in South America (Argentina and Brazil). Infection results from inhalation of fungal spores that can be found in caves, as a result of birds and bats, or from working around chickens. Infection is most problematic in immunocompromised patients. Mucocutaneous lesions are more common in South America than is seen with the North American HIV-infected patients (27). Oral lesions vary and may present as papules, patches, ulcers, or vegetations. Patients may present with only oral ulceration without the finding of extraoral manifestations of histoplasmosis (28). The clinical appearance of the oral findings may mimic squamous cell carcinoma. Treatment involves antifungals, such as itraconazole and amphotericin B, and may require lifetime suppressive therapy in immunocompromised populations (27).

Mucormycosis is a life-threatening invasive fungal infection that occurs predominantly in patients with diabetes who are prone to ketoacidosis. It may also present in neutropenic and posttransplant patients or associated with malignancy (leukemia). Palatal ulceration and necrosis are classic for the rhinocerebral presentation of mucormycosis (29). Vascular invasion by hyphae with thrombosis and infarction of tissue is seen on biopsy specimens. A mortality rate of greater than 40% exists. Treatment requires the removal of the underlying risk factor, aggressive surgical intervention, and systemic antifungal therapy (27).

Viral

Herpes Simplex Virus

Primary herpetic gingivostomatitis is predominantly the result of herpes simplex virus-1 (HSV-1) and occurs in 25% to 30% of children (30). Clear yellowish pinhead vesicles develop after a prodrome of fever, anorexia, and malaise. Vesicles appear on keratinized tissue such as the attached gingiva, hard palate (Fig. 51.7), and the lip at the vermillion border. The vesicles contain active virus and are considered very contagious; however, the contagion potential drops rapidly after rupture. Rupture occurs within hours revealing irregular ulcers covered by a yellow-gray membrane. The oral presentation is variable in extent but is typically asymptomatic. Lymphadenitis and odynophagia may accompany the presentation. Healing typically occurs in 7 to 10 days. Primary herpetic gingivostomatitis in an adult may present very similar to mononucleosis with predominantly pharyngotonsillar symptoms (22,30).

Figure 51.7 Herpes ulceration of the hard palate.

Figure 51.8 Herpes labialis.

During the asymptomatic latent state, the virus resides within the sensory ganglion of the trigeminal nerve. Exposure to a stressor leads to viral replication and reexpression with a subsequent vesicle formation. Stressors may include fever, radiation, chemotherapy, HIV infection, UV light exposure, pregnancy, and surgery (22,30).

Secondary or recurrent herpes affects labial and perilabial surfaces (cold sores) in the majority of cases and is typically unilateral (Fig. 51.8). Secondary presentations within oral cavity are uncommon yet when present occur on gingiva or palate mucosa and do not occur on mobile soft tissues. Multiple small vesicles may coalesce to larger lesions. Treatment is dictated by symptoms. Lubrication may reduce crusting of overlying lesions and enhance healing.

Treatment options include the use of topical agents and systemic antivirals; however, therapy primarily directed to symptom control. When treatment is initiated at the time of prodromal symptoms, reduction in healing time and pain reduction has been reported. Antiviral therapy is unnecessary in the setting of primary infection unless concern over progression to encephalitis arises. Long-term clinical ulceration should prompt investigation for other vesiculobullous conditions rather than an HSV-associated diagnosis (30).

HIV-Associated Stomatitis

HIV-positive patients presenting opportunistic oral lesions are likely to have higher viral loads and lower CD4 counts. Stomatitis may be the first manifestation of an undiagnosed HIV infection. Awareness of this association can prompt HIV testing and facilitate early diagnosis and treatment (31). In the HIV-positive patient undergoing treatment, emergence of stomatitis can signify the failure of an existing antiretroviral regimen.

Oral presentations seen in the HIV-positive population includes candidiasis, oral hairy leukoplakia, recurrent aphthous-like ulceration, orolabial HSV, oral warts, and HIV-associated periodontal disease such as linear gingival erythema (32).

Pseudomembranous candidiasis is the most common form of stomatitis seen in HIV-positive patients (31). Prophylactic fluconazole is not recommended except for in severe or recurrent cases because of concerns it could lead to multidrug resistance. Topical agents are recommended for patients with a CD4 counts greater than 200 cells/mm^3. Culture and sensitivity is advised if the candidiasis does not respond to initial therapy (32,33).

For RAS, initial treatment approaches with topical and systemic steroids is the same for HIV-positive as for HIV-negative patients. Thalidomide has been used in severe refractory aphthous stomatitis in two randomized, double-blind, placebo-controlled trials; however, drug toxicity can limit treatment. Cytomegalovirus (CMV) may also present with painful oral ulcerations and can be associated with the subsequent development of CMV-associated retinitis and encephalitis (32).

In HIV-positive patients with orolabial herpes, if the CD4 T-cell count is greater than or equal to 200 cells/mm^3, topical treatments should be considered first and continued until lesions resolve. Use of a systemic antiviral agent is advocated if CD4 counts are below 200 cells/mm^3, when lesions are extensive, or if a patient did not respond to topical therapy (32).

Epstein-Barr virus is the causative factor in the development for oral hairy leukoplakia in HIV-positive and immunocompromised patients. It has the pathognomonic appearance of elongated filiform papillae associated with white plaques that typically present on the lateral aspect of the tongue. The morbidity of oral hairy leukoplakia is usually low and treatment is reserved for symptomatic presentations (32,33).

Acute necrotizing ulcerative gingivitis, commonly known as trench mouth, can be seen in HIV-positive patients and can spread to involve surrounding oral mucosa causing a necrotizing stomatitis. Fortunately, this condition responds rapidly to local debridement and disinfectants like chlorhexidine or povidone–iodine (33).

Immune reconstitution inflammatory syndrome (IRIS) can be seen in patients with AIDS with oral opportunistic infections, such as candidiasis, that are initiating highly active antiretroviral therapy (HAART). Cell-mediated immunity is suddenly raised and results in an exaggerated response against the opportunistic infections and paradoxically worsens the patient's symptoms. It is recommended to treat the opportunistic infections before starting HAART in order to avoid IRIS (33).

Tuberculosis

Although uncommon, primary pulmonary tuberculosis infection can disseminate to the head and neck region. Primary tuberculosis of the head and neck is also rare and can occur due to direct contact with infected sputum at sites of mucosal trauma in the oral cavity. The clinical presentation of tuberculosis in the oral cavity varies and

may present as a chronic nonhealing ulceration or a discrete submucosal mass. Biopsy demonstrates a granulomatous inflammation and mycobacterial organisms. Sputum cultures assessed with mycobacterial DNA amplification may be used to discriminate between differing strains of *Mycobacterium* that can present in the oral cavity. Chest imaging and tuberculin skin testing are required in the assessment of these patients. Treatment typically requires multiple months of combination antimycobacterial therapy until three consecutive posttreatment sputum cultures are negative (34).

IMMUNOLOGIC

Vesiculobullous Lesions

Diagnoses in this category can be divided into oral intramucosal and submucosal bullous diseases. The submucosal diseases include mucous membrane pemphigoid (MMP), bullous pemphigoid (BP), and epidermolysis bullosa acquisita (EBA). The most notable intramucosal disease that is discussed is pemphigus vulgaris (PV).

Mucous Membrane (Cicatricial) Pemphigoid

MMP, also known as cicatricial pemphigoid, is a chronic autoimmune subepithelial blistering disorder. It has an incidence between 1 in 12,000 to 20,000 and is typically diagnosed in the fifth to sixth decade of life. It is more common in women (1.5:1 ratio) and does not appear to have a racial or geographic predilection (16,35).

MMP can affect both cutaneous and mucosal surfaces and varying degrees of presentation. It most commonly affects the oral and ocular mucosa but may also occur in nasopharynx, esophagus, larynx, and urogenital tract (Fig. 51.9). The majority of patients present with a desquamative gingivitis (Fig. 51.10) and mucosal involvement of the buccal mucosa, palate, alveolar ridge, tongue, and lower lip is common.

After bullae present and rupture, irregular-shaped erosions are present. The term "cicatricial" describes the severe

Figure 51. 9 Blistering in the oral cavity seen in MMP.

Figure 51.10 Desquamative gingivitis of MMP.

adhesions that can form with healing. Resultant webs and stenosis can occur within the aerodigestive tract. Up to 40% of patients will develop scarring of the conjunctiva with scleral fusion, entropion, with potential loss of vision (16,35).

On biopsy, a subepithelial separation with inflammatory infiltrate is noted (Fig. 51.11). DIF of perilesional skin shows linear deposition of IgG, IgA, and/or C3 along the epithelial basement membrane zone. Autoantibodies to multiple components of the basement membrane including BP antigen, laminin 5 and 6, and type VII collagen result in the immune response. Indirect immunofluorescence reveals serum autoantibodies binding to the epidermal or dermal side of salt-split skin (16,35).

Patients who present solely with oral lesions have a better prognosis than those in whom a significant cutaneous component also exists. The mainstay for treatment for MMP has traditionally been corticosteroids. Treatment-related side effects have lead to interest in corticosteroid-sparing regimens that have utilized azathioprine, mycophenolate mofetil, cyclophosphamide, and methotrexate. Patients who are unresponsive to conventional treatment options

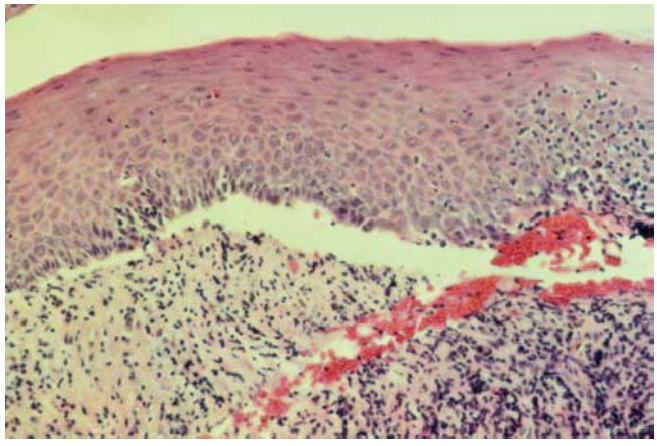

Figure 51.11 H and E histopathology demonstrating the subepithelial split of MMP with resultant blister formation and inflammatory infiltrate.

may be considered candidates for intravenous immunoglobulins, plasmapheresis, and "biologic" therapy (rituximab, etanercept, infliximab) (35,36). Patients require ophthalmology consultation because of the potential complication of symblepharon formation.

Bullous Pemphigoid

BP is a cutaneous subepidermal autoimmune disorder. Oral manifestations can be seen in 10% to 40% of patients and ocular involvement is atypical. BP is uncommon in the United States and is diagnosed most frequently in Europe in patients over 60 years of age (16).

The blistering skin presentation can be widespread and several subtypes of the clinical presentation exist (Fig. 51.12). Onset can be associated with exposure to ultraviolet light, radiation therapy, or as a reaction to selected medications (nonsteroidal anti-inflammatory drugs, antibiotics, etc.).

Diagnostic findings are similar to MMP with DIF studies on biopsy specimens. Treatment alternatives also parallel those offered patients with MMP, yet topical therapies play greater role in management because the advanced age of many patients and the potential side effects with prolonged use of systemic agents. In most patients treated for the condition, the disease remits in 2 to 5 years yet can be life threatening in debilitated patients (16,36).

Epidermolysis Bullosa Acquisita

EBA is a rare bullous condition where autoantibodies develop to type VII collagen of the basement membrane of skin and the mucosa of the upper aerodigestive tract. The inherited form of this disease is called EB. In both conditions, mechanical trauma causes blistering and resultant scarring and severe atrophy of the affected tissues. The scarring and disability seen with EBA is far less than that seen with EB.

Figure 51.12 Cutaneous manifestations of BP.

The clinical presentation of EBA does not manifest until early adulthood and can be easily mistaken for other blistering conditions that present later in life. The diagnosis should be confirmed by biopsy with DIF to rule out other mucocutaneous bullous diseases. High-dose corticosteroids, in combination with other immune-modulating agents, can be effective in addressing these conditions. Unfortunately, the oral scarring and atrophy can lead to debilitating microstomia (37).

Pemphigus Vulgaris

PV is a potentially fatal autoimmune mucocutaneous bullous disease caused by IgG autoantibodies binding to desmoglein 3 and desmoglein 1.

Variants of PV exist and include mucosal-dominant PV (target antigen is desmoglein 3) and mucocutaneous PV (target antigen is both desmoglein 1 and desmoglein 3). The incidence is 1 to 6 per million per year with mean onset at 50 to 60 years of age with a slight female predilection (35). There is a strong association with certain ethnic groups including Ashkenazi Jews and individuals from the Mediterranean and Southern Asia. PV may be seen in association with other autoimmune disorders such as rheumatoid arthritis, myasthenia gravis, systemic lupus erythematosus (SLE), and pernicious anemia (16).

Oral involvement is the hallmark of the clinical presentation of PV and is seen in up to 90% of patients. Most patients present with oral disease for greater than 1 year prior to manifesting to the cutaneous findings of PV. All mucosal surfaces within the body can demonstrate involvement. Lesions present as fluid-filled blisters that break and expose erythematous irregular ulcerated lesions that are painful. The typical oral sites involved include the buccal and palatal mucosa, ventral tongue, and lips (Fig. 51.13). In severe presentations, all sites may be involved and give the appearance of a desquamative gingivostomatitis with cheilitis (Fig. 51.14A and B). Other mucosal surfaces that may be involved include the pharynx, esophagus, conjunctiva, nasal cavity, vagina, penis, and anus (16,35).

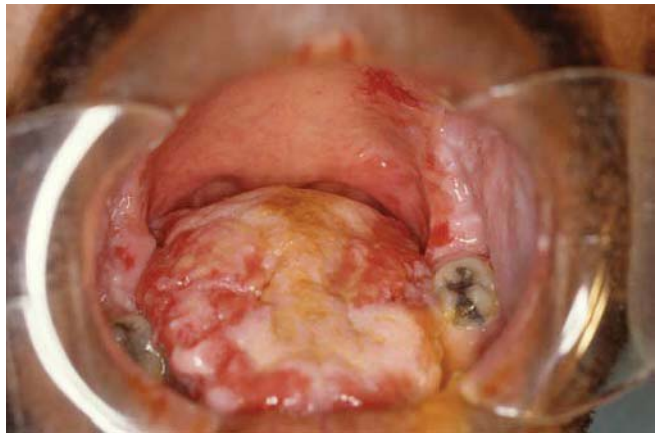

Figure 51.13 Oral findings of PV.

A B

Figure 51.14 Desquamative gingivitis **(A)** and cheilitis **(B)** of PV.

A positive Nikolsky sign, where slight rubbing of the skin or mucous membranes leads to bullae formation or sloughing of epithelium, may be seen. This is the result of the loss of cell-to-cell adhesion through damaged desmosomal proteins and results in bullae formation. The oral epithelium expresses cadherin-type cell adhesion molecule desmoglein 3 to which autoantibodies form. Bullae in PV develop immediately above the basal cell layer (suprabasal bullae). A "tombstone appearance" of a single row of cuboidal basal cells is typically seen below the bullae (16).

Diagnosis is established through a perilesional biopsy that allows for DIF assessment for intercellular deposits of IgG and complement C3. Assays by indirect immunofluorescence microscopy or enzyme-linked immunosorbent assays can assess serum antibody titers (Fig. 51.15) (35).

Systemic immunosuppression with corticosteroids is the mainstay of treatment to achieve control and long-term remission (16). A consensus statement from the International Pemphigus Committee was published 2008 on the definitions of disease and therapeutic response in an attempt to facilitate future clinical advances. The group defined the failure of therapy as the continued development of new lesions, extension of old lesions, or failure of established lesions to begin to heal despite 3 weeks of therapy with 1.5 mg/kg/day prednisone equivalent with or without the following therapies (for 12 weeks): cyclophosphamide 2 mg/kg/day, azathioprine 2.5 mg/kg/day, methotrexate 20 mg/wk, and mycophenolate mofetil 3 g/day. (38).

Pulse therapy of steroids (isolated high-dose noncontinuous dosing) has been postulated as method to decrease the side effects of conventional steroid administration in populations requiring long-term therapy. Mentink et al. assessed the utility of high-dose pulse steroid therapy in PV in a randomized placebo-controlled trial. Dexamethasone was given (300 mg three times per month) in addition to conventional therapy (prednisolone 80 mg/day with taper over 19 weeks and azathioprine 3 mg/kg/day). The trial showed no benefit to pulse therapy compared to placebo in the treatment of PV (39).

In another randomized, double-blind placebo controlled study, dapsone was utilized as a glucocorticoid-sparing agent in individuals unable to tolerate previous steroid taper. Although not statistically significant, dapsone did allow for a decrease in patients' steroid dosing levels. However, because of the expected side effect of methemoglobinemia, patients require close monitoring and were discontinued from therapy if hemoglobin levels fell below 9 g/dL (40).

Additional treatment options for recalcitrant disease are similar to those discussed with MMP and may include

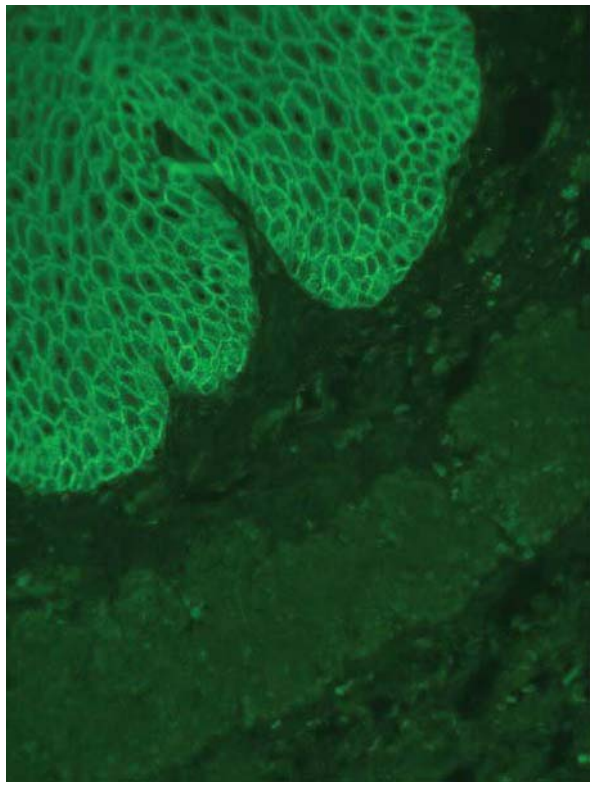

Figure 51.15 DIF microscopy findings seen in PV with cell surface deposition of IgG.

TABLE 51.4 LIST OF NEOPLASTIC AND PROLIFERATIVE CONDITIONS ASSOCIATED WITH PARANEOPLASTIC PRESENTATION OF PEMPHIGUS

Non-Hodgkin lymphoma
Chronic lymphocytic leukemia
Thymoma
Castleman disease
Waldenstrom macroglobulinemia
Hodgkin lymphoma
Monoclonal gammopathy
Systemic mastocytosis
Squamous cell carcinoma—tongue, vagina, skin
Bronchogenic carcinoma
Endometrial carcinoma
Liposarcoma
Poorly differentiated sarcomas
Leiomyosarcoma
Dendritic cell sarcoma
Malignant nerve sheath tumor

plasmapheresis, cyclosporine, or cyclophosphamide (16,35). PV can be fatal if blisters denude large areas of skin and mucous membranes. The mortality has declined to 10% with the use of steroids; however, complications secondary to treatment remain a problem (16).

Paraneoplastic pemphigus can occur as a result of a number of malignancies.

Table 51.4 lists the proliferative conditions associated with this entity. Hematologic neoplasms are responsible for greater than 80% of all presentations (16).

Chronic Ulcerative Stomatitis

Chronic ulcerative stomatitis (CUS) is a rare disease of the oral mucosa that typically presents on the tongue of postmenopausal women as painful nonhealing ulcers. The appearance of the lesions can be mistaken for OLP and biopsy is required to differentiate the two entities. Diagnosis requires direct autoimmunofluorescence studies for autoantibodies to the p63 transcription factor, a member of the p53 family of proteins. The etiology of CUS is unknown. As opposed to lichen planus, which is primarily treated with steroids, CUS is responsive to treatment with antimalarials such as hydroxychloroquine (41,42).

SYSTEMIC CONDITIONS

Lupus

SLE is an autoimmune condition that has a broad range of clinical manifestations including the presentation of stomatitis. Oral ulceration is reported in 5% to 25% of patients with recurrent lesions primarily affecting the palate, buccal mucosa, and gingiva. Oral findings can vary in appearance with focal lesions demonstrating lichenoid or granulomatous changes. Biopsies show epithelial acanthosis with focal basal cell liquefaction and lymphocytic infiltrate. Patients can experience stomatodynia, xerostomia, and recurrent candidiasis. "Lupus cheilitis" involving predominantly the lower lip may also be seen (16,43).

Discoid lupus erythematosus (DLE), a variant of SLE limited to the skin, can present with oral lesions that appear similar to erosive lichen planus (43). The oral lesions of DLE are frequently unilateral yet may be multiple, whereas with lichen planus is typically bilateral and symmetric (37). DIF studies and/or histopathologic examination of cutaneous lesions may aid in differentiating between the two diagnoses (44).

Wegener Granulomatosis

Wegener granulomatosis (WG) is a systemic condition of unknown etiology that is characterized by acute necrotizing granulomas of the aerodigestive tract, a focal vasculitis of small to medium sized vessels, and glomerulonephritis. Oral involvement is characterized by a "strawberry gingivitis" resulting from a friable granular hyperplasia of the gingiva. Erosion of the underlying alveolar bone may result in dental instability and need for extraction. Involvement of the buccal mucosa and palate may also occur but the clinical appearance of these lesions is variable and may mimic aphthous ulceration (43,45). Diagnosis is aided by assay for antineutrophil cytoplasmic antibodies with the majority of WG patients demonstrating c-ANCA positivity.

Crohn Disease

Crohn disease is an inflammatory bowel disease (IBD) of unknown etiology that is characterized by recurring episodic inflammation of the bowel that can result in strictures and fistulae. Greater than 50% of patients present with oral findings that can be nonspecific and include cobblestone changes to the buccal mucosa; granulomatous ulceration; and a firm, painless lip swelling (34,43). Deep linear ulcerations embedded within the base of hyperplastic tissue folds in the gingivobuccal sulcus are considered pathognomonic for the disease (34). The oral lesions typically precede the intestinal lesions by years. Additional potential findings include angular cheilitis or a mucogingivitis with erythematous macules (34,43).

A prospective study by Harty et al. revealed that greater than 40% of patients had oral findings at the time of initial diagnosis of their Crohn disease. A subset underwent biopsy of the oral lesions and noncaseating granulomas were noted in all cases. The authors concluded that the oral cavity could be a source of diagnostic tissue for this disorder but did not demonstrate a correlation between presence of oral lesions and overall disease severity (46).

Colonoscopy is necessary to establish the diagnosis and demonstrates skip lesions that differentiate the Crohn from UC. Laboratory assay is nonspecific (34).

Ulcerative Colitis

UC is an IBD of unknown etiology that is characterized by recurring episodic inflammation of the mucosal layer of the large intestine that is associated with rectal bleeding, colitis, and abdominal pain. Extraintestinal manifestations of disease are common but presentation of oral lesions is more frequent in Crohn than with UC. In one case series, the most common initial presentation of UC was oral aphthae in a patient with anemia (with or without abdominal symptoms) (47).

Patients with UC and Crohn disease may also develop a rare condition called pyostomatitis vegetans. Referred to as a "snail-track," on exam it presents as a line of elevated yellowish pustules on an erythematous mucosa that typically occurs on the buccal and labial mucosa (43). Biopsy demonstrates intraepithelial and subepithelial microabscesses and focal acantholysis. Given that this may be the first sign of an IBD, prompt recognition of this presentation can lead to early evaluation by colonoscopy and initiation of treatment before the onset of abdominal complications. After diagnosis, the clinical course for patients with oral manifestations tends to parallel the activity of the IBD. As a result, a patient's oral examination may be used as a reflection of their response to treatment (47).

Pregnancy

There are several physiologic changes that occur in the oral cavity during pregnancy. "Pregnancy gingivitis" can affect approximately 50% of women with a resultant inflammation and hyperplasia of the gingival mucosa. This can range widely from asymptomatic to severe in presentation with pain and bleeding that can necessitate surgical intervention. Elevated estrogen and progesterone levels are responsible for the increased vascular permeability and decreased immune resistance, which can exacerbate worsening of a preexisting gingivitis (48).

Lobular capillary hemangiomas, also known as pyogenic granulomas, occur in 2% of pregnant women in the oral cavity. They are asymptomatic pedunculated lesions that grow rapidly and bleed easily. Dental plaque and pregnancy-associated gingivitis may trigger the formation of these lesions at any point during the pregnancy and spontaneous resolution after delivery is typically seen (48).

Impetigo herpetiformis, considered by some a variant of pustular psoriasis, is a rare serious condition that can develop the third trimester that is associated with hypocalcemia. This diagnosis has a distinctive cutaneous appearance that initiates on flexural and intertriginous areas of the body and then spreads with erythematous patches and grouped sterile herpetiform pustules that erode and crust. The tongue and oral cavity may become involved with erosive lesions and demonstrate an appearance similar to geographic tongue. The condition continues to worsen during the pregnancy and can pose a significant risk to the fetus and requires early diagnosis, intravenous hydration and treatment with antibiotics, steroids, and may necessitate the induction of labor. Resolution of symptoms is noted to occur rapidly after delivery (48,49).

Oral manifestations of diseases such as PV and Behcet can be exacerbated by pregnancy (48).

Behcet Disease

Behcet disease is a disorder characterized by a classic triad of findings including recurrent aphthous ulceration, uveitis, and genital ulcers. It is most common in the Mediterranean region and in nations along the ancient "Silk Road" (Turkey, Iran, Korea, and Japan). Human leukocyte antigen (HLA) subtype B51 is associated with susceptibility to the disease and a relationship to streptococcal infection has been postulated yet the etiology of this disease remains unknown. The recurrent oral ulcers, typically the first manifestation of the disorder, are painful and can severely limit oral hygiene. This, in turn, can result in an increase in bacterial colonization and worsen the existing ulceration. Oral health (plaque accumulation, probing depth, gingival inflammation, and number of extracted teeth) has been shown to correlate with overall disease severity (50).

The typical oral presentation of Behcet disease is recurrent aphthous ulceration (greater than 3 episodes in 12 months) persisting for up to 6 weeks with each episode. Multiple ulcers of varying sizes with surrounding erythema appear on the soft palate, buccal mucosa, and tongue and can heal with significant scarring. Of note, the ulcerations with Behcet are painful unlike those seen with other connective tissue disorders such as SLE. Mucosal involvement may extend to include the hypopharynx and larynx and result in stenosis. Diagnosis relies on clinical findings and no specific laboratory assay is characteristic of the disorder. Treatment involves topical and systemic steroids with immunosuppressives utilized in severe cases. Low-dose colchicine can effectively aid management of the mucocutaneous manifestation of the disease (51).

Sarcoidosis

Sarcoidosis is a multisystem disorder of unclear etiology. Both genetic and environmental factors appear to play a role in development. Oral findings may be the first evidence of the disease in patients. Submucosal nodular swelling and painless ulceration of the tongue, buccal mucosa, and palate may be seen. Patients may also demonstrate diffuse gingival enlargement. Lupus pernio, presenting a chronic violaceous indurated lesions, may occur on the lips. Biopsy of oral ulcerations will demonstrate noncaseating granulomas and that are nonspecific relative to the differentiation

from other granulomatous disorders. There is no definitive test for sarcoidosis and diagnosis is based on a constellation of signs and symptoms (34,43).

Hematologic Diseases

Cyclic hematopoiesis is a rare disorder that is secondary to episodic bone marrow failure that results in wide fluctuations in neutrophil, platelet, and reticulocyte counts. Patient also experience transient fever, aphthous ulceration and gingivitis, and recurrent skin infections in conjunction with the neutropenia at intervals of approximately every 3 weeks. It most commonly occurs in children and resolve with age but may also present in adults (1).

Stomatitis may be associated with any of the leukemias but is most common with acute and myeloid presentations (1). Oral findings parallel the hematologic disturbance of the individual patient such that oral petechial hemorrhages of the palate are seen with thrombocytopenia and deep mucosal ulcerations and candidiasis will occur in the neutropenic patient. Gingival hyperplasia from the infiltration by the malignant cells of leukemia or lymphoma can also be seen (1,43).

NUTRITIONAL

Malnutrition and Deficiencies

Iron-deficiency anemia can present with angular cheilitis and atrophic glossitis. With the development of atrophic glossitis, the dorsal surface of the tongue appears smooth and red with the loss of fungiform and filiform papillae. The clinical presentation may be preceded by glossodynia. These findings are seen in the setting of a microcytic, hypochromic anemia in conjunction with decreased serum iron and ferritin and elevated total iron-binding capacity (1,52).

Plummer-Vinson syndrome is a rare disorder that presented with a spectrum of iron-deficiency anemia, dysphagia, and esophageal strictures in middle aged women who were associated with an increased risk of oropharyngeal cancer. The iron deficiency associated with the syndrome would result in patients presenting with glossitis, glossodynia, and angular cheilitis at the time of evaluation (1).

Megaloblastic anemia occurs as a result of B12 or folate deficiency and may present in the elderly or in individuals on a vegetarian diet. It may also be seen in patients with HIV, with pernicious anemia, and with gastrointestinal disorders. Patients will typically present with atrophy of oral mucosa, glossitis, and angular cheilitis (1,52).

Water-soluble vitamins that impact the health of the oral mucosa are B2 (riboflavin), B3 (niacin), B6 (pyridoxine), B9 (folic acid), B12 (cyanocobalamin), and C (ascorbic acid). The water-soluble vitamins require regular intake or supplementation because of the lack of durable storage within the tissues that is seen with fat-soluble vitamins. Patients with a deficiency of one of the various B vitamins can present with atrophic glossitis, glossodynia, and angular cheilitis. Vitamin C deficiency presents with mucosal petechiae and hemorrhagic gingivitis with hypertrophy (1).

IDIOPATHIC

Recurrent Aphthous Stomatitis

RAS is defined as recurrent ulcers confined to the mouth and seen in the absence of systemic disease. RAS typically first appears in childhood and abates by the third decade of life (53). There is a familial tendency with a HLA predilection (53). The reported prevalence ranges from 5% to 21% and a lower incidence is noted in smokers (2,22). It is more common in women, in Caucasians, and in people of high socioeconomic status (2).

Independent risk or causative factors of RAS have not been clearly established in population-based studies. The causative factors for an outbreak include trauma, food products (chocolates, nuts tomatoes, and wheat), stress, medications (NSAIDS, beta blockers, ACE-I), and vitamin deficiencies (B1, B2, B6, folate, zinc, and iron) (2,53). No relationship exists to herpes simplex infection. It is thought to be related to both cell-mediated immunologic causes and antibody-dependent cell-mediated cytotoxicity.

On clinical presentation, pain typically exceeds the size of the lesions that may be found on the buccal mucosa, ventral tongue, floor of mouth (Fig. 51.16), labial mucosa, soft palate, and tonsillar fossa. The lower vestibule most commonly affected and a predilection for nonkeratinized and mobile tissue is noted (2,53). The time between episodes could vary from weeks to months. Patients typically have one ulcer but may have up to three ulcers at any one time. Table 51.5 demonstrates a severity scale for RAS that can be used to qualify presentations (54).

The common ulcers of RAS are classified as minor, major, and herpetiform aphthae. Minor aphthae represent 80% of cases are less than 1 cm (2,22,55). Major aphthae are 1 cm

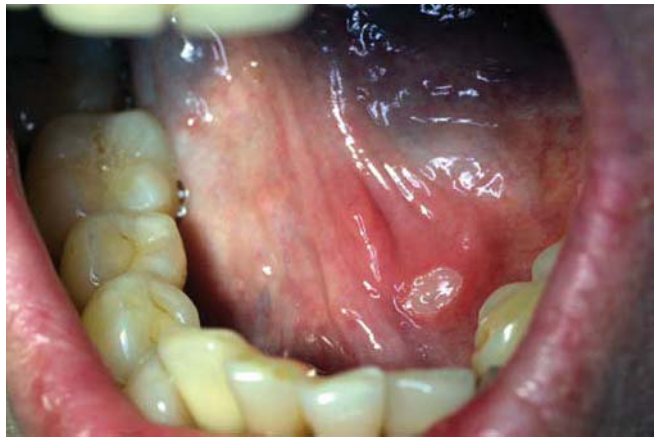

Figure 51.16 RAS ulcer on the floor of mouth.

TABLE 51.5 GRADES OF RAS

Grade	Severity	Findings
1	Mild	Limited number of ulcers with infrequent presentation. Mild functional impairment and pain. Near-normal oral intake
2	Moderate	Intermediate frequency and number of oral ulcers with moderate functional impairment and pain. Modest impact on oral intake with increasing social embarrassment
3	Severe	Frequent presentations with numerous ulcers resulting in major functional disability, severe dysphagia/odynophagia

Adapted from Hello M, Barbarot S, Bastuji-Garin S, et al. Use of thalidomide for severe recurrent aphthous stomatitis: a multicenter cohort analysis. *Medicine (Baltimore)* 2010;89(3):176–182.

or greater in size. Healing with simple recurrent aphthae occurs spontaneously in 10 to 14 days, and unlike vesiculobullous disease, the ulcers heal without scarring (53).

"Herpetiform" or clusterform aphthae (Fig. 51.17) are a misnomer given the lack of relationship to HSV. They are less common than simple recurrent aphthae. Patients exhibit multiple lesions at presentation (upward of 20) that may coalesce into what appears to be individual larger ulcers. Ulcers are not indurated and patients may be febrile during presentations. Lesions tend to be present more commonly than the intermittent presentation seen with simple aphthae. Treatment includes topical steroids in a cream or mouthwash (or use a tetracycline mouthwash if febrile).

An uncommon form of presentation includes craterform ulcers. These may last for months and are associated with deep necrosis and scar formation. Patients are febrile with adenopathy and very symptomatic during presentations. Acute episodes require oral antibiotics and steroids and patients may be transitioned to topical therapy between outbreaks.

Figure 51.17 Herpetiform RAS of ventral tongue.

The differential diagnosis for patients with recurrent oral ulceration is wide and requires careful consideration for alternative diagnoses. Recurrent HSV, Behcet disease, erythema multiforme (EM), periodic fevers with aphthous stomatitis, pharyngitis, and adenitis (PFAPA), Crohn disease, and UC may all present clinically with oral findings suggestive of RAS (2).

As with many sources of stomatitis, the mainstay of treatment of symptomatic patients includes the use of steroids. When using topical steroids, triamcinolone acetonide with Orabase is not considered as effective as more potent glucocorticoids, such as clobetasol propionate (0.05%) or fluocinonide (0.05%) (2). Perilesional injection of steroid is also an option for solitary major aphtha.

Treatment of patients with RAS also requires counseling on the avoidance of potential triggers, advocating for good oral hygiene, use of topical anesthetics for symptom control, and use of antimicrobial mouthwashes such as tetracycline or chlorhexidine. For more severe presentations, systemic therapies are varied and include oral steroids, colchicine, dapsone, clofazimine, levamisole, pentoxifylline, thalidomide, infliximab, and etanercept (2). However, it should be noted that few adequately powered clinical trials have tested the efficacy of therapeutic agents for RAS (53).

In a randomized, double-blinded, placebo controlled trial of pentoxifylline for RAS only a limited benefit with decrease in mean ulcer size was noted. The authors concluded that pentoxifylline may have a role in patients unresponsive to other treatment options but should not be considered first-line treatment for RAS (55).

In a double-blinded placebo controlled trial, vitamin B_{12} was assessed as a treatment option for RAS. Sublingual B12 (1,000 mcg) was given for 6 months. Significant improvement was noted regardless of serum levels of B12. During the last month of treatment, 74% had attained "no aphthous ulcer status" ($P < 0.01$) (56).

In a double-blinded randomized clinical trial, colchicine (0.5 mg/day) was compared to low-dose prednisolone (5 mg/day) for RAS. The study included a 3-month trial with 2-week assessment intervals. Both therapies were found to significantly reduce the presentation of RAS. However, less side effects were noted in the prednisolone group and it was considered by the authors to represent a better alternative for patients with frequent recurrence (57).

An uncommon variant of RAS is termed severe recurrent aphthous stomatitis (SRAS), also known as Sutton disease, that presents with overlapping attacks of craterform oral ulceration with deep necrosis (Fig. 51.18). Patients may be febrile with lymphadenopathy during episodes. SRAS also differs from RAS in that the time to healing is significantly longer and may result in problematic oral scarring. The effect on quality of life can be devastating as speech and swallowing are profoundly affected (54).

Figure 51.18 Crateriform ulcer of SRAS.

In a multicenter retrospective cohort study, thalidomide was found to be effective with 85% entering a complete remission within a median of 14 days of the start of treatment. Treatment was not without side effects with 84% of patients such as adverse events including somnolence (36%), paresthesia (18%), constipation (18%), and weight gain (16%). One in five adverse events was considered severe and included peripheral neuropathy, thromboembolism, and teratogenicity. After 40 months, 60% of patients were still receiving continuous or intermittent therapy.

The authors advocate the benefit of a low-dose maintenance regimen that appears to be effective and well tolerated in patients with SRAS (57).

Recurrent aphthous ulcers can be severe and refractory to treatment in patients with HIV. In some cases, HAART is the best treatment for intractable aphthous stomatitis in this setting (58).

Oral Lichen Planus

OLP is a chronic systemic disease of the skin and mucosal surfaces of unknown etiology. CD8+ T-cell-mediated autoimmune damage of epithelial basal cells is considered the mechanism of this disorder. The pathogenesis remains unclear (19,37,44). OLP occurs in 0.5% to 2.2% of the population and most commonly affects women over that age of 40 (37,44). OLP represents 9% of all white lesions affecting the oral cavity (37,44). It is a clinical diagnosis that may require histopathologic evaluation via biopsy in order to distinguish from dysplasia (37). The hypothetical risk of malignant transformation is controversial yet is considered to be very low (37). No association exists with OLP and habitual alcohol or tobacco use. Most patients diagnosed with OLP will not have associated CLP or involvement at any other mucosal sites in the body (44).

OLP most commonly affects the buccal mucosa (90%) but may also affect the dorsum of tongue, gingival, labial mucosa, and lower vermillion lip (Fig. 19A and B). With most cases of OLP, there are typically multiple lesions that are bilateral and symmetric. It may develop in sites of trauma in what is described as Koebner phenomenon (19). There are multiple described clinical presentations of OLP in the oral cavity and include reticular, popular, plaque-form, atrophic, ulcerative, and bullous forms (37).

OLP can be classified as reticular (white 23%), erythematous (atrophic 40%), and erosive (bullous, ulcerated 37%) (19). The reticular form is usually asymptomatic and exam reveals interlacing white lines (Wickham striae) on the buccal surface (Fig. 51.20). A variant of OLP, erosive OLP, demonstrates atrophic areas with erythema and varying degrees of ulceration and can present similar to desquamative gingivitis (19,22).

The differential diagnosis of OLP always includes oral lichenoid lesions, which can be caused by allergic reactions to dental restorative materials, drug reactions to certain medications, GVHD, or DLE (37). When biopsy is performed, OLP and oral lichenoid reactions share similar histologic features (dense of lymphocyte infiltration at the epithelium–connective tissue interface) and does not differentiate the two diagnoses (Fig. 51.21) (19).

CLP classically presents as pruritic, purple, polygonal, flat-topped papules, and plaques with predilection for the flexural wrists, dorsal feet, and pretibia. CLP does not preclude the finding of oral lesions and greater than 50% of patients with CLP will also have findings of OLP (19). It should be noted that a number of immune-mediated inflammatory dermatoses also cause notable oral manifestations, in addition to their more recognizable skin symptoms, and can be confused with CLP (37).

OLP is seen in 2.3% chronic hepatitis C patients and has been questioned as an extrahepatic manifestation of hepatitis C. In a study examining OLP and chronic hepatitis C in the general population of Brazil, a statistically significant relationship was noted between the two entities. However, other reports in literature dispute this association. Some authors advocate oral exam on hepatitis C patients and consideration for hepatitis C screening on OLP patients. Treatment of hepatitis C with IFN may induce or worsen lichen planus (59).

OLP runs its course over an average of 8 years, but can persist for decades. It often "burns out," but can leave the patient with permanent mucosal scarring. The risk of malignant transformation of lichen planus is very controversial because it has proven very difficult to measure, but is likely quite low. A high index of suspicion is necessary, however, on the part of the clinician, when lesions appear or behave atypically (37).

There is no cure and treatment is given to reduce the pain associated with presentation. Treatment should address oral hygiene and potential etiologies and include elimination of irritants, such as rough edges on dental restorations, spicy or acidic foods, and minimizing bacterial plaque with alcohol-free rinses (19,37). The aim of pharmacologic therapy is to control, rather than cure, the disorder. Reticular OLP does not typically require biopsy and may be treated with topical steroids if symptomatic (22).

Figure 51.19 OLP of the right buccal mucosa **(A)** and tongue **(B)**.

A variety of topical corticosteroids are available with variable efficacy. Preparations that contain adhesives with a steroid, such as triamcinolone in Orabase, will be more effective due to longer contact time with the affected mucosa. Candidal overgrowth can occur with the use of these agents. Systemic steroids can be used either as a high-dose short-term pulse or as a long-term low-dose to complement topical steroids (37,44).

Use of steroid-sparing agents, such as retinoids, topical cyclosporine, topical retinoids, topical calcineurin inhibitors and dapsone, have been reported but side effects may limit its use (19). Levamisole monotherapy is a treatment option for patients with chronic OLP who cannot take steroids (e.g., patients with diabetes, hypertension, malignancy) and has historically been used in combination with steroid therapy (60).

A Cochrane Collaboration review on the topic found that only a few therapies have ever been compared against placebo and no single agent's effectiveness has been confirmed in separate studies (61).

"Burning Mouth" Syndrome

Primary burning mouth syndrome (BMS) is an idiopathic condition associated with a deep burning sensation of the oral mucosa with a lack of identifiable dental or medical pathology lasting for at least 4 to 6 months (62). The burning sensation is noted on the tongue in the majority of patients yet other affected areas include the palate (hard and soft), buccal mucosa, floor of mouth, and lips (63). Patients may also complain of oral dryness or alteration in taste. Symptoms can worsen with stress and exposure to hot food products and may improve with relaxation (62). There is a 7:1 female to male ratio and 90% of sufferers are perimenopausal women (62,63).

There are multiple diagnoses that may present with oral burning (secondary BMS) and include local malignancy, gastroesophageal reflux disease, hormonal disorders, nutritional abnormalities, and infection (Table 51.6). Diagnoses or treatments that result in xerostomia may predispose to the development of BMS.

Assessment of patients with a suspected diagnosis of primary BMS requires a full history and physical examination. A laboratory profile including a CBC, hemoglobin A1c, liver and thyroid function tests, iron, ferritin, vitamin B6/B12/D levels, ESR, ANAs, oral *Candida* swab, and antibodies to *Helicobacter pylori* can be used to fully assess these patients for alternative etiologies.

Reported treatment options are multiple and have included benzodiazepines, amitriptyline, paroxetine, gabapentin, and various topical agents (42). In a Cochrane Collaboration review, Zakrzewska et al. (64) found there was insufficient evidence to show the effect of painkillers, hormones, or antidepressants but there is some evidence that learning to cope with the disorder, anticonvulsants, and alpha-lipoic acid may help. Other authors have demonstrated a lack of efficacy of alpha-lipoic acid in this setting (65). Clonazepam is the only topical treatment studied in prospective double-blind, randomized fashion and has demonstrated efficacy in the reduction in the burning sensation in over one-half of patients treated (63). Treatment should include addressing any underlying xerostomia and psychiatric consultation is advocated (62,63).

The etiology of BMS is an area of debate. The most likely explanation is that it is neuropathy; however, it is unclear as to whether it represents a central or peripheral lesion. It has also been suggested that it may be variable in presentation (some patients central, some peripheral) as assessed by local lidocaine injection assessment. There is also an association of BMS and psychiatric diagnoses, such as depression and anxiety, which are seen in approximately one-half of all patients (62,63).

In terms of prognosis, 30% experience improvement of symptoms and 3% have spontaneous remission within 5 years of onset. Most patients have persistent symptoms for multiple years (62).

TABLE 51.6 ETIOLOGIES OF SECONDARY "BMS"

Classifications	Specific Causes
Contact allergy	Metals, acrylics
Dental	Recent procedure, dentures, poor hygiene
Infectious	*Candida*, bacterial, viral
Inflammatory	OLP, erythema migrans
Neoplastic	Squamous carcinoma, perineural invasion
Autoimmune	Sjogren, lupus
Endocrine	Diabetes, estrogen deficiency
Gastrointestinal	Reflux, Crohn
Pharmacologic	ACE inhibitors, antibiotics, antidepressants, diuretics, antiretrovirals, chemotherapy
Neurologic	Trigeminal neuralgia
Nutritional deficiency	Iron, B vitamins, folate, zinc
Depression	Various
Anxiety	Various

Adapted from Togerson RR. Burning mouth syndrome. *Dermatol Ther* 2010;23(3):291–298.

Orofacial Granulomatosis

Orofacial granulomatosis (OFG) is the term used for a number of conditions with similar characteristics and includes Melkersson-Rosenthal syndrome and Miescher cheilitis. The etiology is unclear and the entity is usually considered a diagnosis of exclusion after differentiation from similar entities such as Crohn disease and sarcoidosis (34,66).

Atopy is found in 12% to 60% of patients suggesting a relationship to a hypersensitivity disorder. The most frequent feature of this disease is persistent painless swelling of the orofacial tissues. This is most commonly manifested in the lips and may lead to vertical fissuring. The intraoral mucosa may develop diffuse edema, erythema, ulceration, and/or papule formation. In Melkersson-Rosenthal syndrome, patients present with fissured tongue, facial paralysis, and orofacial edema. Miescher cheilitis, also termed cheilitis granulomatosis, is characterized by chronic lip enlargement with granulomatous infiltration and lymphatic obstruction. Biopsy of OFG lesions will show noncaseating granulomas. Extensive testing is often needed to distinguish OFG from other granulomatous and allergic processes. Treatment can be challenging and is characterized by frequent recurrences. Local and systemic steroids are routinely used, although immunosuppressives have been used in refractory cases (34,66).

Erythema Migrans

Erythema migrans, also known as geographic tongue or benign migratory glossitis, has a reported incidence of approximately 3%. The etiology is unknown; however,

there is an association with atopy and psoriasis. The condition typically waxes and wanes and presents on the anterior two-thirds of the tongue. It is characterized by central erythema with surrounding raised yellow–white margins caused by nonuniform atrophy of filiform papillae of the dorsal tongue. Oral pain can be experienced with selected food products (acidic or spicy), but otherwise the condition is asymptomatic. Erythema migrans is more common in women and there is no uniformly effective treatment (22).

STOMATITIS UNIQUE TO CHILDHOOD

Marshall Syndrome

Marshall syndrome, also known as PFAPA, is a clinical syndrome of unknown etiology seen in children less than 5 years of age that present with periodic fever, aphthous stomatitis, pharyngitis, and adenitis. The periodic fevers of PFAPA recur every 3 to 6 weeks and the syndrome typically lasts for over 4 years. PFAPA is a diagnosis of exclusion and the differential includes cyclic neutropenia, hereditary periodic fevers, and Behcet disease (67).

Medical treatment has included steroids and cimetidine. Tonsillectomy has been advocated as an option to improve symptom control and may be considered in patients for which medical management is unsuccessful. In one study eight of nine patients experienced complete remission of symptoms within 3 months of tonsillectomy (67).

Traumatic Eosinophilic Granuloma/Riga-Fede Disease

Ulceration of the ventral surface of the tongue and/or lingual frenulum can be seen in newborns due to neonatal teeth. The ulceration can lead to the development of a fibrotic mass that is described as a traumatic ulcerative granuloma with stromal eosinophilia. This finding can be seen in infants with a tongue-thrusting habit or associated with familial dysautonomia (insensitivity to pain). Treatment involves filing or removal of the offending tooth, application of topical steroids to the oral lesion and may necessitate removal if an enlarged fibroma is present (68,69).

MULTIFACTORIAL

Erythema Multiforme

EM represents a spectrum of overlapping immune-mediated mucocutaneous diseases that are classified into four forms: EM minor, EM major, Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN). All forms of EM have an abrupt onset. Regardless of the inciting event, the common pathway for all of these conditions includes apoptosis and necrosis of the basal keratinocytes as a result of cytotoxic CD8+ T cells (37).

EM minor is defined by cutaneous involvement with classic "target" lesions. Hemorrhagic crusting of the lips is common and oral mucosal involvement with ulceration is seen in 25% of patients. EM major involves lesions of the skin, oral mucosa, and at least one other mucosal site apart from the oral cavity. The oral mucosal involvement is more prominent than that seen with EM minor and the length of the episode is longer (up to 6 weeks duration). Both of these two conditions are self-limited and usually caused by underlying infection from HSV-1, HSV-2, or *Mycoplasma pneumoniae* (16,37).

SJS is a severe form of EM and is characterized by stomatitis, conjunctivitis, and multiform skin lesions that can involve greater than 10% of the total body surface area. Oral findings include vesiculobullous lesions that rupture and result in painful ulcerations. SJS has a reported 10% mortality (37).

TEN is the most aggressive form of EM and involves epidermolysis of greater than 30% of the body surface area. Oral and pharyngeal involvement is common, and may result in extensive scarring. TEN has a reported 30% mortality (37).

Both SJS and TEN are the result of adverse drug reactions especially to anticonvulsants such as carbamazepine, phenytoin, phenobarbital, and sodium valproate (34,46). EM drug reactions have also been reported with sulfonamides, oxicam-type NSAIDS, pantoprazole, allopurinol, and tramadol (70).

DIF may be used to differentiate the presentation from other bullous conditions, but otherwise the diagnosis is based on clinical findings. After establishing the correct diagnosis, treatment is centered on determining the etiology of the presentation. With EM minor and major, if an infectious etiology is identified, therapy can be initiated. If an offending drug associated with SJS or TEN is identified, discontinuation is imperative. The extent of supportive care for the mucosal and cutaneous lesions matches the severity of the individual episode and the selective use of systemic corticosteroids can be considered (37).

SUMMARY

The presentation of stomatitis represents a wide spectrum of potential etiologies. A detailed history of presentation and assessment of associated conditions is critical in the diagnostic evaluation of these patients. Clinical presentations of a single diagnosis can vary widely between patients and making recognition on exam challenging.

Clinicians should remember that many of these diagnoses will require the collaborative management of the patient with other branches of medicine and that these colleagues can also be utilized in the diagnostic evaluation of the complicated patient without a clear etiology. Although some of the causes of stomatitis may be treated for cure, many are associated with chronic conditions where symptom control remains the focus of care.

HIGHLIGHTS

- As a result of the rapid turnover of oral epithelial cells, oral lesions may be the first manifestation of systemic disorders, such as sarcoidosis, Behcet disease, and IBD. Unfortunately, these oral lesions are often nonspecific to the disease entity.
- Mucositis remains a formidable challenge for patients undergoing radiation and/or chemotherapy, particularly as treatment regimens become more aggressive. Research efforts continue to focus on prevention, as this has been more successful than identifying new treatments. Overall, there is still a lack of data on effective therapies.
- *Candida* remains one of the most common forms of stomatitis seen in practice. Its incidence is rising due to increased numbers of chronically immunosuppressed patients and other factors. It has multiple varied presentations in the oral cavity, some of which can be challenging to recognize. Multiple treatment options exist, although resistant strains are becoming more common.
- Aphthous stomatitis can be a bothersome, although ultimately self-limited, process. The etiology remains unclear, although many aggravating factors and irritants have been described. Topical, systemic, and intralesional steroids are the cornerstone of treatment, although steroid-sparing agents have been used in severe and refractory cases.
- A number of vesiculobullous conditions present with oral cavity lesions. They can be differentiated on the basis of clinical course as well as direct and indirect immunofluorescence. Investigations into steroid-sparing agents for PV and BP have had promising results. The EM spectrum of diseases requires intensive supportive care for pain, dehydration, and prevention of secondary infection.
- Patients with HIV develop many of the same forms of stomatitis as the general community, but often require more intensive treatment, and earlier use of systemic, as opposed to local therapies. Institution of HAART in previously untreated HIV patients will ameliorate many forms of stomatitis found in this population.

ACKNOWLEDGMENTS

Appreciation is extended to the Tufts University School of Dental Medicine, Department of Oral and Maxillofacial Pathology for assistance with figures for this chapter.

Pharyngitis

52

Stephen R. Hoff *Kay W. Chang*

Pharyngitis refers to inflammation of the pharyngeal mucosa, lymphoid tissue, musculature, and surrounding fatty and fascial tissues. This can be infectious or noninfectious, and can herald more extensive systemic diseases such as autoimmune disease or immunocompromise with human immunodeficiency virus (HIV). Acute pharyngitis is one of the frequent common causes of visits to a physician or health care provider, with over 15 million office visits per year for streptococcal pharyngitis alone (1). Approximately one-third of patients with upper respiratory infection (URI) have sore throat as the chief complaint. The abundance of lymphoid tissue in the pharynx, and the constant communication with the outside world during respiration, leads to the frequency of pharyngitis, and accounts for many of the symptoms.

Pharyngitis typically presents with sore throat, with odynophagia and dysphagia. This may be accompanied by fevers, hoarseness, nasal congestion, cough, halitosis, and malaise, depending on the etiology. Although there is a wide range of possible diagnoses, an accurate assessment of the time course, symptoms, and associated physical exam findings can rapidly and efficiently narrow the differential diagnosis (Tables 52.1 and 52.2). Viral infections are the most common cause of pharyngitis in both children and adults, but pediatric patients have a much higher rate of bacterial infection than adults (30% to 40% and 5% to 15%, respectively) (2,3).

Generally, most patients are treated supportively for the symptoms of pain and dysphagia, but antibiotics may be used when bacterial infection is suspected, or with opportunistic infections in the immune-compromised host. Of paramount importance is distinguishing pharyngitis from an acute infection with abscess formation, including peritonsillar, retropharyngeal, and parapharyngeal abscesses, which require more aggressive management. These are discussed further in Chapter 55. The symptoms of a pharyngeal malignancy may also mimic the clinical presentation of pharyngitis, and a high index of suspicion on the part of the physician is necessary, with biopsy and histologic examination as warranted.

Although there is overlap, the presentation and etiology of pharyngitis is different in the child and the adult. Therefore, this chapter discusses them separately, with a focus on the more common clinically encountered pathologies. Because adolescents tend to have pharyngitis profiles similar to adults, the pediatric section is specific to children less than 14 years of age. Adenotonsillar-specific disease, which obviously overlaps with pharyngitis, is discussed in Chapter 95.

ANATOMY

Anatomically, the pharynx has three divisions: the nasopharynx, oropharynx, and hypopharynx. These divisions are contiguous with each other, but contain different amounts of lymphoid tissue and unique specialized structures, and so are a helpful clinical distinction. The mucosal lining of the pharynx transitions from respiratory epithelium (pseudostratified ciliated) to stratified squamous from superior to inferior.

The nasopharynx is bounded by the nasal cavity and choanae anteriorly, soft palate inferiorly, sphenoid rostrum superiorly, and clivus posteriorly. The adenoidal lymphoid tissue sits on the roof of the nasopharynx, and is typically largest in children 5 to 7 years old. This may lead to obstruction between the nasal cavity and nasopharynx, with rhinorrhea, sleep apnea, and "adenoid facies" as a result. Typically, the adenoids begin to regress in late childhood, and are nearly absent in the adult. Presence of prominent adenoids in the adult should lead the physician to suspect pathologies such as HIV, lymphoma, or malignancy, and biopsy or testing may be warranted. Posterolaterally, the nasopharynx contains the eustachian tube orifices and associated muscles (salpingopharyngeus, levator veli palatini) and torus tubarius cartilage. Rosenmüller fossa (pharyngeal recess) is

located adjacent to the medial part of the eustachian tube orifice in the nasopharynx, and contains a small amount of lymphoid tissue known as Gerlach tonsil.

The oropharynx is bounded by the circumvallate papillae anteriorly, and contains the lingual tonsil of the posterior one-third of the tongue. Laterally, it is bounded by the pharyngeal tonsils, which are supported by the palatoglossus and palatopharyngeus muscles. The tonsillar capsule sits on the superior pharyngeal muscle, with the peritonsillar space between them. Together, the pharyngeal, lingual, and adenoidal tonsils form Waldeyer's ring. Just deep to the superior pharyngeal muscle sits the glossopharyngeal nerve, which can transmit the pain and odynophagia of inflammation during pharyngitis and tonsillitis.

The hypopharynx extends from the level of the hyoid bone to the inferior border of the cricoid cartilage, where it meets the cervical esophageal introitus, and contains the pyriform sinuses, postcricoid region, and posterior pharyngeal wall. The superior, middle, and inferior constrictor muscles form the open-tubed structure of the pharynx, and fuse in the posterior midline at the pharyngeal raphe. Due to this raphe, retropharyngeal abscesses form posterior to the constrictor muscles and tend to be bounded to one side of the retropharynx without crossing the midline. There are several important muscular/fascial layers and spaces between the pharyngeal wall and vertebrae. From anterior to posterior these are: the buccopharyngeal fascia (covering of pharyngeal constrictor muscles), retropharyngeal space, alar fascia, "danger space," prevertebral fascia, prevertebral space and musculature, and bony vertebral body. The deep spaces of the neck are covered in more detail elsewhere in this text.

Innervation of the pharyngeal musculature is via the vagus nerve through the pharyngeal plexus, except the stylopharyngeus muscle is innervated by the glossopharyngeal nerve. The arterial supply of the pharynx is mainly from the external carotid branches, including the ascending pharyngeal arteries, dorsal lingual arteries, tonsillar branches of the facial arteries, and palatine branches of the maxillary arteries. In the posterior pharyngeal submucosa, there is an extensive venous plexus, which drain inferiorly into the internal jugular veins. Lymphatic drainage from the pharynx is via the retropharyngeal, lateral pharyngeal, and deep jugular nodes.

INFECTIOUS CAUSES OF PHARYNGITIS IN THE CHILD

BACTERIAL

Streptococcal Pharyngitis

The most important distinction to make in a child with acute pharyngitis is to determine whether the etiologic agent is Group A Beta-Hemolytic Streptococcus (GABHS) a.k.a

Streptococcus pyogenes. This is the only common pathogen that necessitates the use of antibiotics (4). The overuse of antibiotics in pharyngitis from other pathogens, usually viral, should be avoided, with the exception of the rare bacterial infections. Treatment with antibiotics for GABHS will shorten the patient's symptoms by 24 to 48 hours and reduce infectivity as well as suppurative complications, but the most important reason to give antibiotics is to prevent late sequelae (rheumatic fever and rheumatic heart disease) (2–8). Because the symptoms of viral and bacterial pharyngitis are similar, and physicians using clinical judgment have been shown to overestimate the occurrence of GABHS, laboratory testing is required in pediatric patients (1,4,5,7).

GABHS infection is common in the 5- to 15-year-old age group, with a peak incidence during the early school years, and a decline in incidence in late adolescence and adulthood. In temperate climates, it is most common in the winter and early spring months (4,7). GABHS accounts for 20% to 30% of cases of pharyngitis in children, compared to 5% to 15% in adults, and is rare in patients less than 2 to 3 years (2). According to a 2008 study, the economic burden from pediatric streptococcal pharyngitis in the United States is estimated between $224 and $539 million per year, with most of the cost attributed to parent's time off from work (9). In addition to GABHS, infection with other serogroups of streptococcus is possible but much less common. These include Streptococcus C and G, which have been responsible for foodborne and waterborne outbreaks of pharyngitis, but with generally less severe symptoms than GABHS (8).

The incubation period for streptococcal pharyngitis is 1 to 4 days, after which patients will develop rapid onset of severe sore throat and odynophagia, with fevers, malaise, and possibly headache and gastrointestinal (GI) symptoms, such as abdominal pain and vomiting. In general, viral symptoms, such as cough, coryza, and nasal congestion are absent, and the presence of these symptoms makes the diagnosis of GABHS less likely. Tender, enlarged cervical lymph nodes are common. Pharyngeal examination shows erythematous oropharyngeal mucosa, including a beefy red uvula and possibly soft palate petechiae. Tonsils are also erythematous and inflamed, and may have a whitish, creamy exudate. Infants often have red, excoriated nares, with minimal rhinorrhea. Occasionally, patients will have a characteristic "scarlet fever" rash, consisting of fine, blanching, erythematous papules beginning on the trunk and spreading to the extremities, with sparing of the palms and soles (3). This rash has a texture like sandpaper, and will last 6 to 9 days. In addition to the rash, enlarged tongue papillae with erythema (strawberry tongue) may be present, with circumoral pallor. Infants and children less than three with GABHS tend to present predominately with irritability, fevers, and abdominal symptoms, such as vomiting.

Diagnosis of GABHS depends on clinical judgment and laboratory testing, and there are several different clinical guidelines available. A scoring system has been developed and validated, which assigns points for symptoms consistent with GABHS, and may help determine the risk of GABHS in each patient (10). All guidelines recommend against further testing if the patient does not have symptoms typical of GABHS. However, physicians have been shown to overestimate the incidence of GABHS, and overtreat with antibiotics (10). Therefore, in patients less than 15 years of age, with typical symptoms of sore throat, fever, adenopathy, and inflamed pharynx, laboratory testing should always be performed. The gold standard laboratory test is a pharyngeal swab, with culture on a blood-agar plate, which has a sensitivity of 90% to 95% (7,10). Throat swabs should be taken from bilateral tonsils and the posterior oropharyngeal wall, and not the oral cavity. However, culture results typically take greater than 24 hours to obtain, and a "rapid-strep" (rapid antigen detection test, RADT) has been developed. RADT results are available in 5 to 10 minutes, which allows for immediate antibiotic treatment of a positive result. Unfortunately, traditional RADT tests only have a sensitivity of 80% to 90%, making a false-negative result more likely (5,6,11). Newer RADT, which use optical immunoassays and chemiluminescent DNA probes, are 90% to 99% sensitive, but these are more expensive and may not be available. Therefore, a reasonable approach to the pediatric patient with sore throat is as follows: If the patient has symptoms typical of GABHS (fever, sore throat, lymphadenopathy), RADT should be performed in the office. If positive, the patient is started on antibiotic therapy immediately. If negative, a throat culture is obtained, and the patient is discharged home with a prescription for oral antibiotics. If the culture is positive, the patient is informed to fill the prescription and start therapy; if negative, they do not fill the prescription and are treated symptomatically. Practitioners should rely solely on the RADT if they have independently verified that their RADT has sensitivity greater than 90% (Fig. 52.1).

Penicillin or amoxicillin, which is more palatable for children, is an effective treatment for GABHS. First-generation cephalosporins, azithromycin, or clindamycin may be used in patients with penicillin allergy (1,6). Corticosteroids have not been proven to have benefit in acute streptococcal pharyngitis (12). Patients are not considered contagious after 24 hours of antibiotics, and should be allowed to return to school and regular activities at that time. If untreated, the GABHS pharyngitis is typically self-limited, with symptom resolution at 8 to 10 days, although throat cultures may be positive for up to 6 weeks in 50% of patients (8). Patients are considered contagious during the acute illness and 1 week thereafter if not treated (3). Testing or treatment of close contacts is generally not warranted, except in cases with recurrent pharyngitis between family members, or severely invasive strains of GABHS (e.g., necrotizing fasciitis). In children with recurrent strep throat and tonsillitis, tonsillectomy with or without adenoidectomy may be of benefit.

Approximately 10% of patients are considered carriers of GABHS, and will have positive strep testing without

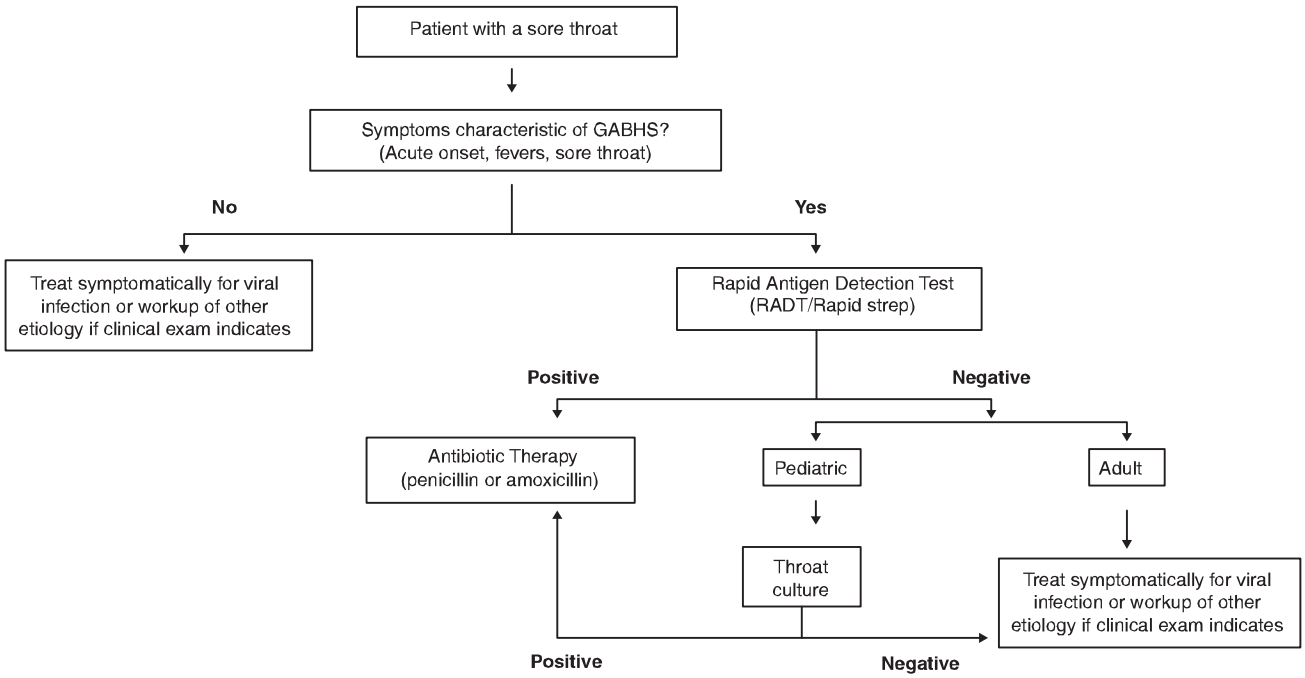

Figure 52.1 Algorithm for the diagnosis and management of sore throat and GABHS pharyngitis.

acute illness or immune response. Treatment of carrier patients, or their family members (and pets) has not been shown to be useful and should be avoided (13). However, antibiotic therapy may be appropriate with a personal history or close contact with someone who has had acute rheumatic fever or poststreptococcal glomerulonephritis, invasive strains of GABHS, or workers in health care facilities or nursing homes. Carrier patients can still develop pharyngitis from another serotype of GABHS or viral infection, and treatment should be started as appropriate.

Complications from streptococcal pharyngitis are rare but well described. These include rheumatic fever; rheumatic heart disease; poststreptococcal glomerulonephritis; suppurative complications such as peritonsillar, retropharyngeal, and parapharyngeal abscess; suppurative lymphadenopathy; mastoiditis; bacteremia; and sepsis. Rheumatic fever is diagnosed based on the Jones Criteria, which includes major and minor criteria such as carditis, polyarthritis, and chorea, and carries a mortality risk. Traditionally, the major role of antibiotic therapy is prevention of rheumatic fever, and rheumatic heart disease. It is estimated that 3% of patients with untreated GABHS infection will develop rheumatic fever, compared to 0.3% of patients treated with antibiotics. In the United States, rheumatic heart disease has largely been eliminated as a complication, but rates remain relatively high in undeveloped and underdeveloped countries, such as India. Antibiotics also decrease the rate of suppurative complications and associated abscess development.

Of special note is a relatively recently described but controversial entity, known as Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal (PANDAS) infections. After streptococcal infection, including pharyngitis, these patients rapidly develop neuropsychiatric symptoms of obsessive-compulsive disorder (OCD) and tic disorders (14–17). The OCD and tics will last for several weeks before remitting, then abruptly return after the next streptococcal infection. In general, neuropsychiatric symptoms are from minimal to absent between episodes. It has been hypothesized that GABHS antineuronal antibodies cross-react with cells in the basal ganglia, giving rise to behavioral and motor disturbances (16). In several case series, tonsillectomy has been of benefit, with resolution of neuropsychiatric symptoms (17). The etiology of PANDAS is yet unknown, and its association with streptococcal infection has not been absolutely proven.

Corynebacterium Diphtheriae

Although now extremely rare, *Corynebacterium diphtheriae* historically claimed the lives of millions of children and adults. Death usually occurred from cardio- or neurotoxicity from the exotoxin, or from asphyxiation from membranous pharyngitis. Vaccine introduction began in the 1920s, and there has not been a confirmed case in the United States since 2003, although diphtheria remains endemic in developing countries with low vaccination coverage (18). *C. diphtheriae* is a gram-positive filamentous rod, which is transmitted via nasal, eye, or oral secretions, or from skin lesions.

In addition to the typical symptoms of sore throat and malaise, diphtheria is characteristically associated with a gray pharyngeal/tonsillar membrane, which is produced by the local tissue response and necrosis from the bacterial exotoxin

(present in approximately one-third of patients). This can extend to cover the oropharynx and larynx, and cause rapid death by asphyxiation, particularly in the young child. The pseudomembrane is firmly attached to the mucosa, and removal characteristically leads to bleeding of the underlying site with an edematous submucosa. Patients may also have a prominent reactive cervical adenopathy leading to a "bull-neck" appearance (1). Exotoxin-induced systemic cardiotoxicity and neurotoxicity are also possible and account for many of the adverse consequences of infection (19).

When strongly suspected based on clinical grounds, the diagnosis is confirmed with culture of the pseudomembrane on Loeffler or tellurite medium. Treatment consists of antibiotics and antitoxin, typically with penicillin or erythromycin, and the equine hyperimmune diphtheria antitoxin. Current recommendations for immunization include combined vaccination during childhood and booster injection every 10 years in adults (19).

Viral

In both children and adults, viral infection is the most common cause of pharyngitis, and is typically self-limited. Viruses that produce the common cold predominate, particularly the rhinovirus family followed by coronavirus and adenovirus (Table 52.1). The onset of viral pharyngitis may be more gradual than of bacterial pharyngitis, and symptoms typically include rhinorrhea, cough, and diarrhea. A viral etiology is suggested by the presence of conjunctivitis, coryza, hoarseness, and cough, and presence of these symptoms makes GABHS infection much less likely (1,7).

Preschool-aged children have an average of five to seven episodes of viral URI per year. This rate steadily decreases into adulthood, and plateaus at two to three episodes per year. Spread of viral pharyngitis is by direct contact and inhalation/ingestion of respiratory secretions, and is greatly increased by contact with other children at home or in daycare and school environments. Especially in the northern states, there is a seasonal incidence during the fall, winter, and early spring months, from September to April. Parainfluenza virus, the main etiologic agent of acute croup attacks, peaks in the late fall and late spring, whereas respiratory syncytial virus (RSV) and influenza viruses are highest between December and April (20).

Symptoms begin 1 to 3 days after transmission, and a sore, scratchy throat and inflamed pharynx is often the first sign. This is followed by the typical symptoms of URI, including nasal congestion and rhinorrhea. Influenza and RSV infections are more likely to produce fevers. The symptoms of URI last for approximately 1 week, then spontaneously resolve. Traditionally, patients were treated with over-the-counter medications such as saline rinses, decongestants, antipyretics, and antitussives, if necessary. However, recent evidence has shown that there is a high risk for overdose and serious adverse consequences in infants under 2 years of age; in addition, there is no conclusive evidence that these medications are effective for symptom resolution in pediatric patients. Therefore, over-the-counter cough and cold medications are no longer recommended for infants under 2 years of age, and caution should be used in recommending these medications to patients 2 to 11 years of age (21).

Treatment is symptomatic, and reassurance should be given. Parents may bring their child to the pediatrician or emergency room requesting antibiotics, but antibiotics should be avoided for viral pharyngitis. Aside from the cost of medication, development of antibiotic resistance is a concern when overused.

Coxsackie Virus

Herpangina, characterized by palatal vesicular enanthem and throat pain, is caused by the Coxsackie virus, and is often mistaken for acute bacterial tonsillitis. Coxsackie virus is in the enterovirus family, and was traditionally divided into Group A or Group B Coxsackie virus types, each of which has multiple strains. New molecular techniques have reclassified enteroviruses into five species, with the Coxsackie viruses coming under Human Enterovirus B and C groups (22). Herpangina usually occurs in children 3 to 10 years of age. Spread is by direct contact with infected saliva, fluids, or feces, commonly on unwashed hands in children, with a predilection for the summer months. Outbreaks in military barracks and other close quarter situations have been reported in older populations.

Symptoms begin suddenly, with fevers, myalgia, headache, and vomiting. Patients progress to severe sore throat and odynophagia, followed by the appearance of small vesicular lesions, typically on the soft palate and anterior tonsillar pillars, with sparing of the oral mucosa and gingiva. These lesions have characteristic appearance, starting as erythematous punctate lesions and developing quickly into small, 2 to 4 mm vesicles with central ulceration and erythematous base. These lesions may last for up to a week, although the fevers and other symptoms will resolve much more quickly in the first 3 to 4 days. Coxsackie A virus is also one of the causative agents in hand-foot-and-mouth (HFM) disease, which has a similar oropharyngeal presentation and the addition of vesiculopapular lesions on the palms and soles of the feet. Treatment of both herpangina and HFM is symptomatic, and both will spontaneously resolve in 1 week. Infection with Coxsackie virus or other enteroviruses in neonates is associated with significant morbidity and mortality, particularly when the infection occurs antenatally (23).

Inflammatory

PFAPA

A syndrome of periodic fever (>39°C), aphthous stomatitis, pharyngitis, and cervical adenitis (PFAPA) was first described in 1987, and the exact etiology is yet unknown (24). PFAPA occurs sporadically in children less than 5 years of age, and is defined by the periodic high fevers

and oral/neck manifestations, which occur regularly every 2 to 8 weeks (average of 30 days) and last for 2 to 7 days (average of 4 days). These episodes have been described to occur like "clockwork," with a predictable and stable interval between symptomatic periods (25). Between episodes, patients return to complete health and are asymptomatic. In addition to the cardinal symptoms, headache, rash, arthralgia, and GI symptoms may be present (26). PFAPA is one of a spectrum of disorders with periodic fevers, and recent evidence points to an autoimmune or hyperactive immune response of Th1 cells to IL-1 cytokines (27). PFAPA is a diagnosis of exclusion, and other causes of pharyngitis, including GABHS, should be considered, and a thorough fever workup should be performed in every case. Cyclical neutropenia also needs to be evaluated and ruled out.

Steroids have been shown to be of benefit during acute episodes, and one or two doses of prednisone (1 mg/kg) aborts the fever episodes within a few hours, whereas the other symptoms will take longer to resolve. Cimetidine and colchicine have been used for prevention of episodes (28). Two well-designed randomized-controlled trials have concluded that tonsillectomy in PFAPA patients will lead to a decrease in episodes, longer interval between episodes, and in some cases complete resolution of PFAPA (29–31). However, given the tendency for spontaneous resolution and the possible efficacy of prophylactic treatment, the indications for tonsillectomy are still under investigation. PFAPA patients are often referred to the otolaryngologist with an established diagnosis of PFAPA for tonsillectomy evaluation, and clinical judgment should be exercised on a case-by-case basis (32).

Kawasaki Disease

The initial symptoms of Kawasaki disease (KD) may be mistaken for pharyngitis, and there are several case reports of KD presenting similarly to a retropharyngeal abscess or deep neck cellulitis (33,34). KD, also known as acute mucocutaneous lymph node syndrome, is a systemic vasculitis of unknown etiology which occurs in children less than 10 years of age. The classic symptoms of KD are high fever, adenopathy, mucositis (strawberry tongue), cheilitis (dry, cracked lips), conjunctivitis, erythematous rash, and erythema and desquamation of the palms and soles. Because of the initial high fevers and mucositis, patients may present for treatment of presumed pharyngitis. However, a high index of suspicion must be had for this syndrome, with examination of the eyes, trunk, and extremities as necessary, to avoid the long-term complications of coronary artery aneurysms and sudden death. Children with KD should be admitted to the hospital and started on IVIG and aspirin to prevent progression of large vessel disease.

Caustic Ingestion

Caustic ingestion is covered in depth in Chapter 93. Depending on the substance, ingestion of a variety of chemical agents may lead to necrosis or inflammation of the pharynx and upper GI tract. Visual inspection of the oral cavity and oropharynx, starting at the lips, may reveal ulceration, chemical burns, or exudative contact patches, and will help guide the treatment decision for endoscopy. In a patient with smoke and fire exposure, the pharynx needs to be closely examined for evidence of soot or burns, which would indicate smoke inhalation injury requiring close airway monitoring with a low threshold for intervention. In adolescents and adults, fumes from smoking tobacco and crack cocaine can cause acute pharyngeal mucosal inflammation and pain; edema of the supraglottis in these patients may lead to airway distress (35).

Posttransplant Lymphoproliferative Disorder

Posttransplant lymphoproliferative disorder (PTLD) is characterized by abnormal proliferation of lymphocytes (usually B cell) in chronically immunosuppressed patients, with a spectrum of lymphoid hyperplasia to non-Hodgkin lymphoma. Various risk factors for the development of PTLD have been identified, including young age, Epstein-Barr Virus (EBV)-seronegative status, high degree of immunosuppression, male gender, and Caucasian race (36). In the head and neck, PTLD can manifest at any site, including the paranasal sinuses, but the abundance of tonsillar tissue in the nasopharynx and oropharynx makes these sites particularly common. Patients present with hypertrophy of tonsillar tissue, including lingual, may also have mononucleosis-like symptoms including sore throat, muffled voice, and an increase in sleep-disordered breathing (37). Diagnosis requires biopsy via tonsillectomy, adenoidectomy, or lingual tonsillectomy, with histologic examination of tissue and flow cytometry. A correlation has been found between EBV viral load and the presence of PTLD and in some medical centers EBV levels are routinely monitored in stem cell transplant patients. Patients are treated with a reduction in immunosuppressive therapy, antivirals, and rituximab (anti-CD20) if EBV titers are high.

Oral Mucocutaneous Diseases: Epidermolysis Bullosa/Pemphigoid/Pemphigus/Stevens-Johnson Syndrome

Epidermolysis bullosa (EB) is an autoimmune disorder of skin and mucous membranes, which can be inherited or acquired, and is characterized by severe mechanical fragility of epithelial tissues, with blistering, erosions, and poorly healing ulcers (38). Similarly, mucous membrane pemphigoid is an autoimmune disorder of the basement membrane and presents with blistering and ulceration of mucosa and skin. Pemphigus is also an autoimmune disorder with several subtypes (including pemphigus vulgaris), and presents with cyclical vesicular and bullar eruption in the mucous membranes (39). Stevens-Johnson syndrome has numerous causes, most commonly drug reactions, and presents with large areas of ulceration and blistering on the skin and mucosal surfaces. Although these entities are pathologically

very different, the pharyngeal manifestations can be similar: mucosal blistering or ulceration, with sloughing of large patches of mucosa, usually with severe pain and dysphagia. Diagnosis is clinical and can be confirmed with biopsy of an oral or oropharyngeal lesion. These lesions can be quite extensive, with loss of mucosa over the lips, tongue, buccal mucosa, palate, and pharyngeal surfaces. The larynx and esophagus are susceptible, and great care must be taken in the examination of these patients in the operating room to prevent further skin and mucosal loss during instrumentation. In severe forms, laryngeal and mucosal sloughing leads to scar formation and stenosis, which may require a tracheostomy and/or G-tube. Further pathologic discussion is found in Chapter 51.

INFECTIOUS CAUSES OF PHARYNGITIS IN THE ADULT

Viral

Viral infection is the most common cause of pharyngitis in adults (30% to 60%), followed by inflammatory and bacterial (5% to 10%), and is typically self-limited. Rhinovirus, coronavirus, and other viral causes of the common cold, as described above, predominate. In adults, the typical disease course consists of 1 to 3 days without symptoms after transmission, followed by 3 to 5 days of sore throat, cough, headache, and nasal congestion. As in pediatric viral pharyngitis, fever is rare, and may point toward a bacterial etiology. Adults typically have two to four episodes of the common cold per year, compared to five to seven episodes in young children.

Epstein-Barr Virus

EBV is a common cause of acute sore throat, fever, and lymphadenopathy in adolescents and young adults. Any age group may be infected, but the clinical manifestations vary widely by age, and children may be asymptomatic or present with a cutaneous rash or neutropenia (40). EBV is a double-stranded DNA virus in the herpesviridae family, with a predilection for B lymphocytes. EBV has been associated with nasopharyngeal undifferentiated carcinoma, Burkitt lymphoma, and PTLD, but acute infectious mononucleosis (IM) remains the primary pathology from this virus.

In the classic form of IM, symptoms of pharyngotonsillitis predominate, with the addition of lymphadenopathy, splenomegaly (50%), and hepatomegaly (10% to 15%) (40). Transmission is via oral and respiratory secretions, with subsequent entry into the lymphoid tonsillar tissue of the pharynx. After an incubation period of 30 to 50 days, there is a prodromal period of fevers, chills, malaise, and anorexia, followed 10 to 14 days later by the classic triad of sore throat, fever, and lymphadenopathy (41). The onset of sore throat may be abrupt, and it is usually accompanied by severe odynophagia. Lymphadenopathy is variable, but usually involves the posterior cervical nodes and may involve the submandibular, jugular, and axillary nodes as well. More rare complaints are headaches, abdominal pain, and rash; the administration of amoxicillin will produce a pruritic, maculopapular rash in most patients with acute IM (42).

Patients may have muffled, "hot potato" voices, with or without increased work of breathing. Severe respiratory distress from tonsillar and lymphoid hypertrophy is extremely rare, and can usually be prevented with the use of steroids (42). Oropharyngeal examination shows symmetric tonsillar enlargement, which can be quite impressive, and all components of Waldeyer's ring may show enlargement and inflammation. Whitish exudates may be present on the tonsils and pharyngeal wall. The oropharyngeal mucosa is inflamed and erythematous, and may be difficult to examine due to tonsillar size. Petechiae at the junction of the hard and soft palate are seen in 25% to 60% of patients, and are typically 1 to 2 mm in diameter, although these are not diagnostic of IM. Hepatomegaly and splenomegaly may also be seen, and periorbital edema has been reported (41).

On laboratory testing, patients with acute IM have mononuclear lymphocytosis, with greater than 10% abnormal lymphocytes. Cold-agglutinins, usually of the IgM class, may be present, and are more common in patients who develop an autoimmune hemolytic anemia. Heterophile antibodies are associated with IM caused by EBV infection, are present in approximately 90% of adolescents with IM, and are the basis of the Monospot test (40). When the Monospot test is negative, but IM is highly suspected, EBV-specific antibody studies (to viral capsid antigen) can confirm the diagnosis. Although IM and peritonsillar abscess have similar symptoms of fever and pharyngitis, physical examination showing symmetric tonsillar enlargement with exudate makes IM much more likely. In adolescents and young adults, obtaining a Monospot test in the emergency room when IM is suspected can confirm the diagnosis, and spare the patient unnecessary procedures or imaging.

Patients with IM are treated symptomatically with rest, hydration, antipyretics, and analgesics. Respiratory support, including oxygen, sitting position, CPAP, or even intubation (rare), is given as needed. A single dose of dexamethasone during acute symptoms provides relief (42). Sore throat and dysphagia symptoms will peak at 3 to 5 days then resolve over the next week. Fevers may persist for 10 to 14 days, but improve over the late course of the illness. Most patients have resolution of symptoms by 2 to 3 weeks, but feelings of lethargy and malaise may linger for weeks or months.

Complications of IM include secondary bacterial infection, splenic rupture, hemolytic anemia, thrombocytopenia, and hepatic transaminase abnormalities. Bacterial infection is treated with antibiotics, but amoxicillin is avoided due to the rash, as mentioned above (42). Steroids

can be effective for hematologic complications. Patients should be informed to avoid contact sports to decrease the risk of splenic injury and hemorrhage, until splenomegaly is resolved on ultrasound examination.

Cytomegalovirus

Cytomegalovirus (CMV) is the pathogen responsible for 5% to 7% of IM (or IM-like illnesses), with clinical features similar to EBV-related IM (43). CMV is also in the herpesviridae family, and is present as an asymptomatic latent infection in a substantial portion of the population. CMV-related IM is more common in adolescents and adults who have had contact with children less than 2 years of age, such as daycare workers and teachers. CMV infection has similar symptoms of fatigue, malaise, and sore throat, but with less associated lymphadenopathy (44). Elevated transaminases are common (92%), but the heterophile-antibody test (Monospot) will be negative (43). Monoclonal antibodies against CMV can be tested to confirm the diagnosis, and treatment is symptomatic, similar to EBV-related IM. Other causes of non-EBV IM-like illness include human herpesvirus 6, HIV, herpes simplex virus (HSV), adenovirus, toxoplasmosis, and GABHS.

Human Immunodeficiency Virus

Acute retroviral syndrome (ARS) of early HIV infection has symptoms similar to IM, including sore throat, headaches, fevers, and malaise, in addition to myalgias, arthralgias, and nausea (45–47). ARS occurs abruptly after an incubation period of several days to 6 months, and affects up to 93% of patients with HIV. Twenty eight percent of patients will have oropharyngeal mucosal ulcerations, which may also be present in the cervical esophagus and genitalia (45). Nontender lymphadenopathy is present in the cervical, occipital, and axillary nodes, and a maculopapular skin rash involving the face and trunk is seen in up to 72% of patients. During this period of acute illness, patients have profound viremia, and are considered highly infectious (46). Diagnosis is based on enzyme-linked immunosorbent assay (ELISA) testing, with Western-blot confirmation. ARS is treated symptomatically and will resolve in 2 to 3 weeks; treatment for HIV infection is usually determined by an infectious-disease specialist.

Established HIV infection can have several manifestations of pharyngitis due to immunodeficiency and decreased host mucosal resistance. These include candidal infections (most common), CMV reactivation, HSV, human papillomavirus (HPV), among others. These are treated for the specific infection, concomitantly with treatment for HIV infection.

Herpes Simplex Virus

HSV, a double-stranded DNA virus with HSV-1 and HSV-2 strains, is an important cause of acute pharyngitis in the adolescents and adults. In the newborn and young child, primary HSV infection presents with gingivostomatitis, and the pharynx is usually spared (48). The virus is usually spread via sexual contact, with direct contact of infected oral salivary or genital secretions. HSV-1 is more common in the oral cavity, but HSV-2 can also occur and will present with the same clinical findings. An increased incidence of primary HSV infection in college students has been documented, but it is clinically difficult to distinguish primary HSV infection from other causes of acute pharyngitis including GABHS, and testing is required (49,50). In adolescents and young adults, HSV pharyngitis presents with fevers, pharyngeal erythema, and tonsillar exudates, with enlarged and tender cervical lymphadenopathy. One-third to one-half of patients will have characteristic painful herpetic ulcerations of the mouth or lips, which may also be present in the pharynx along the posterior wall and tonsillar pillars (48–50). Ulcers are characteristically shallow and covered with gray exudates. Vesicular lesions that bleed easily may be present, and covered with a blackened crust/clot. Gingival tenderness, erythema, and swelling are also characteristic (48). The disease is more severe in immunocompromised individuals, such as HIV. However, HSV infection can cause painful esophagitis even in the immunocompetent patient, which is typically rare, and if this is present, may help the clinician come to a diagnosis, particularly in an adolescent or college student.

Primary HSV symptoms resolve after 7 to 10 days, with the development of neutralizing antibodies. Reactivation of latent HSV infection presents with vesicular lesions of herpes labialis, and does not typically involve the pharynx. Diagnosis of primary HSV infection can be made by viral culture, which requires 12 to 48 hours. Cytologic examination may reveal multinucleated giant cells on a Tzanck smear, and other testing (ELISA, PCR) may be available. Patients are usually treated symptomatically for pain and dysphagia. Antiviral medications, including acyclovir, valacyclovir, and famciclovir, decrease the duration of disease and viral shedding, but is not standard and should be considered on a case basis (48). Immunocompromised patients should be started on antiviral medication immediately to prevent severe symptoms and systemic dissemination.

Human Papillomavirus

HPV infections of the oral cavity and oropharynx present with characteristic papillomatous growths on mucosal surfaces, which are typically asymptomatic. There are over 80 subtypes of HPV, with types 6 and 11 being the most common in the pharynx and upper respiratory tract. Pharyngeal infection is usually acquired through genital–oral sexual contact. In pediatric patients, HPV leads to recurrent respiratory papillomatosis, via transmission *in utero* or during birth. However, in a child with no history of RRP with new oral/oropharyngeal papillomas, sexual abuse needs to be considered. In the immunocompetent adolescent and adult, pharyngeal HPV infection leads to

papillomas, which are limited in size and can usually be easily removed in the office. However, removal does not eradicate the virus, which will still be present in the underlying mucosa and may lead to further papillomas. The infection can be more disseminated along mucosal surfaces in immunocompromised patients, including those with HIV. HPV infection has been implicated in the development of squamous cell carcinoma of the oropharynx, described elsewhere in this text.

Bacterial

Streptococcal Pharyngitis

GABHS infection is more rare in adults than in children, as stated above, and transmission is typically from close contacts or with children with GABHS. Presentation is similar to pediatric patients, with acute onset of sore throat, fevers, chills, malaise, with possible headaches or abdominal symptoms. Absence of tender cervical lymphadenopathy makes GABHS less likely in the adult (5). As in pediatric patients, the presence of typical viral symptoms of pharyngitis, including cough and coryza, also point away from GABHS infection. Because of the low incidence in adults, testing is usually not necessary (7). If GABHS is highly suspected, the rapid strep test can be performed. If the RADT is positive, patients are treated with penicillin V or amoxicillin; if the RADT is negative follow-up throat culture is NOT necessary in this age group.

Neisseria Gonorrhea

Oral gonorrhea is considered a sexually transmitted disease, and is a relatively uncommon cause of pharyngitis (<1%) (51,52). *N. gonorrhea*, a gram-negative diplococcus, typically affects the genital–anal region, and manifests as pain with urination, urethral discharge, and perianal inflammation and itching. Oropharyngeal gonorrhea is typically transmitted during oral sex, and rarely occurs as the only site of infection. It has been shown that the majority of patients (50% to 84%) will be asymptomatic, although culture positive (52,53,54). Symptomatic patients present with typical tonsillitis complaints, including sore throat, dysphagia, odynophagia, and throat itching. Examination may reveal evidence of oropharyngeal trauma, erythematous pharyngitis, and a whitish–yellow exudate from the tonsillar crypts. Cervical lymphadenopathy is only reported in 9% to 10% of patients (51). Severe oropharyngeal ulcerations have also been described (53). Pharyngeal swab with gram stain may reveal the diagnosis, but this is considered unreliable, and a culture on chocolate agar should be performed. Some laboratories have PCR testing available. Although the pharyngeal symptoms may be self-limited, antibiotics should be given in all cases in order to treat the likely infection of the genital site, and prevent further transmission. All patients should be treated concomitantly for *Chlamydia trachomatis*, as the two have a high incidence of coinfection (54,55). Typical antibiotic treatment is a single dose of intramuscular ceftriaxone for the gonorrhea and a single oral dose of azithromycin for the chlamydia.

Arcanobacterium Haemolyticum

Arcanobacterium haemolyticum is a rare cause of bacterial pharyngitis, implicated in 0.5% to 2.5% of patients, with similar symptoms of acute streptococcal pharyngitis (8,56,57). In addition to sore throat and inflammation, 20% to 25% of patients develop a scarlatiniform rash on the trunk and extremities, but with the face, palms, and soles spared. Infection tends to occur in adolescents and young adults, and should be suspected in this age group when the rapid strep test or culture is negative (57). *A. haemolyticum* is not part of the normal respiratory flora, and may become invasive after acute pharyngitis or tonsillitis, and lead to a peritonsillar abscess, other deep neck abscess, endocarditis, meningitis, or sepsis (58). Erythromycin is the standard antibiotic therapy, although a more broad-spectrum antibiotic regimen may be used.

Syphilis

Syphilis is caused by the spirochete *Treponema pallidum*, which has primary, secondary, and tertiary clinical stages of infection. Involvement of the pharynx is usually during the primary or secondary stages, and is generally acquired through oral sex (59,60). Oral sites are the most common, including the lips and tongue, and 4% to 12% of patients with primary syphilis will have oral or oropharyngeal manifestations (59,61–63). Primary syphilis in the pharynx presents as a painless ulcer on the tonsil or pharyngeal wall after an incubation period of 3 to 90 days (average 3 weeks). This may be unnoticed and therefore untreated. The primary chancre lasts from 2 to 8 weeks, and may be associated with lymphadenopathy during the first few weeks (60). Painless ulceration of the tonsil with lymphadenopathy has been mistaken for neoplasm, and a thorough social history should be emphasized (62). The secondary stage of syphilis represents systemic dissemination, and will present 2 to 12 weeks after primary infection. During the secondary stage, lymphadenopathy and skin lesions (maculopapular scaly, nonpruritic rash) are the most common findings. The features of secondary syphilis in the pharynx are highly variable, but the most characteristic are mucous patches, which are slightly raised, with silvery-gray pseudomembranes surrounded by erythema (59,62). Typical sites are soft palate, tonsillar pillars, buccal mucosa, and tongue. Confluent oral lesions may become painful, and these lesions are highly contagious. The symptoms of primary and secondary syphilis may be more pronounced and severe in patients with HIV, and the incidence of syphilis is increasing in this population (60). The gumma lesions of tertiary syphilis may present anywhere in the body, including the oral cavity and oropharynx. Further information concerning diagnosis and treatment of syphilis is found in Chapter 17.

Fungal

Candidal Infections

Fungal infections generally do not lead to acute pharyngitis in the immunocompetent patient. However, in chronically debilitated or immunosuppressed patients, including those with HIV, transplant patients on antirejection medications, chronic systemic or inhaled steroid use, broad-spectrum antibiotics, radiation therapy, and diabetes mellitus (DM), fungal infection can occur and may lead to severe systemic disease (64–66). *Candida albicans* is by far the most common isolated organism, leading to "thrush"—a pseudomembranous candidiasis infection of the oral cavity, oropharynx, and possibly larynx and cervical esophagus. *C. albicans* is a normal commensal organism of the oral cavity and does not typically cause symptoms. With immune compromise, the fungus will invade into mucosal surfaces, and is considered an opportunistic infection—the most common type in patients with HIV (67).

C. albicans infection presents with oral and pharyngeal pain, dysphagia, and burning sensation. With hypopharyngeal and cervical esophageal involvement, the dysphagia and odynophagia can be quite severe, and candidal infection should always be considered in immune-compromised patients with these symptoms (64). Examination shows the characteristic white, cheesy mucosal plaques, which can be scraped off to reveal an erythematous underlying mucosa. KOH preparation and microscopic evaluation is performed of the exudate, and budding yeasts with pseudohyphae can be seen to confirm the diagnosis.

Candidal infection can occur in any age group with immunocompromise. Two to five percent of normal newborns exhibit signs of oral/oropharyngeal thrush, which is self-limited and may not require treatment. Neonatal invasive disease is well described, and risk factors include: very low birthweight (less than 1,500 g), broad-spectrum antibiotic administration, prolonged ventilatory support, parenteral alimentation or IV catheterization, and abdominal surgery (65,68). Infection may be isolated to the oropharynx and mucosal surfaces, or become disseminated and severe. In children and adolescents, candidal infection is usually due to immunodeficiency from transplants or malignancy. Isolated patches on the pharyngeal mucosa and larynx may be due to inhaled steroids from asthma treatment. Oropharyngeal candidal infection is much more common in adults, where HIV and DM play a larger role (68).

Candidal infection, which is isolated to the oral cavity and pharynx, is treated with topical nystatin or fluconazole, in isolation or as part of a "stomatitis cocktail." Recurrent infections should be treated with systemic antifungal therapy (69). Prophylactic fluconazole is generally not recommended due to concerns of antimicrobial resistance, but may be helpful in patients at high risk for invasive fungal infections.

Other species of *Candida*, including *Candida krusei*, *Candida glabrata*, and *Candida tropicalis*, are much more rare, but may be increasing as the population with HIV increases. These will present with similar symptoms and exam findings as *C. albicans* (65).

Infection by other mycoses in the pharynx, including *Cryptococcosis*, Histoplasmosis, Rhinosporidiosis, and Blastomycosis, are rare and associated with involvement at other sites.

Inflammatory

Reflux Pharyngitis

Gastroesophageal reflux disease (GERD) and laryngopharyngeal reflux (LPR), in addition to hiatal hernia and *Helicobacter pylori*-positive gastritis, commonly present with symptoms of pharyngeal and laryngeal inflammation. This may include chronic sore throat, burning sensation in the throat, sour taste in the mouth, frequent dry cough, hoarseness, and globus sensation with throat clearing (70–73). Sleep may be disturbed by coughing, and morning halitosis is a common complaint (73,74). As shown on experimental histologic examination, gastric acid has an inflammatory effect on the pharyngolaryngeal mucosa including submucous gland hyperplasia, edema, and vascular engorgement (75,76). Both the inflammatory changes as a direct effect of stomach acid contacting mucosa and a vagal-mediated signaling leads to cough and other symptoms. It should be noted that many patients (especially children) with reflux of gastric contents that reaches the pharynx (LPR) do not have typical symptoms of GERD, including heartburn or indigestion. Therefore, patients may falsely believe that acid reflux is not the cause of their symptoms.

Examination findings are nonspecific, and may include erythema and edema. Oropharyngeal "cobblestoning," a granular, bumpy appearance to the posterior oropharyngeal wall, is a classic description, but is not found in all patients and its absence does not exclude reflux disease. Laryngeal findings of edema and pachydermia on the interarytenoid mucosa are more revealing, although the only test which can definitively confirm the diagnosis is a pH probe (74). Dual probe pH testing, with a proximal pharyngeal sensor and a distal esophageal sensor, can be performed to specifically assess for LPR. However, most practitioners will start empiric treatment with lifestyle modifications and proton-pump inhibitors, with improvement of patient's symptoms to confirm the diagnosis (72–74).

Postnasal Drip

Postnasal drip (PND) is associated with nasal inflammation with increased mucous production and drainage into the pharynx, most commonly from allergic rhinitis. PND is a common cause of globus pharyngeus and chronic cough, but may also cause a chronically irritated and sore throat (irritative pharyngitis) (77). In addition, nasal congestion with obstruction, seen with inflammatory processes that produce increased edema and nasal secretions, can lead to chronic mouth breathing, particularly at night. Mouth

breathing provides less humidification, and leads to a dry and irritated posterior pharyngeal wall with a sore throat. After a thorough history, patients are treated for rhinitis with nasal saline, nasal steroids, and possibly humidification, which improves the pharyngeal symptoms.

Granulomatous Disease

Granulomatous diseases are characterized by the presence of granulomas, containing macrophages, giant cells, fibroblasts, and other inflammatory cells. These are manifest in a wide variety of infectious, inflammatory, autoimmune, and neoplastic disorders. In the pharynx and tonsils, caseating granulomas due to *Mycobacterium tuberculosis* (TB), accompanied by sore throat and nasal obstruction, are possible as a primary infection or after expectoration of infected sputum (78). Although rare in the United States, this diagnosis should be considered in a patient with fevers, lymphadenopathy, tonsillitis, as well as typical pulmonary symptoms (cough, hemoptysis) and night sweats of TB. After diagnosis, patients are treated with systemic antimycobacterial medications, with examination and treatment of close contacts.

Crohn's disease is a granulomatous inflammatory bowel disease of unknown etiology, with a classic histologic triad of noncaseating granuloma formation, fissures, and transmural inflammation with lymphoid aggregates. The distal ileum and colon are the most commonly affected sites, but any portion of the GI tract, including the oral cavity and pharynx, can be involved (0.5% to 20%) (79). Oral and pharyngeal manifestations include hypertrophic gingivitis, aphthous ulcers, lip swelling, and cobblestoning of the buccal or pharyngeal mucosa. These lesions can occur any time during the course of the disease, and multiple recurrences are common. Diagnosis is confirmed by biopsy and colonoscopy, and patients are treated with systemic steroids with variable response.

Foreign body reaction and granuloma as a response to exogenous materials in the pharynx are also possible, including traumatic (e.g., fish bone), iatrogenic (e.g., suture), or by abnormal deposition of hair or keratin debris. Foreign body granulomas can mimic an infectious process, which is unresponsive to antimicrobial therapy. Biopsy and removal will reveal the granuloma surrounding the foreign substance.

Radiation Pharyngitis

Ionizing radiation for the treatment of head and neck malignancies has both acute and long-term effects on the pharynx. These side effects are generally dose-dependent, starting at 20 Gy of standard fractionated radiotherapy, and prevention is impossible (80). Acutely, radiation exposure can cause pharyngeal edema and erythema, with a patchy fibrinous exudate, and is a result of cell damage and high cell turnover rates. If a high dose of radiation is given over a short time, ulceration may develop. Mucositis symptoms are worse with concomitant chemoradiation therapy, and may be treatment-limiting. Spontaneous healing takes 3 to 4 weeks, and is inhibited by tobacco smoking and high-dose radiotherapy (80). Chronically, radiation treatment leads to atrophy of the submucous glands in the oral cavity and pharynx, with decreased salivary production. In addition to symptoms of dry, sore throat and dysphagia, a decrease in saliva can lead to an increase in local and systemic infection. Treatment of mucositis consists of oral hygiene and topical anesthetics, analgesics, antibiotics, and antifungals, which may be given separately or as part of a "stomatitis cocktail" (81). Systemic analgesics are commonly used for pain management.

HIGHLIGHTS

- Pharyngitis is a common disorder of the head and neck.
- Symptoms of pharyngitis include: sore throat, dysphagia, odynophagia, and voice changes.
- Viral infection is the most common cause of pharyngitis in children and adults.
- Children have a higher rate of bacterial infection, especially GABHS, than adults.
- Children should undergo strep testing (RADT or culture), with penicillin or amoxicillin for a positive result.
- Adults with a negative RADT do not need to be cultured or treated for GABHS.
- EBV causing mononucleosis is a common cause of pharyngitis in adolescents and young adults.
- Sexually transmitted diseases, including *N. gonorrhea*, HSV, syphilis, and HPV, can present with pharyngitis.
- Candidal pharyngitis is common in immunocompromised patients.
- LPR disease and PND can lead to an irritative pharyngitis.

53 Odontogenic Infections

Timothy D. Doerr

Odontogenic infections are common infections primarily treated by dental professionals. These infections are usually associated with dental caries or periodontal disease and are seen more often in underserved populations where regular dental care is lacking. In most cases, odontogenic infections are successfully treated in the early stages by the dental professional with a minor dental procedure and oral antibiotics. The initial treatment commonly consists of drainage of infectious tissue with extraction or endodontic treatment of the diseased tooth.

In some cases, the infection will spread from the dental alveolar structures into the adjacent soft tissue spaces. This can lead to serious infections of the fascial spaces of the face and neck. When these infections are not promptly managed, serious, even life-threatening complications can arise. It is often in the setting of an advanced odontogenic infection that the otolaryngologist first becomes involved. Patients will have local anatomy that can be distorted by infection and are at risk for airway obstruction. The otolaryngologist needs an understanding of the progression of odontogenic infections to properly treat these patients.

This chapter focuses on the microbiology, pathways of spread, and appropriate management of odontogenic infections. This knowledge will allow the surgeon to successfully treat these infections and help prevent major complications. The chapter also highlights the importance of the dental anatomy and fascial spaces in predicting and treating the spread of an odontogenic infection.

DEMOGRAPHICS

The incidence of an odontogenic infection will vary with the population studied. Those individuals with poor dental hygiene and those who are immunosuppressed are most susceptible. The peak incidence of odontogenic infections is in the third and fourth decades with a larger percentage of the complicated infections occurring in diabetic patients (1–4). There is nearly equal distribution between male and female patients although this has varied in some studies (2,3,5).

Although any tooth can produce an odontogenic infection, most infections involve the mandibular first, second, and third molars (2). In the pediatric population, odontogenic infections are less common overall, but are more likely to occur in maxillary teeth (1).

MICROBIOLOGY

Normal flora in the oral cavity contains over 1,000,000 organisms per cubic centimeter of which 10% are aerobic cocci and 90% anaerobic bacteria. The bacterial flora varies among the different oral cavity sites and with the health of the individual. The flora is also influenced by patient age, immune status, diet, environment, and host factors (6). Streptococci are the most common aerobic bacteria found in the oral cavity with the *viridans* species most prevalent. Staph is relatively infrequent in the oral cavity but becomes more prevalent in the setting of a mixed flora infection. Anaerobes increase in number in the setting of chronic infections like periodontitis (7).

An odontogenic infection is primarily caused by bacteria that colonize the mouth. These bacteria, when given the appropriate circumstances, can become pathogens. As a general rule, odontogenic infections are polymicrobial with a large percentage being primarily anaerobic infections (6,8).

Prior studies have shown that approximately one quarter of the infections were caused by aerobic or facultative anaerobic bacteria while about three-fourths were caused by strict anaerobes (9). Studies have also shown that when anaerobes predominate, the clinical infection is more severe. Based on these published culture data, appropriate empiric antibiotic therapy for odontogenic infections requires antimicrobial agents able to treat streptococcus and oral anaerobes species.

SPREAD OF LOCALIZED INFECTIONS

Most odontogenic infections begin with necrosis in the dental pulp from deep caries. Pulp necrosis is then followed by the spread of bacteria through the pulp chamber into the adjacent bone and soft tissues (Fig. 53.1).

Infected teeth are usually tender to percussion and may show a diminished or absent response to electrical tooth vitality testing. With the initial onset of pain, there may be no changes seen on the initial radiograph, but later periapical bony changes can be seen. With a chronic infection, a periapical cyst will be visible on imaging. Typically, treatment during this initial period with either endodontic treatment or extraction should alleviate the tooth pain and can also effectively drain the infection.

It is important to recognize that the initial steps in the development of a severe odontogenic infection may progress very slowly. It may take several months and even years for an infection from dental decay to reach the dental pulp and produce pulp necrosis and periapical abscess. The vast majority of patients will have had several signs and symptoms alerting them to an impending infection. In fact, 100% of patients experienced pain before presentation. In many cases, that pain was intermittent, but the patient did not seek a dental evaluation until severe pain or acute swelling with trismus ensued (10).

Once the infection is in the bone, it will usually follow a path of least resistance until reaching a plate of cortical bone. An infection can remain contained in the medullary bone space or erode through the cortical bone into the soft tissues (Fig. 53.2).

If the infection involves the adjacent soft tissue, it can cause a diffuse inflammatory response with cellulitis or form an abscess. A walled-off abscess in the labial or buccal gingiva is termed a parulis while an infection extending into the alveolar mucosa forms a vestibular space abscess.

The direction of spread of odontogenic infection is in part predicted by the location of the diseased tooth. Maxillary tooth roots are in closer proximity to the labial and buccal bone plates. The root position combined with the thick alveolar bone in the hard palate usually results in extension of infection to the labial or buccal side. This direction of spread produces swelling of the upper lip (Fig. 53.3).

On the rare occasions when an infection travels medially (lingually), a tender unilateral mass can form on the palate. By comparison, the mandibular tooth roots are closer to the lingual cortex posteriorly, and infections of these teeth can spread through the thinner plate of bone into the floor of the mouth. Despite this anatomic relationship, the vast majority of mandibular tooth infections (both anterior and posterior) will also spread through the buccal cortex.

As a rule, an odontogenic infection produces pain when the necrotic pupal contents are under pressure and also when the soft tissues and periosteum over the cortical bone are distended. The pain associated with a localized infection can decrease significantly as the tissue pressure drops when infection spreads through the bone and periosteum into the soft tissues. The position and root anatomy of an infected tooth are generally predictive of the location of the associated dentoalveolar abscess (Table 53.1).

The treatment of a dental infection at this stage involves a thorough drainage of the infected soft tissues combined with extraction of the offending tooth and administration of systemic antibiotics (Fig. 53.4).

SPREAD OF LOCALIZED INFECTIONS

When the infection of a diseased tooth spreads more deeply into the soft tissue instead of exiting superficially through an oral or cutaneous path, the spread is greatly influenced by the tooth position and the adjacent fascia

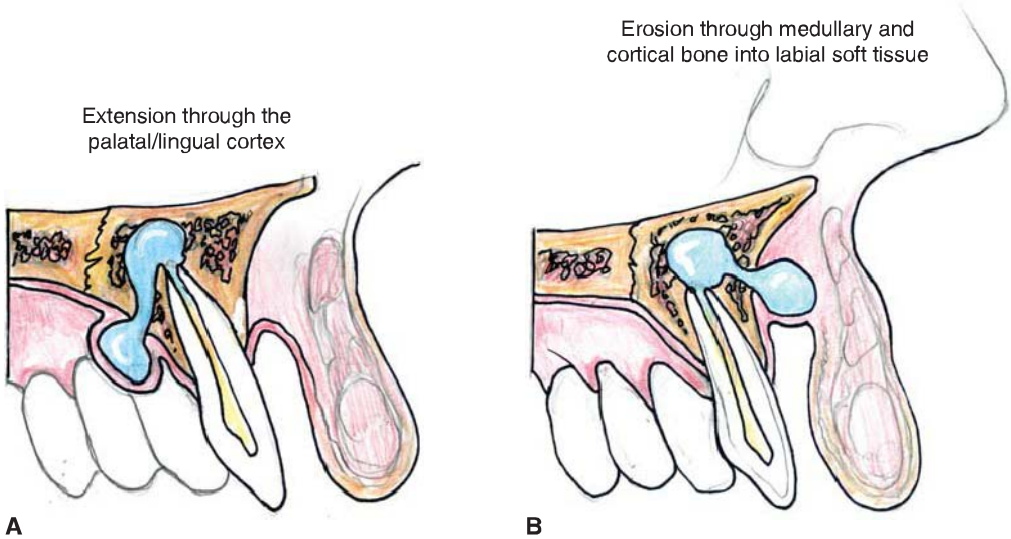

Figure 53.1 Spread of infection from an infected tooth root through the palatal/lingual cortex (**A**) and labial/buccal cortex (**B**).

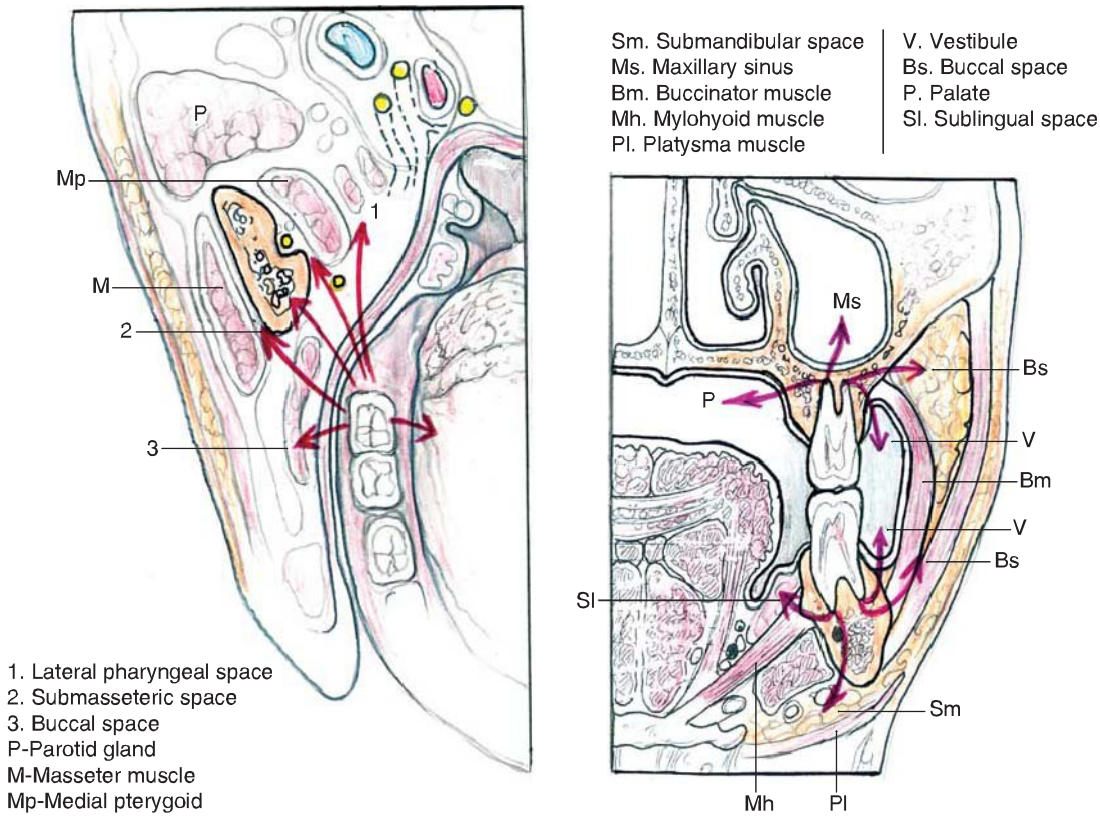

Figure 53.2 Various routes of spread for odontogenic infections.

attachments. Maxillary and mandibular teeth thus have distinctly different patterns of spread based on these anatomic relationships.

In general, dental infections of the anterior maxilla will spread superiorly into potential spaces bounded by the mimetic muscles. Maxillary tooth infections occasionally can also spread via the dental roots into the maxillary sinus.

Figure 53.3 Lip cellulitis in a child secondary to a fractured maxillary incisor tooth with pulpal exposure.

The masticator spaces are in close proximity to the roots of the maxillary molars, and they may be involved directly by odontogenic infections from these teeth. Once an infection reaches the masticator and cervicofacial spaces, it can spread into the deeper parapharyngeal space.

TABLE 53.1 PRESENTATION AND LOCATION OF DENTAL ABSCESSES

Tooth		Common Abscess Location	Less Common Abscess Location
Mandible	Central incisors	Labial	Lingual
	Lateral incisors	Lingual	Labial
	Canine	Labial	Lingual
	Premolar	Buccal	Lingual
	Molars	Buccal	Lingual
Maxilla	Central incisors	Labial	Palatal
	Lateral incisors	Labial	Palatal
	Canine	Labial	Palatal
	First premolar	Labial (buccal roots) Palatal (palatal roots)	—
	Second premolar	Buccal	Palatal
	Molars	Buccal (buccal roots) Palatal (palatal roots)	—

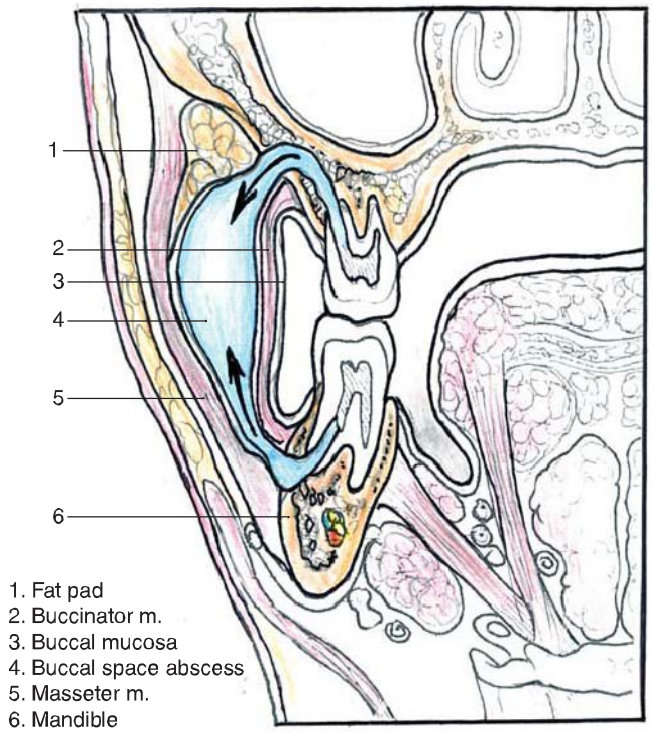

Figure 53.5 Formation of a buccal space abscess.

CANINE SPACE INFECTIONS

The canine space represents a potential space bounded by the muscle heads of the upper lip levators. These lip elevator muscles originate high on the maxilla and insert at the upper lip at the angle of the mouth. Although this space is infrequently involved with dental infections, it becomes involved if an infection from a maxillary cuspid tooth perforates the lateral cortex superior to the attachment of those upper lip elevators. Such an infection usually produces a firm swelling of the medial cheek and lateral surface of the nose that blunts the nasal labial crease. Rarely, this infection can spread from canine space through the valveless facial veins to involve the orbit. Most canine space infections are successfully treated by drainage with an intraoral incision placed high in the maxillary vestibule combined with extraction or root canal therapy of the diseased tooth.

BUCCAL SPACE INFECTIONS

The buccal space is located between the buccal muscle and buccopharyngeal fascia medially and the cheek skin laterally. Its anterior limit is the lip, and its posterior boundary is the pterygomandibular raphe. Superiorly the space is bounded by the zygomatic arch, and inferiorly it extends to the lower aspect of the mandible. As noted previously, infections from mandible and maxillary bicuspids and molars tend to drain in a lateral direction through the buccal cortex. Infection perforating the bone above the attachment of the buccinator muscle on the maxilla or below the attachments of the buccinator muscle on the mandible leads to a buccal space infection or abscess (Fig. 53.5).

Clinically, a buccal space infection produces tender swelling of the cheek that can extend to the mid upper lip. Here the space is limited by orbicularis oris muscle fibers at the philtrum. The buccal space extends posteriorly over the ramus of the mandible and to the border of the parotid. Superior spread of a buccal infection leads to swelling of the soft tissues of the orbit that "closes the eye" (Fig. 53.6).

Usually a buccal infection will be superficial to the orbital septum and not involve the orbital contents. However, the swollen eye needs to be carefully examined to ensure that the infection has remained preseptal and does not put the vision at risk. An infection that becomes postseptal will involve the orbital contents including the extraocular muscle and may extend to the orbital apex and cavernous sinus.

Because of its lax lateral soft tissue boundary, the buccal space has an ability to expand to a surprisingly large volume with purulent secretions. Despite the impressive swelling, a patient may not have much trismus. Although these buccal infections may be approached intraorally, most advocate draining these infection pockets through well-placed skin incisions. Incisions placed at the angle of the mandible allow complete drainage of the space and are cosmetically acceptable. The space should be opened with careful blunt spreading to avoid injuring branches of the facial nerve.

Figure 53.6 Submandibular space abscess from a pulpally involved mandibular molar tooth. The swelling over the mandible is ill defined and prevents palpation of its inferior border.

MASTICATOR SPACE INFECTIONS

The masticator spaces include the masseteric space, the pterygoid space, and the temporal spaces. These constituents of the masticator space are distinct anatomic entities that communicate with each other as well as with the more lateral buccal space. Additionally, these spaces communicate with the submandibular space inferiorly and the parapharyngeal space medially (Fig. 53.7).

The most superior of the masticator spaces is the temporal space. This space is divided into a superficial and a deep portion. The superficial temporal space exists between the temporalis fascia and the lateral surface of the temporalis muscle, while the deep temporal space rests between the medial surface of the temporalis muscle and the skull. Inferiorly the temporal space merges into an infratemporal space. The lateral extent of the infratemporal space is the temporalis muscle, and the medial limit is the skull base.

The second of the masticator spaces is the masseteric space. Its boundary is the masseter muscle laterally and the surface of the mandible medially. The third masticator space is the pterygoid or pterygomandibular space. This space extends from the pterygoid muscles to the mandible. Both the masticator and pterygoid compartments communicate freely with each other and with the temporal space above. The largest communication exists between the deep temporal and pterygoid/pterygomandibular space such that infections can spread easily from one to the next.

Infections of the temporal space can usually be drained either intraorally or externally but are probably best drained with an external incision along the zygomatic arch paralleling the course of the facial nerve. Infections that involve the masseteric space are most commonly associated with infection of the molar teeth. The source is usually the mandibular molars but can also be a maxillary molar. Chronic infections including pericoronitis of the molar gingival flap can also cause masseteric space infections.

The clinical hallmark of masticator space infections is trismus. Without trismus, the examiner may assume that masticator spaces are not involved. A notable exception to this rule is the immunocompromised patient in whom the presentation may lack the inflammation and signs of a deep space infection. With masseteric space infections, there can be some fullness over the muscle from myositis, but swelling is not seen initially because the infection is deep to a large muscle. The absence of swelling with the presence of trismus allows the clinician to differentiate a buccal from a masseteric space infection. As infection of the masseteric and pterygoid spaces spreads to involve the temporal space, swelling will increase with continued trismus.

Infections of the masseteric and the pterygoid spaces are potentially accessible from both an intraoral and external approach depending on the clinical circumstances. However, trismus can limit intraoral access and cause potential difficulty if an airway is needed. In these cases, the abscess should be drained through an external incision placed at the angle of the mandible so that all the masticator spaces can be entered.

MANDIBULAR SPACES

Although the submandibular and sublingual spaces represent distinct anatomic spaces, they can be viewed as a unit in terms of their surgical management. The mylohyoid is the critical structure in understanding sublingual and submandibular space infections. The mylohyoid forms the floor of the oral cavity and separates the sublingual space above from the submandibular space below. The muscle attaches to the lingual surface of the mandible along an oblique downward line from posterior to anterior. The tooth roots of the premolars and first molars are usually above the mylohyoid line, while the second and third molar roots are often below this line (Fig. 53.8).

Sublingual Space

The sublingual space is bounded anteriorly and laterally by the mandible. Superiorly its boundary is the sublingual mucosa, and inferiorly it is the mylohyoid muscle. The posterior boundary of the space is the hyoid, while the medial border is the genioglossus, styloglossus, and geniohyoid muscles. Only loose connective tissue separates the two sides of the floor of the mouth.

Infections of the sublingual space typically start out as tender brawny swellings of the lateral floor of the mouth near the mandible. As the infection progresses, it spreads towards midline and often to the opposite sublingual space. There may be some elevation of the tongue with more

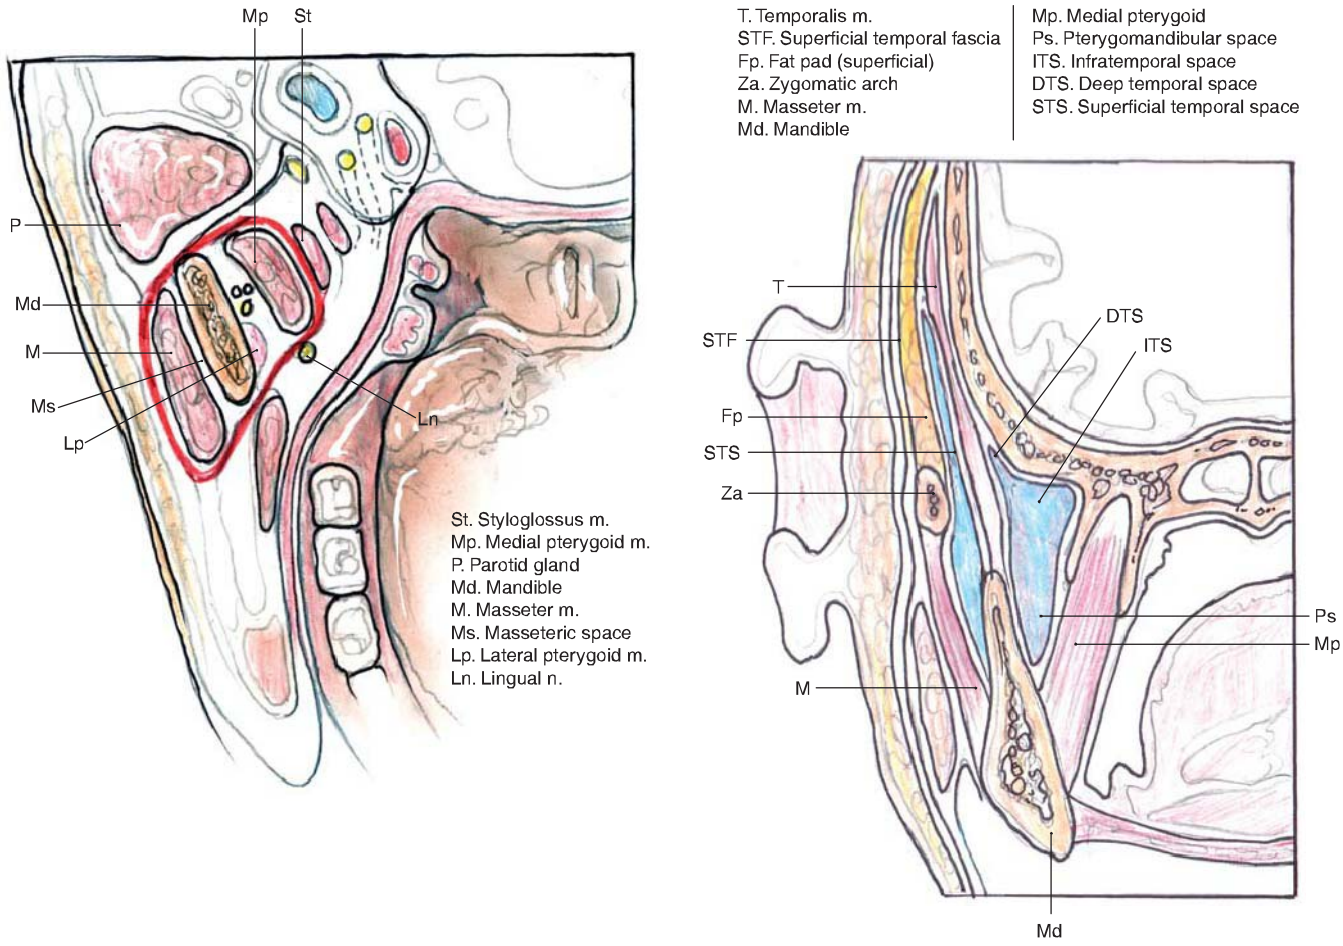

Figure 53.7 Masticator space infections.

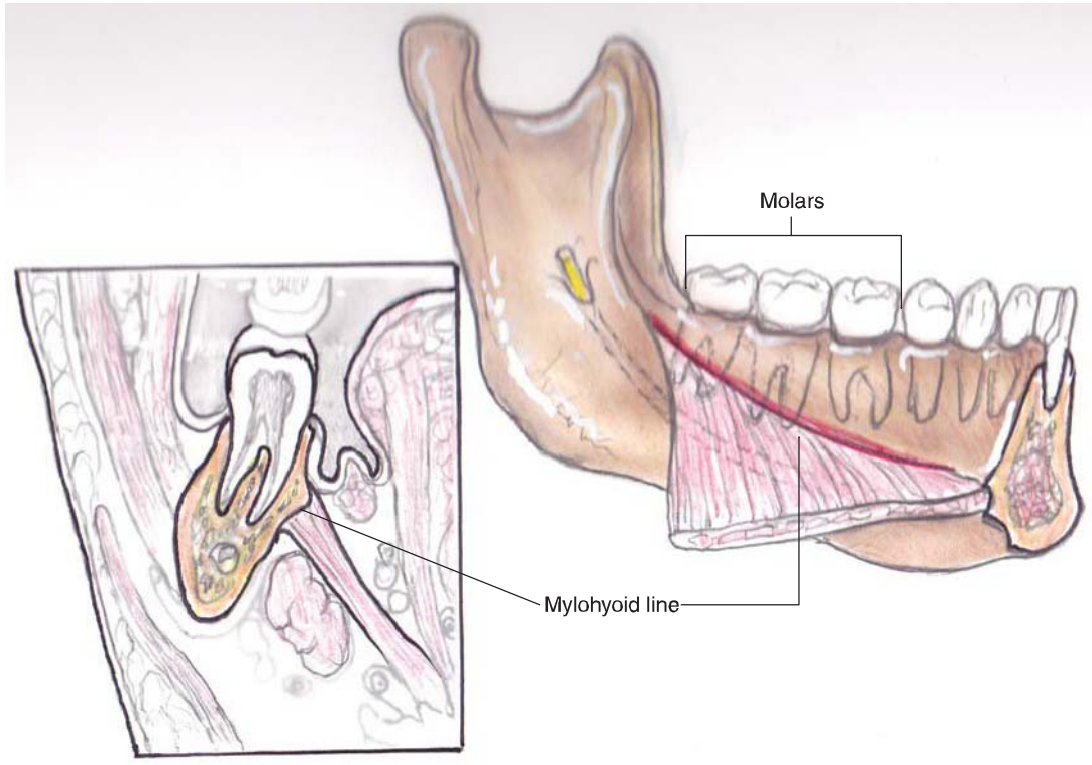

Figure 53.8 Mylohyoid line on mandible.

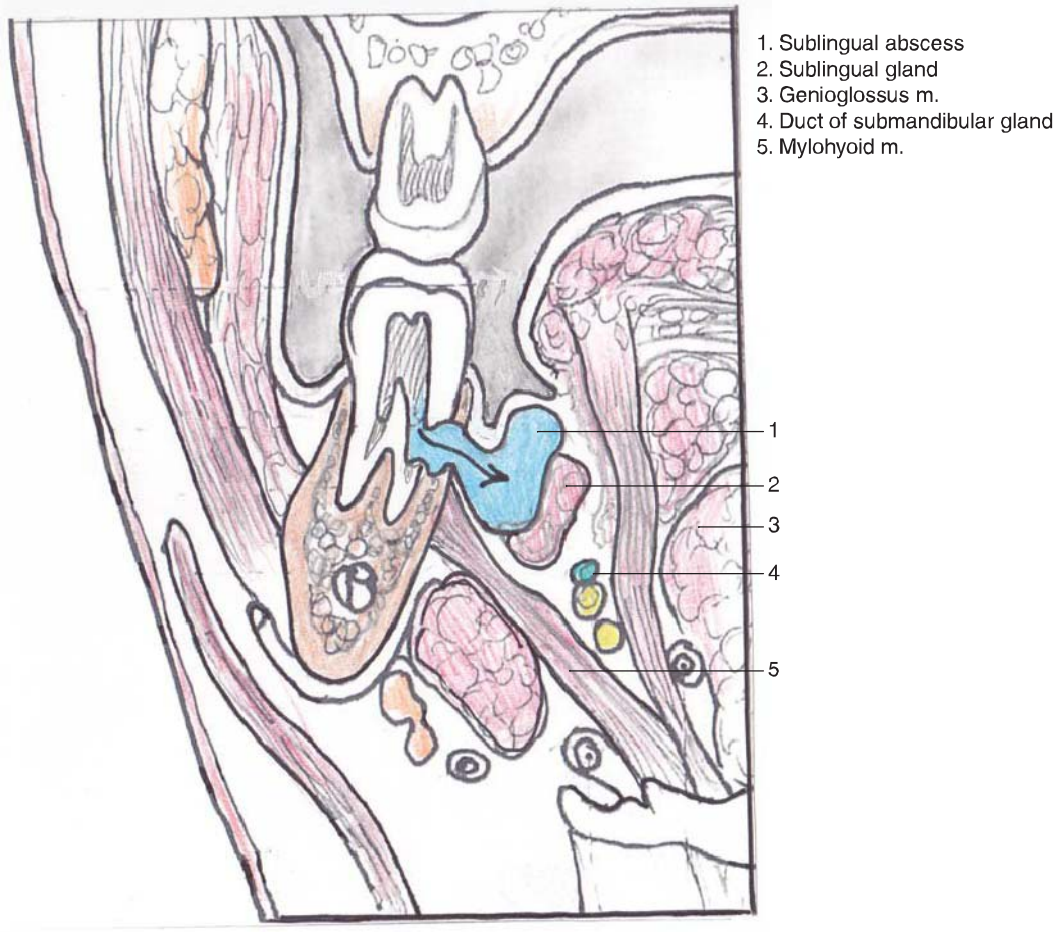

Figure 53.9 Sublingual abscess.

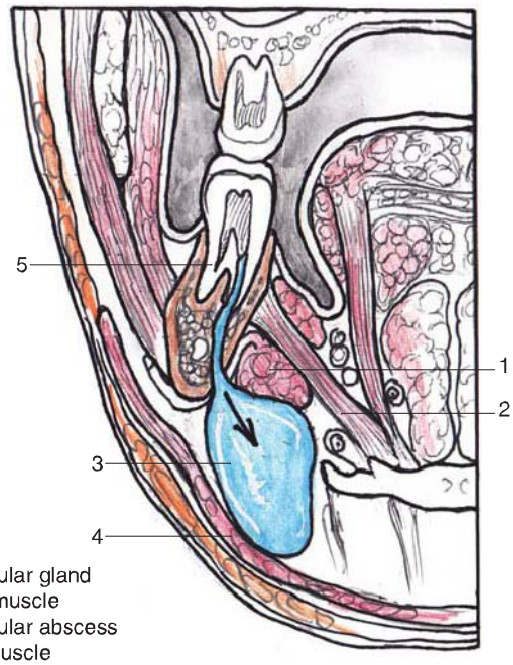

advanced cases. Infections of the sublingual space can extend anteriorly where the space communicates with the submental space. The treatment of sublingual space infections is with surgical drainage using an intraoral incision that parallels the submandibular duct to avoid its injury (Fig. 53.9).

Submandibular Space

The submandibular space is separated from the overlying sublingual space by the mylohyoid muscle. The lateral extent of the submandibular space is the skin, superficial fascial, and platysma muscle. The medial limits of the space are the mylohyoid, hypoglossus, and styloglossus muscles, while the inferior border is the anterior and posterior digastric muscles. The anterior portion of the submandibular space communicates freely with the submental space, while the posterior portion communicates with the sublingual space and deeper neck spaces (Fig. 53.10).

Submental Space

The submental space represents a midline space beneath the anterior aspect of the lower jaw. Its boundaries are

1. Submandibular gland
2. Mylohyoid muscle
3. Submandibular abscess

5. 2nd /3rd molar

Figure 53.10 Submandibular abscess.

both anterior digastric muscles, while the roof consists of the mylohyoid muscle and the floor of the mouth mucosa. The anterior and lateral borders are formed by the anterior mandible arch, while the hyoid is the posterior border. Rarely the space may be involved by infection directly from the lower central incisors. Far more frequently, the submental space is involved by the extension of infections from the submandibular and submental spaces originating in the second and third and rarely first mandibular molars.

LUDWIG ANGINA

Ludwig angina is a distinct pattern of infection that usually originates in the submandibular or sublingual space and then disseminates to all the floor of the mouth spaces by way of the posterior border of the mylohyoid to involve the submandibular and sublingual spaces bilaterally as well as the submental space. The infection begins as a cellulitis, advances to a fasciitis, and then becomes a true suppurative infection. Over 90% of cases of Ludwig angina are odontogenic, usually arising from infected second and third mandibular molars (5,11). Ludwig infections tend to spread quickly from one space to another, resulting in progressive brawny edema of the anterior and lateral neck skin with the floor of the mouth swelling and elevation of the tongue. As the tongue becomes more posteriorly and superiorly displaced, it leads to odynophagia, dysphagia and drooling. The tongue displacement can lead to supraglottic airway obstruction and asphyxiation if the airway is not secured. In the era before antibiotic and surgical therapy, the progression of the Ludwig infections was steady and unrelenting with death from airway obstruction occurring at 10 to 12 days (12).

Effective treatment of Ludwig angina involves three critical elements. These are (a) securing a safe airway, (b) administering appropriate antibiotics, and (c) surgical drainage of the infected spaces. The surgeon has to also be aware of secondary issues of sepsis. Because the potential for rapid spread and precipitous airway obstruction, the physician must ensure that the airway is secure. The decision of when and how to secure the airway is based on careful patient evaluation. The surgeon must look for signs and symptoms of respiratory distress and intervene before there is critical airway compromise. Patients who have significant tongue swelling, posterior tongue displacement, dyspnea, or stridor need to have the airway secured. Likewise, patients with airway edema on fiberoptic laryngoscopy, or significant swelling of radiographic exam, need to have a secure airway.

If a patient is seen in the early stages of an odontogenic infection before the airway shows signs of compromise, close airway monitoring with supplemental oxygen can be considered. However, these patients should be observed closely in an intensive care unit setting where the necessary resources to establish a difficult airway are readily at hand. When choosing to closely observe a patient without an established airway, the otolaryngologist must be aware of the danger of precipitating airway obstruction that can occur by placing a patient supine for diagnostic studies.

When the diagnosis of Ludwig angina is made and the disease puts the airway at risk, all authors agree that establishing a secure airway is critical. There is, however, no consensus on the best means of establishing the airway. Considerable debate exists in the recent literature over the need for a surgical airway. The historical standard had called for an awake tracheostomy prior to surgical drainage of the infection. These recommendations were based on studies reporting that up to 75% of cases of Ludwig's required a surgical airway (11). Dependence on this surgical approach is not without risks including the inherent difficulties of performing a tracheotomy in the setting of neck swelling and distorted anatomy.

Other authors have suggested alternative strategies for airway management (13–15). A number of recent studies support the use of fiberoptic oral or nasal intubation. Ovassapian et al. were successful in intubating 25 of 26 patients with deep neck abscess including 17 patients with Ludwig angina. Although fiberoptic techniques are feasible, it must be recognized that fiberoptic intubation can be much more difficult by infections that distort anatomy, produce immobile soft tissues, and cause trismus. A fiberoptic intubation does offer the potential advantage of more rapid control of the airway and avoids the risks and complications of a surgical airway. Intubation, however, is a less secure airway, and patients are at increased risk for accidental extubation. In the scenario of severe infection, re-intubation may not be possible.

The assessments of both the surgical and anesthesia teams are critical in deciding how to secure the airway. As a general rule, fiberoptic endotracheal intubation can be attempted in most cases of advanced odontogenic infection. It must be done by an experienced team member working in concert with a surgeon who is ready and capable of establishing an emergent surgical airway. The fiberoptic intubation is best performed in the semi-seated position with the instruments for a surgical airway immediately on hand. Newer devices including the intubating fiberoptic laryngoscope (Glidescope) have not yet been established for these cases but show clinical promise. Under no circumstances should induction of general anesthesia be followed by attempts at blind nasal or oral intubation. This approach is likely to precipitate loss of the airway and the associated potential lethal complications.

Those patients with Ludwig or other deep neck infection who have potential for respiratory embarrassment require the airway be secured and maintained or at least very closely monitored for at least 48 hours after surgical drainage because of the potential for postoperative swelling.

Simultaneous with securing the airway, patients with Ludwig angina must be started promptly on parenteral antibiotics targeting the expected pathogens. Empiric treatment directed against mixed aerobic and anaerobic flora has proven successful. It is rare that culture results will have a significant influence on patient management. After starting antibiotic therapy, patients should be kept on the appropriate coverage until swelling resolves. In a severe infection, this could take several days. There is considerable controversy concerning the use of systemic steroid in the setting of severe odontogenic infections. Those patients with airway swelling may derive some benefit from the use of steroids, but they are not to be relied on for airway management. Certainly for patients with diabetes the use of systemic steroids will impact control of blood glucose.

Surgery for Ludwig Angina

Surgical drainage is clearly indicated for patients with an abscess, patients with impending complications, and those showing no improvement after 24 to 48 hours of appropriate parenteral antibiotics. Many authors contend that earlier surgical intervention improves clinical outcomes (16,17). Often, in patients with Ludwig's, the surgeon does not encounter a discrete abscess but rather a malodorous "dirty dishwater" fluid.

Traditional surgical management of Ludwig angina called for a horizontal incision placed superior to the hyoid and extending laterally to a few centimeters below each angle of the mandible. Recent studies reported early surgical drainage using multiple small incisions as equally effective in treating the infection (5). Bross-Soriano et al. drained the infection with a 1.5- to 2.0-cm incision placed 2 cm below the lower border of the mandible dissecting in a subplatysmal plane into the submandibular and sublingual spaces. A similar incision and dissection below the symphysis of the mandible is used to open the submental space. Posteriorly all of the spaces are joined together by the dissection. When other spaces are involved, additional incisions are necessary to get to the parapharyngeal and the retropharyngeal spaces to drain fluid collections.

Needle aspiration is an accepted method for obtaining material for culture but is inadequate to sufficiently drain the infection. Aspiration can remove infected fluid but can delay recovery because dependent drainage is not established and irrigation of the wound is not performed. Aspiration with placement of indwelling catheters that allow repeat aspirations and irrigation can serve as an alternative to surgical incision and drainage in carefully selected cases.

GENERAL TREATMENT GUIDELINES

The appropriate management of an odontogenic infection can involve medical, surgical, or dental treatment or some combination of all of these. The dental management is probably least familiar to the otolaryngologist. The controversies in the management of the infected tooth are beyond the scope of this chapter. However, it is imperative that the source of the infection be eliminated. Generally, for more extensive infections, tooth extraction is required. However some infected teeth may be salvaged with endodontics. This management decision is a matter of clinical judgment for the dentist, but generally, extraction is the most rapid way to alleviate an infection while simultaneously providing egress for the infectious materials. Any associated dentoalveolar abscess need to be drained at the time of tooth extraction (18,19).

Prior studies have demonstrated improved outcomes with early surgical drainage of odontogenic infections. The mechanism by which early surgical drainage speeds resolution of odontogenic infections is unknown. A number of factors including improved local perfusion, decreased hydrostatic pressure, and the introduction of superficial mucosal flora all may have a role in halting spread of infection and speeding recovery (11). Anaerobic bacteria can cause significant tissue destruction, and this debris is far better cleared with an open wound. Trismus also resolves more quickly and allows earlier return to function (12).

The surgical approaches to drain the various spaces involved in odontogenic infections is detailed within the various subsections of this chapter. The use of drains in treating infections has not been studied specifically. Some surgeons prefer suction drains, while others favor passive dependent drainage. Drains that provide the ability to irrigate the wound cavity will offer a theoretical advantage in treating complex infections. Regardless of the type of drain used, the key is making sure that all the involved spaces are entered and that all loculations are opened. This can usually be accomplished with blunt digital dissection using any preoperative imaging as a guide.

Imaging

The use of diagnostic imaging has become routine in the management of an odontogenic infection. When seen in the initial stages of a suspected dental infection, dental imaging including dental films and an orthopantogram is usually sufficient to manage a patient. Dental films often will reveal a radiolucency, and orthopantograms may show some thinning of the cortical bone. In more advanced infection where there is involvement of adjacent soft tissue, computerized tomography (CT) with contrast is the most commonly ordered study. The CT scan can show the presence or absence of a fluid collection as well as involvement of the various anatomic spaces. Involvement of the masticator spaces and the parapharyngeal spaces is better revealed (20). The use of intravenous contrast better delineates the relationship of the great vessels of the neck. The presence of subcutaneous

air is an ominous sign and mandates the surgeon to drain the area quickly. When there is involvement in the lower neck or when there are findings of gangrene in the neck, the scan should be extended down into the mediastinum and chest. It is important to recognize that with many odontogenic infections, especially Ludwig angina, a true abscess may not be appreciated on CT scan. A decision to operate should be based on a careful clinical assessment and not on imaging alone. Regardless of imaging results, patients who do not improve on therapy deserve exploration.

Magnetic resonance imaging (MRI) has a limited role in the management of odontogenic infections. Although it provides excellent soft tissue resolution, in most cases, an MRI provides limited information beyond that gained from a contrast-enhanced CT scan. In addition, the additional time required for MRI image acquisition is potentially problematic when there are airway concerns. Ultrasound also has only a limited role in managing odontogenic infections. It is good at examining superficial spaces for involvement but is not able to clearly define the deeper spaces of the neck (21).

Treatment with Antibiotics

The initial treatment of odontogenic infections requires the administration of appropriate antibiotics. Given the prevailing microorganism found in these infections, gram-positive anaerobic cocci and gram-negative anaerobic rods. Empiric therapy directed against these pathogens is necessary and appropriate. Penicillins continue to be effective against most of the microorganisms present in these infections. It is inexpensive and presents minimal side effects. There are, however, reports of varying levels of resistance against this group of antibiotics. Given the increasing resistance seen, most would recommend beta-lactam stable antibiotics or those used in combination with beta-lactamase inhibitors (6,11,18,19,22). Clindamycin is also appropriate for patients with a possible allergic reaction to penicillin. It has excellent action against aerobic and anaerobic bacteria, and is not susceptible to the action of beta-lactamases. Clindamycin has been shown to have similar efficacy in a number of clinical studies to amoxicillin–clavulanate (23).

Previous studies have reported that culture and sensitivity data did not result in changes in antibiotic or other treatments (1). In many cases, the patient had already received antibiotics, which could further limit the utility of culture results. Clinical improvement with antibiotic treatment is the desired end point. Nonetheless, obtaining culture data at the time of incision and drainage may provide some information for those few patients who do not improve sufficiently on empiric therapy. Appropriate antibiotic treatment should be continued until there is resolution of symptoms and findings of inflammation. In severe cases, this may require extended periods of treatment (Table 53.2).

COMPLICATIONS OF ODONTOGENIC INFECTIONS

Dental infections may produce a virulent local infection that spreads to the adjacent deep neck spaces. These infections can then progress to life-threatening conditions including systemic sepsis, necrotizing fasciitis, and descending mediastinitis.

Deep Neck Space Infections

It is well recognized that the majority of deep neck spaces are of odontogenic origin. It is therefore mandatory to look for a potential dental source in any patient with a deep neck space abscess. As previously noted, the mandible teeth, particularly the molars, are statistically the most likely source of infections. Maxillary teeth are more likely to serve as the dental source in the pediatric population (1,2,11,17). The deep neck space infections associated with odontogenic sources include infections involving the retropharyngeal space and the parapharyngeal space. These generally require treatment with incision and drainage and administration of systemic antibiotics (2,11,18,19).

While the current chapter focuses on the issues unique to odontogenic infections of the head and neck, it does not comprehensively examine deep neck space infections. For a review of the management of deep neck space infections, the reader is referred to Chapter 55 of this text.

Cervical Necrotizing Fasciitis

Necrotizing fasciitis is a rare but severe bacterial infection of the soft tissues of the neck and its fascia. A necrotizing infection can arise from any head and neck source, but dental sources are most common. When the diagnosis is missed or when treatment is delayed, the infection can spread rapidly to involve the subcutaneous fat, deep fascia, and muscles. These polymicrobial infections produce tissue necrosis with subcutaneous emphysema. The infection requires emergent surgical debridement of all nonviable tissue at which time cultures can be obtained. These patients may require serial surgical procedures to treat the disease. Early, aggressive surgical management with appropriate medical therapy can preserve more of the overlying skin and reduce morbidity and mortality (24,25).

Mediastinitis

Infections that reach the deep neck spaces as well as those that extend in the soft tissues of the lower neck can extend to involve the mediastinum. There are a number of factors that promote the spread of odontogenic deep neck infections towards the mediastinum. These include the enclosed cervical fascial spaces of the neck that communicate with the chest. The negative intrathoracic pressures with respiration that combine with gravity to channel infection

TABLE 53.2 ANTIBIOTICS FOR ODONTOGENIC INFECTIONS

	Oral	Parenteral
Very effective	amoxicillin/clavulanic acid penicillin clindamycin metronidazole (anaerobes only)	ampicillin/clavulanic acid penicillin clindamycin metronidazole (anaerobes only)
Effective	erythromycin cephalexin tetracycline	cefazolin cefoxitin carbapenems
Not effective	sulfa quinolone	gentamicin tobramycin amikacin Third generation cephalosporins

inferiorly into the mediastinum is another factor. These infections are potentially lethal and must be treated aggressively. Surgical drainage of both the neck and mediastinum, eradication of the odontogenic source, and broad-spectrum intravenous antibiotic therapy are all required. Wide exploration of the neck and mediastinum with debridement of all nonvital tissue is needed (26,27). Again, in these circumstances appropriate airway management is critical.

HIGHLIGHTS

- Odontogenic infections are caused by the microorganisms of the oral cavity. These infections are usually polymicrobial and frequently involve aerobic streptococci as well as anaerobic peptostreptococci, *Prevotella*, and *Fusobacterium*.
- The infections usually begin in a carious tooth where the infection enters the bone through the pulp chamber. Although any tooth can be involved, mandibular molars are the most common.
- Amoxicillin/clavulanic acid and clindamycin represent effective oral antibiotic therapy for odontogenic infections while ampicillin/clavulanic acid and clindamycin are effective parenteral therapy.
- A buccal space abscess usually presents with significant facial swelling and pain but no significant trismus. In contrast, infections of the masticator spaces are recognized by pain and limitations on mouth opening.
- The mylohyoid attachment to the mandible is important in understanding the spread of infections to the submandibular and sublingual spaces. Infected teeth whose roots reside below the mylohyoid usually produce an infection of the submandibular space while those whose roots are above the line infect the sublingual space.
- Ludwig angina is an infection of the floor of the mouth and submandibular spaces. With progression, the infection can produce airway obstruction. Proper management of Ludwig's requires securing of the airway, appropriate intravenous antibiotics, and surgical drainage.
- Localized odontogenic infections usually require extraction of the infected tooth, drainage of any fluid collection, and the administration of antibiotics. Untreated odontogenic infections can spread and lead to severe, life-threatening complications including airway obstruction, mediastinitis, systemic sepsis, and death.

54 Management of Temporomandibular Joint Pain and Dysfunction

Joseph J. Fantuzzo *Sveta Karelsky*

Temporomandibular disorders (TMDs) are conditions affecting or arising from the temporomandibular joint (TMJ), muscles of mastication, or both. TMD typically manifests as pain in the head and neck region and there is often an effect on neighboring structures. The pain can mimic other painful disorders of the head and neck as well. TMDs may be interpreted as facial pain, headaches, earaches, aural fullness, clicking or popping of the ears, mild hearing loss, tinnitus, dizziness, difficulty with mouth opening, chewing or speech, closed or open lock of the TMJ, wear of the occlusal (biting) surfaces of the teeth, joint noises (clicking or popping), and other complaints. TMDs occur in an estimated 5% to 15% of the general population, peaking in young adults age 20 to 40 years. Signs of TMD occur equally in males and females, but symptoms occur and are reported more frequently in women of childbearing age. Approximately 2% of the general population seeks treatment for TMJ-related symptoms (1,2).

Patients with complaints of TMJ-related pain often have parafunctional oral habits or a history of trauma, as well as concomitant medical or psychological conditions. TMJ disorders TMDs may be divided into nonarticular muscle disorders and articular (intracapsular) disorders. Nonarticular disorders include masticatory muscle (myofascial) pain and dysfunction and can commonly be associated with fibromyalgia or other chronic pain states and irritable bowel syndrome (3). Trauma can affect the TMJ itself and associated structures. Articular disorders include osteoarthrosis, inflammatory joint diseases, infections, and benign and malignant lesions.

The role of the otolaryngologist is both to differentiate temporomandibular from other regional pathology and to initiate a treatment plan for the disease. Because of the variety of symptomatic presentations of TMDs patient perceptions of the origin of symptoms vary widely. Patients may be referred to the otolaryngologist for presumed pathology of the ear, sinuses, or parotid gland. It is not uncommon for patients to have been treated for infectious disorders of these structures prior to referral. An appropriate explanation of the anatomic basis of pain must be provided for the patient if trust is to be gained and recommendations are to be carried out. Symptoms and their severity must be accepted as reported and treated accordingly. Accurate diagnosis is important in the development of an effective treatment plan.

Patients should be reassured that TMD is generally a benign condition and clinical improvement is expected in time and with appropriate therapy. Complete elimination of symptoms is difficult and at times impossible. The goals of therapy include patient education, alleviation of pain, and improvement in jaw function.

Pain and jaw dysfunction are the hallmarks of TMD, and the pathophysiology, differential diagnosis, and management of the problems behind pain and limited jaw function are the primary focus of this chapter.

ANATOMY AND PHYSIOLOGY OF THE TMJ

The TMJ exists between the base of the skull (temporal bone) and the mandible (condylar process). The articulating bony surfaces, the articular disk, several ligaments, and numerous associated muscles make up the joint (Fig. 54.1). The purpose of the temporomandibular (or craniomandibular) articulation is to provide range of motion and to allow for the functional aspects of the mouth and jaws during breathing, speech articulation, mastication, and swallowing.

Of the bones of the head, only the TMJ and the ossicles of the ear have articulations. The secondary TMJ in humans develops by the 10th week of gestation, from mesenchymal condensations of two separate blastemas for the condyle and temporal bone. The TMJ and ear ossicles are derived from membranous bone (4,5). Superior to the condylar blastema, a band of mesenchymal tissue differentiates into

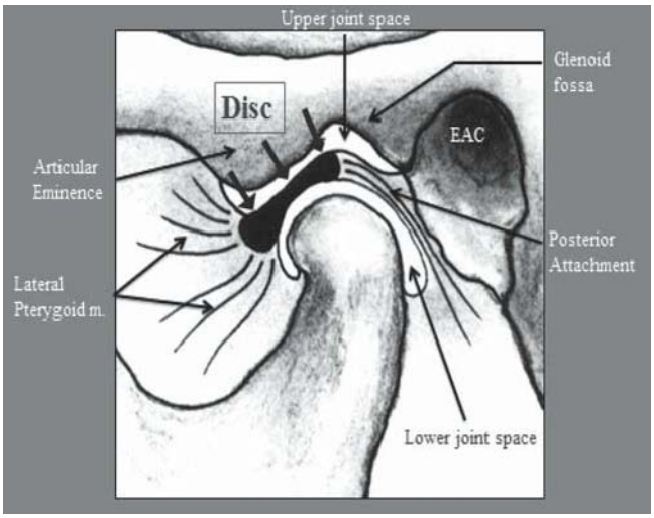

Figure 54.1 TMJ—Normal anatomy.

the disc as an extension of the lateral pterygoid muscle (4–6). Embryologic studies suggest an intimate relationship between the fetal TMJ and the middle ear through the petrotympanic fissure. This relationship may contribute to referred pain patterns or the spread of infection (7).

The articular disc is a biconcave structure that prevents bone on bone contact of the articulating surfaces and more evenly distributes articular forces. It has an anterior and posterior band and intermediate, thinner avascular zone. The disc is also attached at the medial and lateral condylar poles. The disc divides the articular space of the TMJ into a superior and inferior joint space. Posteriorly, the retrodiscal attachment is bilaminar and has significant neurovascularity. This retrodiscal tissue is intracapsular, and pain within the joint itself may be due to retrodiscal injury or inflammation. Theories of intracapsular pain are discussed later in the chapter (4,5).

The development of the primary and adult dentition influences the shape of the fossa, eminence, and condylar head. The glenoid fossa represents a concavity within the temporal bone that fits the mandibular condyle. The anterior wall of the fossa is the articular eminence. The posterior wall, made up of the tympanic plate of the temporal bone, is also the anterior wall of the external acoustic meatus. An early periosteal lining becomes the dense, avascular, fibrous connective tissue cover for the articular surfaces. The articulating surfaces are different from hyaline cartilage surfaces of other synovial joints. Edentulism leads to secondary change within the fossa and eminence (8).

The TMJ is thinly encapsulated anteriorly, medially, and posteriorly, with a thick capsule laterally forming the temporomandibular ligament. The ligament has a narrow deep portion and wider fan-shaped lateral portion. The fibrous capsule and ligament provide support and limit jaw range of motion.

The sensory innervation of the TMJ is from the auriculotemporal, deep temporal, and masseteric nerves. The blood supply to the capsule and disc is from the branches of the maxillary artery.

The motor activity of the joint results from motor innervation of the masticatory musculature, through the third division of the trigeminal nerve. The various muscle groups of the face, tongue, palate, and hyoid are also involved in functions that include the TMJ: The masticatory muscles (masseter, temporalis, medial pterygoid, and lateral pterygoid) and other important muscles (digastrics and supra- and infrahyoid muscle groups) play a significant role in the functioning of the TMJ. The actions of the muscles together on the hyoid, mandible, and related structures are important during jaw function. This interrelationship is important to consider when arriving at a differential diagnosis. A thorough review of anatomy including the actions of this musculature is beyond the scope of this chapter.

Movements of the mandible include opening and closing, protrusion, retrusion, and lateral excursions. The motion of the mandible at the TMJ is hinge-like occurring primarily within the lower compartment and gliding or translatory within the upper compartment. Unlike other joints, the left and the right side disc, condyle, and associated musculature function simultaneously. Maximum mandibular opening (between incisors) is 40 to 55 mm, is generally less in women, and decreases with advancing age (4,5,9).

PATHOPHYSIOLOGY

TMDs typically present with pain with mandibular function, limitation of mandibular movement, and joint sounds. Muscle-related pain is more common than internal joint–related pain, but they often occur together. Muscle pain may adversely affect internal joint function and vice versa, over time. Differentiating muscle pain from internal derangement is important to successful treatment. Myalgias generally present regionally with muscle weakness or fatigue and limited passive range of motion. Palpation reveals muscle tenderness. Typical problems include myalgia and myositis due to parafunction, trauma, or infection. The involved musculature may be tender, swollen, and warm. Chronic masticatory muscle contraction may be seen, with myofibrosis limiting range of motion. Previous trauma, surgery, and planned restricted range of motion (maxillomandibular fixation) will result in limited range of motion that may or may not return to normal over time.

The literature suggests that patients with myofascial TMD pain may be hypersensitive to pain, or have altered pain perception pathways. Some have features of brain morphology consistent with other chronic pain states, such as fibromyalgia. In such patients, studies of CNS regions involved in pain processing indicate changes to areas processing pain signals from the trigeminal system (10,11).

An intracapsular disorder implies a disc–condylar fossa abnormality and is associated with joint noise, and abnormal, often limited condylar movement. Intracapsular disorders are referred to as internal derangements and represent anterior disc displacement with or without reduction. The anterior displacement is thought to represent adaptive change

Wilkes Classification of Internal Derangement

Stage I	Early reducing disk displacement No pain or limitation, early opening click
Stage II	Late reducing disk displacement One or more episodes of pain, mid to late opening click, transient catch & lock
Stage III	Nonreducing disk displacement: acute/subacute Multiple painful episodes, locking, restricted mobility
Stage IV	Nonreducing disk displacement: chronic Increasing functional disturbance
Stage V	Nonreducing disk displacement: chronic with osteoarthritis, crepitus, scraping, grating, grinding symptoms; pain, restricted motion, difficult funtion

Figure 54.2 Wilkes classification of internal derangement.

within the joint to functional demand. Disc displacement with reduction is associated with joint noise, and may or may not progress to disc displacement without reduction. Anterior displacement without reduction is present when the disc remains displaced throughout mandibular motion. The disc may interfere with condylar movement. Typically there is an absence of joint noise. A nonreducing disc is thought to represent a more chronic problem (12) (Fig. 54.2).

Mouth opening is typically limited to less than 25 mm with a nonreducing disc displacement (closed lock). The mandible will deviate to the affected side upon opening, as the unaffected side translates normally. Lateral excursion (toward the unaffected side) is limited on the affected side as well. Degenerative changes of the bone may or may not be present with disc displacement. Intracapsular adhesions may be present. These fibrous adhesions are thought to occur with stretching and bleeding within the superior joint space.

Psychosocial Comorbidity

TMD patients often present with a level of pain, stress, and depression beyond that expected by the clinician. It is not clear whether these occur as a result of chronic pain, or whether they contribute to the parafunctional habits that can generate TMJ-related disorders. A large Finnish study found that patient-reported TMD symptoms are significantly associated with stress, depression, overload at work, life satisfaction, and work satisfaction. Pain perception and predisposition to TMD may be significantly affected by psychosocial stressors (13). When evaluating patients with TMD stress must be addressed by the treating clinician.

Molecular Biologic Mechanism of Injury

Both mechanical functional limitation and inflammation contribute to pain. Inflammation may lead to intracapsular swelling and pain. There can be inflammation of the joint capsule (capsulitis) and of the synovial lining (synovitis) resulting in pain and limitation in movement.

Trauma to the vascular and richly innervated retrodiscal tissues can also cause effusion, pain, and limited range of motion. The inflammation within the joint can cause secondary muscle splinting leading to more limitation in range of motion and more discomfort.

Milan described a theory of direct mechanical stress leading to the creation of free radicals contributing to a degenerative process within the joint. Direct mechanical injury from excessive load leads to increased levels of IL-8 and production of nitric oxide synthetase with NO release and free radical formation causing direct tissue damage and induction of arachidonic acid, inflammation, and tissue breakdown within the joint (14).

Other causes of free radical formation include the theories of hypoxia–reperfusion and that of neurogenic inflammation. The theory of hypoxia–reperfusion proposes that clenching increases pressure within the joint, which overwhelms capillary perfusion pressure, leading to hypoxia. Reperfusion leads to free radical formation. Neurogenic inflammation occurs with the release of neuropeptides (substance P, calcitonin) released from activated nerve terminals within the capsular ligament and retrodiscal tissue contributing to the inflammatory response.

Another hypothesis for closed lock of the TMJ is that of adhesion of the disc to the articular eminence secondary to insufficient lubrication of the joint from overloading. Nitzan described impairment of joint lubrication due to free radical formation. Inflammation secondary to macro- or microtrauma causes free radical formation and increased oxidative stress within the joint leading to the loss of lubricating hyaluronic acid (HA) and chondroitin sulfate within synovial fluid. Increased hyaluronidase leads to breakdown of HA, the major lubricant within the joint. Loss of lubrication causes capsular fibrosis and immobility of the TMJ disc. Arthrocentesis has been proposed by Nitzan and colleagues to allow for immediate release of the disc. Decreased lubrication increases viscosity and contributes to disc dislocation as the disc adheres to the glenoid fossa during motion. Adhesions vascularize and add to restriction. Increasing laxity of the lateral disc attachment occurs and the disk is gradually displaced (15,16).

Synovial fluid analysis attempts to identify the underlying pathogenesis of TMDs. The synovial membrane provides nutrients to cartilage. Diminished synovial fluid quality and quantity is thought to compromise nutrition of the articular surfaces and diminish protection and lubrication of the joints (15).

Inflammatory mediators within the injured joint worsen and prolong pain and dysfunction. Cytokines, proteases, and other substances have been implicated in internal derangement and degenerative joint disease (17). Osteoarthritis may be an imbalance between protease and protease inhibitor. Specific cytokines and growth factors have been implicated. Cytokines (IL-1, IL-6, IL-8, interferon, and TNF) may

induce proteases. Growth factors induce tissue inhibitor of metalloproteinase. Matrix metalloproteinase has been identified as a mediator of cartilage degradation (18). PGE2 synthesized by synovial cells, mediated by IL-1, plays a role in bone resorption. LTB4, synthesized by synovial cells, is elevated in painful joints and is chemoattractant for inflammatory cells. Synovial fluid analysis demonstrates increased IL-B and IL-6 in osteoarthritis (19–24).

Surgical procedures have been developed, based on the above theories. The goal of arthrocentesis or arthroscopy as the initial surgical intervention for internal derangement and osteoarthritis is to reduce the presence of inflammatory mediators as well as to lyse adhesions.

Hypomobility Disorders

Causes of TMJ hypomobility may be trismus or anatomical obstruction such as bony or fibrous ankylosis. Pain and limited range of motion may also be secondary to internal derangement of the joint. Imaging is helpful in arriving at a diagnosis. A screening panoramic radiograph may be helpful to rule out fracture, unusual anatomy (coronoid hyperplasia), or pathology. Computerized tomography (CT) imaging may be necessary to identify a fracture, degenerative disease, ankylosis, or neoplasia. Magnetic resonance imaging (MRI) is helpful when evaluating the location of the articular disc, presence of joint effusion (inflammation), and in revealing the presence of fibrous ankylosis. Hypomobility due to trismus is most frequently caused by infection, inflammation, neoplasm, radiation, or trauma. If painless, trismus may be associated with the presence of a tumor. Rarely temporal arteritis can cause trismus (25–27).

Ankylosis can be due to fibrous scar formation, bone formation, or a combination of both. Trauma is the most frequent cause in developed nations. Children who are unable to translate with opening the jaw are at increased risk of developing ankylosis. TMJ infections are rare but are reported as the cause of TMJ ankylosis in 10% to 49% of cases (28). Inflammatory arthritis such as rheumatoid and psoriatic arthritis contributes to another 10%. Juvenile idiopathic arthritis can affect the TMJ often with absence of symptoms in 50% of children (29–31). Clinical examination findings of limited opening or deviation with opening without pain should prompt the clinician to evaluate further with MRI. Intra-articular steroid injections may be beneficial (32).

The ankylotic joint requires surgical management to release fibrous tissue or resect heterotopic bone. Reankylosis is a common complication. Gap arthroplasty has a low (50%) success rate and TMJ reconstruction is often indicated with autogenous or alloplastic materials (28).

Hypermobility Disorders

Hypermobility leading to subluxation or dislocation of the TMJ can occur with yawning, prolonged opening, during a seizure, or due to trauma. A subluxed condyle becomes temporarily trapped anterior to the articular eminence. Typically, the patient will spontaneously self-reduce the mandible. Treatment is often necessary with dislocation. Dislocation implies the need for manually assisted mandibular reduction. Immediate manual reduction is essential as manipulation becomes more difficult with time. If the patient experiences repetitive dislocations with pain interfering with daily function, surgical intervention is considered. Surgical options include plication with wires, osteotomy of the zygomatic arch (Le Clerc procedure) to create an obstruction and eminectomy to remove obstruction and allow spontaneous reduction of the subluxed mandible. With eminectomy, subluxation will continue to occur, but without risk of dislocation. Lateral pterygoid myotomy is described by some authors as beneficial therapy (33–36).

Posttraumatic TMDs

Maxillofacial trauma may be the initiating event in certain cases of TMD. Many types of traumatic events are associated with temporomandibular dysfunction, including accidental, assault-related, or surgical trauma. Fractures of the mandible and surrounding structures often require treatment by the otolaryngologist, and awareness of their effect on the temporomandibular articulation is helpful.

Mandibular fractures often cause pain, malocclusion, restricted opening, loss of mandibular height, muscle spasm, or deviation of the mandible to one side. If not properly addressed, any of these features may cause disabling TMD. Normal TMJ function requires a complex mechanism of intact bone and balanced muscular forces, and traumatic disruption of any of these elements can lead to joint pathology. Anatomic reduction and rigid fixation, when indicated, are important for a good functional outcome.

Fracture of the mandibular condyle, in particular, tends to predispose to pathology of the TMJ. Condylar fractures comprise around 30% of mandible fractures, and may involve the condylar neck or, more rarely, be intracapsular. The position of the articular disc relative to the fracture site is thought to have prognostic significance. Disk displacement from the fracture appears to strongly predispose to posttraumatic joint ankylosis, as the insulating role of the disk between the articulating surfaces is lost. Joint ankylosis, or fusion, is perhaps the most severe form of TMD and produces complete joint immobility on the affected side. This is not frequently encountered in the industrialized world, but in developing countries it is quite a common consequence of mandibular trauma. Up to 98% of ankylosis cases have been estimated to originate from trauma to the mandibular condyle (37). This may be particularly common in sagittal fractures, especially when a bone fragment with a raw edge is displaced laterally or there is another, associated mandible fracture (38–40) (Fig. 54.3).

The treatment of mandible fractures involving the condylar process has long been controversial. Generally, anatomic reduction and fixation of condylar fractures in

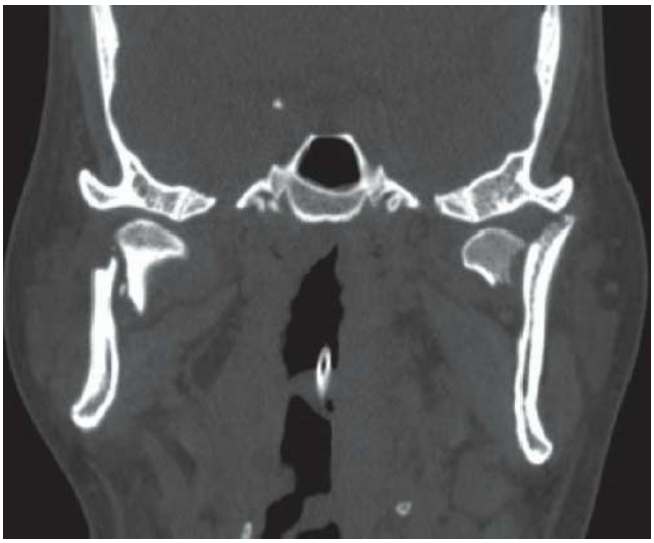

Figure 54.3 CT—bilateral mandibular condyle fracture.

adults is recommended when there is loss of mandibular height or gross comminution or dislocation of fractured segments. Anatomic fracture reduction along with postoperative rehabilitation seems to generate good results (41). However, there is a lack of studies directly comparing different treatment modalities for fracture with regard to TMJ function in adults. In children and adolescents, nonsurgical management yields excellent functional TMJ results (42).

Fractures of the skull base may affect the TMJ by involving the glenoid fossa or the adjacent external auditory meatus. Such trauma may directly disrupt the joint or cause bleeding and inflammation in the joint space, resulting in pain and dysfunction. Often these fractures are the result of life-threatening multitrauma and the involvement of the TMJ is not noticed or is not a priority. When evaluating fractures through the temporal bone, which are covered in detail elsewhere, the otolaryngologist is well-served to note their relationship to the TMJ. These fractures are generally not addressed surgically, but diagnosis and institution of TMJ rehabilitation may be helpful.

FOCUSED HISTORY AND PHYSICAL EXAM

When obtaining a history, trauma is occasionally discovered as a precipitating event. As previously mentioned, other contributing physical, emotional, and psychological factors need to be identified. It is important to define the duration of symptoms, any history of trauma or other inciting factors, the nature of pain including its onset, location, quality, timing, associations (with motion, with mastication, with awakening, or after the day's work), modifying factors that make symptoms better or worse and the presence or absence of joint sounds, limitation in range of motion, and presence of parafunctional habits. It is helpful to inquire about whom the patient has seen for the presenting problem and what studies and/or treatments (medical, surgical, appliances, physical therapy, occlusal adjustments, or counseling) have been attempted.

As part of the head and neck examination, evaluation of the TMJ generally includes an assessment of the jaw range of motion, auscultation for joint sounds and palpation, with the goal of reproducing the patient's chief complaint.

The head and neck should be inspected for symmetry and alignment of the face, jaws, and teeth. The muscles of mastication, specifically the temporalis and masseter muscles, should be palpated for point tenderness.

When assessing mandibular range of motion, the maximum comfortable opening, maximum opening with pain (active range of motion) and maximum assisted opening (passive range of motion), should be measured. Measurements are made from maxillary to mandibular incisal edges and recorded in millimeters. Normal opening should be smooth, pain free, and without noise or deviation. The location of pain with opening and the presence and location of joint sounds should be noted along with the presence and direction of deviation.

With internal derangement, deviation is toward the side of obstruction (disc displacement) as the normal side functions appropriately. An early deviation with return to smooth midline opening and closing implies early disc displacement with reduction. Deviation toward the affected side along the entire, yet limited range of motion, with no joint sounds, is a sign of disc displacement without reduction. As disc displacement becomes more chronic in nature, the range of motion follows a similar pattern but is generally greater.

Lateral excursive movements are measured from the midline incisal edge at starting, to end lateral excursive movement—recorded in millimeters. Lateral excursions are diminished in a direction away from the involved joint when a nonreducing disc displacement is present. Limited range of motion with consistent deviation on opening but equal lateral excursive movements implies a muscular disorder.

Joint sounds are common in the general population. Nonpainful joint noises without restriction in range of motion do not require intervention. Clicks are described as early, middle, or late, occurring during opening or closing. Crepitus can also be auscultated and/or palpable and may be present with disc perforation, osteophytes, or bone on bone articulation.

The TMJ should be palpated bilaterally evaluating condylar movement, pain, swelling, and crepitus. The patient can be examined for tenderness over the joint capsule or retrodiscal tissue. Preauricular and endaural palpation should be performed.

Intraoral inspection and palpation for odontogenic or other sources of pain and inflammation should be carried out. The clinician should evaluate for signs of parafunction such as bruxism (e.g., wear patterns on teeth inappropriate for age or normal function, excessive tooth mobility, buccal mucosal ridging, or lateral tongue scalloping) (43–45).

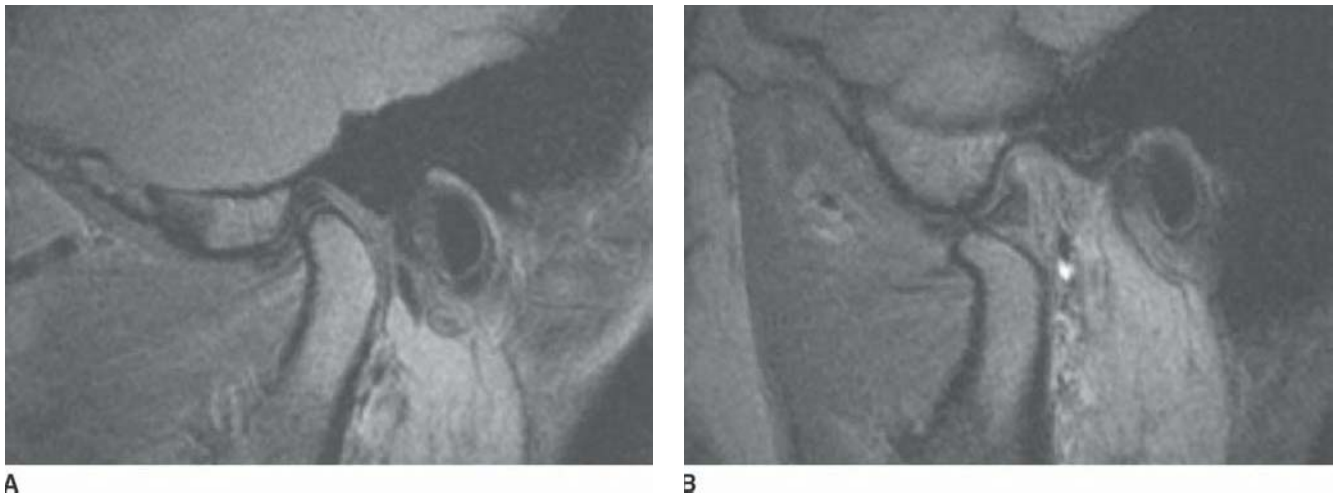

Figure 54.4 **A:** MRI—normal TMJ closed mouth view. **B:** MRI—normal TMJ open mouth view.

IMAGING

Imaging often begins with the panoramic radiograph. The panorex is an excellent screening tool. It is readily available, and quickly and easily rules out fracture, gross arthritic changes, tumors, cysts, or malformations. As with other evaluations of the head and neck, CT is helpful for evaluating bony abnormalities and gives information about the soft tissue structures as well. MRI gives greater soft tissue detail and is considered the imaging modality of choice for suspected disc–condylar abnormality (internal derangement) (Fig. 54.4A and B). Radiographic findings need to be interpreted with caution, however. Disc displacement and degenerative joint disease is frequently seen in asymptomatic "normal subjects" (46,47).

DIFFERENTIAL DIAGNOSIS

TMD pain frequently mimics other diseases seen by the otolaryngologist. Ear complaints are the most common such presentation of TMD and often consist of otalgia, aural fullness, tinnitus, and crackling or popping sounds of the ear on the affected side. Less commonly, patients report hearing loss or hearing described as "in a tunnel" on the affected side. Feelings of imbalance and dizziness are occasionally reported.

In 996 patients referred by an otolaryngology practice to a TMD treatment center, 85% complained of ear symptoms, including otalgia (64%), dizziness (42%), and muffled hearing (30%). Sixty percent complained of throat symptoms, while headaches were reported by 81% (48). In all comers with TMD, the reported prevalence of otologic complaints varies widely, but it is well established that they are an important part of the symptom complex of TMD. Ear symptomatology as a whole may be more prevalent in patients with myofascial disorders than in those with internal joint derangements, and overall pain perception referable to TMD tends to be worse in those with ear symptoms than those without. One group reports a statistically significant association between pain on palpation of the condyle and otalgia derived from TMD. Ear symptoms do tend to improve with treatment of TMD, as seen in studies comparing symptoms before and after conservative treatment with dental occlusal appliances and nonsteroidal anti-inflammatory drugs (NSAIDs) (49,50).

A comprehensive otologic workup must be carried out by the otolaryngologist to rule out ear disease before aural symptoms are attributed to TMD. In the presence of an ear exam that does not correspond with the presenting complaint, preauricular tenderness to palpation, as well as pain on palpation of the lateral anterior wall of the external auditory canal (EAC), indicates temporomandibular involvement. Occasionally, the degree of inflammation of the TMJ is such that it creates pain and edema of the shared anterior wall of the EAC, which may be mistaken for otitis externa. The dentition should be examined for signs of wear and the appropriate history elicited with regard to bruxism and other TMD risk factors.

TMJ dysfunction may masquerade as many other complaints in the head and neck, or be associated with these complaints. Occasionally, the patient with severe TMD that produces facial pain, tenderness to palpation, and edema will be diagnosed with and treated for parotitis. The proximity of the parotid gland to the TMJ contributes to this confusion, and the gland must be examined with care to rule out pathology.

Perhaps not surprisingly, emerging evidence suggests a link between TMD and headache. Certainly the two disorders appear to share psychosocial predisposing factors. Tension type, chronic daily headaches, and temporal headaches are most closely associated with TMD, and TMD severity appears to be correlated with frequency in some headache types (51–53). Neck pain or stiffness may also be present, as has been reported in up to a third of TMD patients (54).

MANAGEMENT

Management of TMDs is divided into surgical and nonsurgical options. The majority of TMDs are self-limiting. No consensus exists across the practicing community regarding when and how to treat various TMDs and even which TMD problems should be treated. Since no good long-term studies exist, data does not as yet support the superiority of any method of management. The efficacy of most treatment approaches is unknown. Noninvasive, reversible therapies that include educational, dietary, medical (nonsteroidal anti-inflammatory pain medications and muscle relaxants), prosthetic (occlusal appliance), physical therapy (heat, ice, exercise) or behavioral approaches (eliminating parafunctional habits—such as clenching or grinding—that may be harmful), and psychotherapy are therefore preferred for the majority of TMJ-related issues. The goal of therapy is to do what is least invasive and reversible if at all possible while attempting to decrease pain and improve function. Clinical studies indicate that when conservative, reversible, noninvasive therapy is emphasized, the presenting signs and symptoms improve in the vast majority of patients.

No evidence exists to say that restorative dentistry, orthodontic treatment, or orthognathic (jaw-straightening) surgery predisposes to, prevents, or causes TMD. Extensive restorative dental procedures should be avoided. No treatment is necessary when there is absence of pain and/or no loss of function.

Excessive over jet (a smaller lower jaw relative to the upper jaw in the anteroposterior plane) is the only jaw deformity that correlates with an increased risk of TMD (55). TMDs such as condylar resorption may contribute to anterior open bite malocclusion. No evidence exists to suggest that anterior open bite causes TMJ pain. Overall, with the exception of mandibular deficiency with associated Angle Class II malocclusion, the current literature does not support the role of dental malocclusion as an etiologic factor in disorders of the TMJ (56).

Treatment planning for TMDs may be based on medical and dental history, physical exam, audiology testing, speech and swallowing evaluation, psychosocial assessments related to quality of life, and imaging. A multidisciplinary approach is favored. Consultation with pain specialists, physical therapists and behavioral therapists and/or psychiatrists is often requested. Depression is associated with TMJ complaints and chronic pain (57–60).

The role of surgery to address TMJ disc abnormalities is controversial. Nonsurgical, conservative therapies are undertaken with good success in most cases. A small percentage of patients who have persistent, significant pain and disabling dysfunction with pathology directly involving the TMJ proper (degenerative disc and intracapsular disease), and for whom conservative treatment has failed, may be considered candidates for surgical intervention. Temporomandibular arthrocentesis (joint lavage), arthroscopy, or open joint surgeries are all options, but randomized controlled trials to support the efficacy of individual surgical procedures have not been performed. Additional TMJ problems that may require surgery include trauma, arthritis and disc disease, ankylosis, growth disorders, recurrent dislocation, neoplasia, and fractures.

Whatever the problem or treatment approach entails, the patient and clinician should share a common understanding of the scientific basis, indications, goals, risks and benefits, and prior history of the proposed intervention before moving ahead.

Supportive patient education, nonsteroidal anti-inflammatory agents, a diet limited to what is comfortable and physical therapy are attempted prior to irreversible interventions such as surgery. Occlusal appliance therapy and psychological assessments and behavioral therapy are often employed as nonsurgical means of treatment with good success. Surgery is considered a last resort, for those who fail conservative treatment, or for those with severe pain and loss of function.

Occlusal Appliance (Splint) Therapy

Parafunction (bruxism) is related to the development of myofascial pain (61,62). Multiple, various TMJ splints have been used over the past century. They differ in design, rationale for use, and manner of use. Occlusal appliances include repositioning devices meant to "unload" the joint, position the lower jaw anteriorly, or increase the vertical dimension of occlusion. Studies have shown TMJ splints to be effective for myofascial pain and for protection of the dentition in patients with parafunctional habits, but the type of splint has little consequence. Splint therapy has not been shown to be efficacious in treatment of intracapsular TMDs other than to possibly "unload" the joint and reduce inflammation. Reduction in inflammation may result in an improvement in jaw range of motion (63–65). Posttreatment imaging (MRI) studies have not shown an effect on disc position (66). Splint therapy does not alter the course of degenerative or inflammatory joint disease (67,68).

Each type of splint has its proponents. Soft splints are thought to encourage bruxism (69,70). Repositioning appliances have shown a high rate of recurring joint noise and progressive pain (71,72). Bite plane splints cover the anterior teeth with no posterior contact and are used with the hope of disrupting mandibular proprioception to decrease muscle activity (73). Prolonged use can cause changes in the occlusion.

The authors prefer an appliance that does not introduce irreversible change in either the occlusion or disk/condylar morphology. The indication is primarily for management of myofascial pain (74–76), effective in approximately 70% of cases (77). It is not known why splint therapy is effective, but electromyographic studies have shown a short-term decrease in temporalis and masseter muscle activity (78–80). A flat plane occlusal appliance fabricated in centric relation and adjusted to maintain posterior and

Figure 54.5 Maxillary flat plane occlusal appliance with ball clasps.

anterior even contacts with canine guidance or group function in protrusive and lateral excursions, serves this purpose. The flat plane occlusal appliance is made of a hard acrylic and covers the occlusal surface of the teeth and is worn on the maxillary or mandibular arch. Ball clasps may be used to aid retention (Fig. 54.5).

The Cochrane Database states that there is insufficient evidence to either support or discourage use of TMJ splint therapy (81,82). Further studies are necessary to validate the use of TMJ splints. Cognitive awareness and positive patient expectations may have more to do with the success of splint therapy than the biomechanical impact of occlusal appliances (83–86). In a patient with a significant parafunctional habit, at the very least, occlusal appliances may provide protection for the dentition.

Pharmacotherapy

Medical management is used to reduce pain and inflammation. NSAIDs are effective in myofascial pain, synovitis, osteoarthritis, and symptomatic disc displacement (87). Corticosteroids are useful in acute hypomobility disorders associated with pain. Prolonged use is not indicated due to the negative effects of long-term steroid use. The decision to use narcotic analgesics is a difficult one. The clinician should realize that TMDs often represent a chronic pain condition and opioid analgesics are therefore only indicated for short durations and used with caution. Many clinicians prescribe muscle relaxants for patients with TMDs. Patients report little benefit and the authors therefore do not routinely use muscle relaxants. Muscle relaxants may play a role in myofascial pain, bruxism, and hyperactivity of the masticatory musculature in parafunction. There is no benefit in patients with intracapsular TMDs. Botulinum toxin A is effective in treatment of a hyperactive masticatory system and in patients with dystonia (88–91). Anxiolytics and antidepressants also play a role in the management of chronic pain conditions. A full discussion of pharmacologic agents used in the management of facial pain is beyond the scope of this chapter.

Physical Therapy

Physical therapy includes range of motion exercises, massage, thermal treatments, ultrasound, and electrical stimulation. At home physical therapy prescribed by the treating clinician or provided by a trained physical therapist is beneficial and directed toward reducing pain and inflammation and improving range of motion.

TMJ SURGERY—CLOSED

Arthrocentesis

Joint effusion seen on MRI is an indicator of inflammation associated with hypertrophy of the synovial lining and production of exudates. Arthrocentesis is an effective initial procedure used to dilute inflammatory mediators with the hope of reducing pain in patients who have not responded to nonoperative therapy (92). Arthrocentesis is also indicated for patients with increased negative pressure within the joint causing the disc to be adherent to the fossa during motion. This may be secondary to a dysfunction of the natural lubrication system within the joint secondary due to cellular injury caused by hypoxia and reperfusion as discussed earlier in the chapter. Reactive oxygen species lead to degradation of surface-active phospholipids. Hyaluronic acid serves to protect these phospholipids from phospholipase A2, and helps maintain mobility of the joint. Degradation leads to a reduction in synovial fluid viscosity (93) and restricted mobility. Proinflammatory cytokines (IL-1B, TNF-α, IL-6, IL-10) induced by inflammation are associated with pain and dysfunction within the joints. Arthrocentesis reduces proinflammatory mediators within the joint to decrease pain and improve range of motion.

Arthrocentesis is performed using an 18 gauge needle as an inflow track positioned at a 10:2 point along the tragal–canthal (Holmlund-Hellsing) line. A second 18 gauge needle is placed just anterior, as an outflow track, and 100 mL normal saline is used to lavage the joint. After completion, the jaw is manipulated with a goal of achieving 40 mm interincisal opening. Steroids or sodium hyaluronate can be injected to reduce inflammation or improve the lubrication of the joint. Nitzan et al. (94) demonstrated the rationale and effectiveness of arthrocentesis in relieving closed lock with improvement in function and pain reduction. Laskin reported an 88% success rate in 39 joints.

Arthroscopy

In 1975, Ohnishi (95) was the first to use a Watanabe small-joint arthroscope to enter the TMJ. TMJ arthroscopy was initially developed as a diagnostic procedure.

As techniques have evolved, arthroscopy has become more than a diagnostic tool and is most often employed to improve range of motion and decrease pain through removing scar tissue, stretching the capsular ligament, resurfacing the joint surfaces, disc repositioning, lysis of adhesions, and lavage (to wash out inflammatory mediators) with or without direct injection of therapeutic agents. The success rate approximates that of arthrocentesis (96,97). Dolwick and Nitzan showed that arthrocentesis with lysis and lavage without placement of a scope gives similar results (92). Potential complications of both arthrocentesis and arthroscopy are rare, although risk is greater with arthroscopy. For the majority of TMJ surgeons, arthroscopic lysis and lavage have been replaced by arthrocentesis alone (98).

Open TMJ Surgery for Internal Derangement

The goal of open surgery is to allow the patient to return to normal daily function through reduction in pain, improved range of motion, and the ability to tolerate a regular diet by addressing the anatomical limitation and restoring a near normal anatomy of the joint. More often than not, open surgery is employed after attempts at nonoperative management, arthrocentesis, and/or arthroscopic lysis and lavage have failed. Occasionally, with significant pain and functional impairment, surgery is attempted early on.

Open surgery attempts to repair or reposition the disc or remove the disc with or without replacement. Arthrotomy is reserved for ankylosis, tumor resection, trauma, growth disturbances, and severe degenerative joint disease. Preauricular, postauricular, or endaural skin incision approaches allow access to the joint.

Complications of open joint surgery include persistent pain, hemorrhage, infection, auriculotemporal nerve and facial nerve injury, formation of fibrous adhesions, occlusal change, and ankylosis (more commonly with discectomy alone) (99).

After surgery, the author recommends the following TMJ surgery–specific postoperative instructions: Patients are asked to apply ice for the first 24 hours after surgery and then heat. The occlusal appliance is worn continuously after surgery and adjusted as necessary to maintain even occlusal contacts.

Patients need to understand that mouth opening will be limited during the first week to 10 days after surgery. Postoperative jaw opening exercises are prescribed.

After the initial 2 weeks analgesics are taken only as needed, and exercises can be performed on a less formal basis. In addition, patients are asked to continue oral appliance wear, and to remove the oral appliance only for routine oral hygiene. The postoperative diet is initially full liquid and advanced to mechanical soft over 2 weeks, and to regular as tolerated. Patients are asked to avoid hard, chewy foods such as pizza crusts, bagels, and submarine sandwiches indefinitely.

Figure 54.6 Prosthetic joint TMJ concepts, Inc., Ventura, CA.

TMJ Reconstruction

TMJ reconstruction is indicated for congenital or developmental deformity, after tumor resection, in severe degenerative joint disease, and for treatment of bony ankylosis. Reconstruction is currently performed using autografts (costochondral) or alloplastic joint replacements (Fig. 54.6). The preauricular approach is combined with a submandibular incision in most cases, although transparotid/transfacial approaches are also of value. TMJ alloplasts have strong supporters and opponents. TMJ alloplasts have resulted in significant past failures (100,101). A few FDA approved joint replacements have shown success (102).

CONCLUSION

TMJ dysfunction is common in the general population and often will be diagnosed by the otolaryngologist when investigating complaints related to the ear or other head and neck structures. TMD can be broadly divided into intracapsular and myofascial pathology and the distinction is an important one to make if the correct treatment is to be instituted. Parafunctional habits, chronic pain states, psychosocial comorbidity, or a history of trauma is often elicited from patients with TMD. Treatment should begin

with patient education and proceed conservatively with reversible pharmacologic measures, lifestyle modifications, and occlusal appliance therapy. Surgery is generally reserved for those failing conservative measures or experiencing unrelenting symptoms, and no surgical approach has been shown to be superior to others. TMD therapy remains a highly individualized process, with long-term participation required of both the patient and clinician.

HIGHLIGHTS

- TMDs refer to conditions affecting the TMJ, muscles of mastication, or both and often has an effect on neighboring structures.
- Patients with complaints of TMJ-related pain often have parafunctional oral habits or a history of trauma, as well as concomitant medical or psychological conditions.
- The TMJ exists between the base of the skull (temporal bone) and the mandible. The articulating bony surfaces, the articular disk, several ligaments, and numerous associated muscles make up the joint.
- TMDs typically present with pain with mandibular function, limitation of mandibular movement and joint sounds.
- Intracapsular disorders imply a concrete disc–condylar fossa abnormality and are associated with joint noise, and abnormal, often limited condylar movement.
- TMD pain frequently mimics other diseases seen by the otolaryngologist.
- Supportive patient education, nonsteroidal anti-inflammatory agents, a diet limited to what is comfortable, occlusal appliance, behavioral and physical therapy are attempted prior to irreversible interventions such as surgery.
- Open surgery attempts to repair or reposition the disc or remove the disc with or without replacement.
- Arthrotomy is reserved for ankylosis, tumor resection, trauma, growth disturbances, and severe degenerative joint disease.
- TMJ reconstruction is indicated for congenital or developmental deformity, after tumor resection, in severe degenerative joint disease, and for treatment of bony ankylosis.

55 Deep Neck Infections

Behrad B. Aynehchi *Gady Har-El*

Deep neck space infections (DNSIs) are a relatively infrequent entity in the postpenicillin era. Their occurrence, however, poses considerable challenges in diagnosis and treatment and they may result in potentially serious or even fatal complications in the absence of timely recognition. The advent of antibiotics has led to a continuing evolution in etiology, presentation, clinical course, and antimicrobial resistance patterns. These trends combined with the complex anatomy of the head and neck underscore the importance of clinical suspicion and thorough diagnostic evaluation. Proper management of a recognized DNSI begins with securing the airway. Despite recent advances in imaging and conservative medical management, surgical drainage remains a mainstay in the treatment in many cases.

ETIOLOGY

Knowledge of the portal of entry enables the surgeon to anticipate the pathway of extension within the neck, potential complications, and sites for drainage. In the preantibiotic era, the majority of deep neck infections in adults and children originated from the tonsils and pharynx, most commonly leading to parapharyngeal space infections (1). Acute rhinosinusitis in children may also cause retropharyngeal lymphadenitis. Suppuration of these inflamed nodes can eventually culminate in abscess formation. Early administration of antimicrobials in adult patients has led to a decreased incidence of upper respiratory tract infections and consequently significantly fewer DNSIs originating from this site. This trend has given way to infections of odontogenic sources becoming the primary source of deep neck infection in adults, recognizing a strong association with poor oral hygiene and lower socioeconomic status (2). Additional but less common origins of deep neck infections include salivary gland infections, penetrating trauma, surgical instrument trauma, spread from superficial infections, necrotic malignant nodes, mastoiditis with resultant Bezold's abscess, and unknown causes (3–5). In inner cities, where intravenous drug abuse (IVDA) is more common, there is a higher prevalence of infections of the jugular vein and carotid sheath from contaminated needles (6–8). The emerging practice of "shotgunning" crack cocaine has been associated with retropharyngeal abscesses as well (9). These purulent collections from direct inoculation, however, seem to have a more benign clinical course compared to those spreading from inflamed tissue (10). Congenital anomalies including thyroglossal duct cysts and branchial cleft anomalies must also be considered, particularly in cases where no apparent source can be readily identified. Regardless of the etiology, infection and inflammation can spread throughout the various regions via arteries, veins, lymphatics, or direct extension along fascial planes. When confined to a certain area or space, this inflammatory process will eventually form a phlegmon or abscess.

FASCIAL ORGANIZATION OF THE DEEP NECK

An understanding of the applied anatomy of the neck includes a consideration of the layers of the deep cervical fascia and the compartments or spaces formed by the arrangement and attachments of these layers. This knowledge is crucial for planning treatment strategies and anticipating potential complications. The cervical fascia is divided into the superficial and deep fascia. The deep fascia is further subdivided into three layers or components: the superficial, middle, and deep. A summary of the organization of the cervical fascia is presented in Table 55.1. Figure 55.1 features a midsagittal visualization of the fascia and deep neck spaces.

TABLE 55.1 CLASSIFICATION OF FASCIA IN THE NECK

- Superficial cervical fascia
- Deep cervical fascia
  - Superficial layer of the deep cervical fascia
  - Middle layer of the deep cervical fascia
    - Muscular layer
    - Visceral layer
  - Deep layer of the deep cervical fascia
    - Alar fascia
    - Prevertebral fascia
  - Carotid sheath formed by contributions of superficial, middle, and deep layers of deep cervical fascia

Superficial Cervical Fascia

The superficial cervical fascia lies beneath the skin of the head and neck, extending from the top of the head down to the shoulders, axilla, and thorax. This layer covers adipose tissue, sensory nerves, superficial vessels, lymphatics, the platysma muscle, and the muscles of facial expression. The platysma is absent in the midline. In contrast to the deep cervical fascia, which is composed of mainly fibrous connective tissue, the superficial cervical fascia is a layer of fibrofatty tissue connecting the overlying skin to the deeper fascial layers. Infections of this superficial space should be managed with appropriate antibiotic therapy in the case of cellulitis or extended to incision and drainage in the presence of an abscess (11).

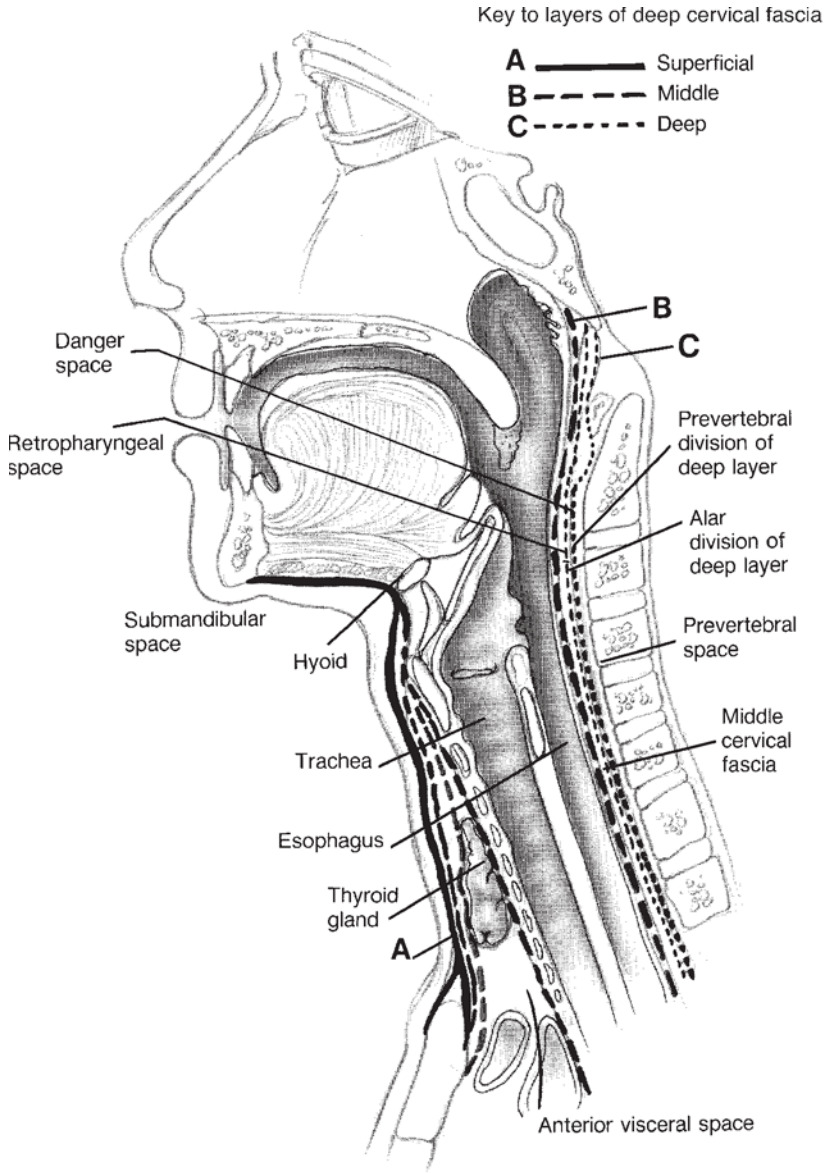

Figure 55.1 Midsagittal section of the neck shows the fascia and spaces of the neck.

Deep Cervical Fascia

As noted earlier, the deep cervical fascia is a fibrous connective tissue layer that is, for surgical purposes, subdivided into the superficial, middle, and deep components. The appropriate designation for each layer is as follows: the superficial layer of the deep cervical fascia, the middle layer of the deep cervical fascia, and the deep layer of the deep cervical fascia. A practical observation is that layers overlying nonexpansile components such as the sternocleidomastoid muscle (SCM) are well-developed membranes that can be sutured. On the other hand, fascia surrounding expansile visceral organs such as the pharynx and cheeks is a loose areolar tissue, not amenable to suture retention. Additionally, muscles and organs within these layers are generally free to glide upon contraction and relaxation.

The superficial layer of the deep cervical fascia, also referred to as the investing layer, completely surrounds the neck. The superior nuchal line, ligamentum nuchae of the cervical vertebrae, and the mastoid process are the posterior attachments. The fascia splits to envelope the sternocleidomastoid and trapezius muscles as it courses anteriorly. In the anterosuperior direction, an attachment is made to the inferior zygomatic arch. Moving inferiorly, the parotid gland is enveloped superficially, while the deep extent involves the carotid canal of the temporal bone. The stylomandibular ligament, which separates the parotid and submandibular glands, is formed as this investing fascia tracks anteriorly to cover the submandibular gland and muscles of mastication. The inferior extent includes attachments to the hyoid, acromion, clavicle, and scapular spine. The suprasternal space of Burns is formed as the fascia surrounds the intermediate tendon of the omohyoid muscle. This space may contain a lymph node along with a vessel bridging the two anterior jugular veins (12). A useful tool in understanding the contents of this plane is the "rule of two's," referring to the two muscles above the hyoid bone (masseter and anterior belly of the digastrics), two muscles that cross the neck (trapezius and SCM), two salivary glands (parotid and submandibular), and two fascial compartments (parotid and masticator spaces) (11).

The middle layer of the deep cervical fascia, also called the visceral fascia, is divided into a muscular and visceral division. The muscular division of the middle layer of the deep cervical fascia surrounds the sternohyoid, sternothyroid, thyrohyoid, and omohyoid strap muscles. Contents of the visceral division include the parathyroid glands, thyroid gland, esophagus, trachea, larynx, pharyngeal constrictor muscles, and buccinator muscle. This visceral division further contributes to two additional planes: the pretracheal fascia and buccopharyngeal fascia. The pretracheal fascia overlies the trachea. The buccopharyngeal fascia lies posterior to and separates the esophagus from the deep layer of the deep cervical fascia. This plane also marks the anterior border of the retropharyngeal space. The buccinators, pharyngeal constrictor muscles, and esophagus lie between the pharyngobasilar fascia anteriorly and the buccopharyngeal fascia posteriorly (12). The two raphes formed by the buccopharyngeal fascia include the posterior midline raphe, which attaches to the alar layer of the deep layer of the deep cervical fascia, and the pterygomandibular raphe within the lateral pharynx (11). Portions of the middle layer of the deep cervical fascia that surround the trachea and esophagus merge with the fibrous pericardium in the superior mediastinum, representing a possible portal of spread of infection.

The deep layer of the deep cervical fascia, also known as the prevertebral fascia, is composed of two divisions as well: the prevertebral and alar divisions. The prevertebral division contains the cervical vertebra, phrenic nerve, and paraspinous muscles. This fascia runs from the skull base to the coccyx, forming the anterior wall of the prevertebral space, with lateral and posterior attachments to the transverse spinous processes, respectively. The clinical significance of this boundary is the confinement of primary vertebral infections to the prevertebral space with very limited spread to the danger space. The alar division is situated between the prevertebral division posteriorly and the buccopharyngeal fascia of the visceral division of the middle layer of the deep cervical fascia anteriorly, separating the retropharyngeal and danger spaces. This layer extends from the skull base to the second thoracic vertebra. The notable structure within this plane is the cervical sympathetic trunk. In reviewing the deep fascial and special relationships within the neck, the following structures are encountered as one goes from anterior to posterior: the pharyngobasilar fascia, the esophageal or constrictor musculature, the buccopharyngeal fascia of the visceral division of the middle layer of the deep cervical fascia, the retropharyngeal space, the alar division of the deep layer of the deep cervical fascia, the danger space, the prevertebral division of the deep layer of the deep cervical fascia, the prevertebral space, and finally the vertebral body (12).

The carotid sheath is formed by contributions of all three layers of the deep cervical fascia, extending from the skull base to the thorax. Contents of this sheath include the common carotid artery, internal jugular vein (IJV), vagus nerve, and ansa cervicalis (11).

DEEP NECK SPACE ANATOMY

The above-mentioned planes of the deep cervical fascia form various real and potential spaces within the neck. These spaces though are not completely impermeable often communicate with each other in generally predictable routes. Strong fascial connections to the hyoid bone anteriorly that may function as a barrier to the inferior spread of infection have led to the classification of these spaces based on their relationship to this landmark. The spaces will be described as those involving the entire neck (retropharyngeal space, danger space, prevertebral space, and carotid space), those that lie above the hyoid bone (parapharyngeal space,

TABLE 55.2 DEEP NECK SPACES

- Spaces involving the entire length of the neck
  - Retropharyngeal space
  - Danger space
  - Prevertebral space
  - Carotid space

  - Parotid space
  - Masticator space
  - Peritonsillar space
  - Temporal space
- Spaces limited to below the hyoid bone
  - Anterior visceral space
  - Suprasternal space

submandibular space, sublingual space, parotid space, masticator space, peritonsillar space, and temporal space), and those that lie below the hyoid bone (anterior visceral space and suprasternal space). Table 55.2 outlines the classification of the aforementioned spaces.

Spaces Involving the Entire Neck

Retropharyngeal Space

The retropharyngeal space extends from the skull base to the tracheal bifurcation in the superior mediastinum (Figs. 55.2–55.4). The space is medial to the carotid sheath, anterior to the danger space, and posterior to the buccopharyngeal fascia of the visceral division of the middle layer of the deep cervical fascia. The nodes of Rouviere reside within this space and may cause abscess formation upon drainage from the paranasal sinuses or nasopharynx, especially in children. A midline raphe connecting the alar division of the deep layer of the deep cervical fascia to the buccopharyngeal fascia accounts the off-midline presentation of infections within this space, facilitating distinction from disease processes originating within the danger and prevertebral spaces, which generally lie in the midline. Routes of direct spread are mainly from the parapharyngeal space (12).

Danger Space

The danger space is flanked by the prevertebral and retropharyngeal spaces, extending from the skull base to the level of the diaphragm with minimal resistance (hence the name). It is bordered laterally by the transverse processes of the vertebrae (Fig. 55.4). The most noteworthy structure within this space is the cervical sympathetic trunk. Common sources of infectious spread are from the retropharyngeal, parapharyngeal, and prevertebral spaces (12).

Prevertebral Space

This space runs from the skull base to down to the coccyx, bordered by the vertebral bodies posteriorly, danger space anteriorly, and transverse processes laterally (Fig. 55.4). The dense areolar tissue within this space is in contrast to the loose counterpart found within the danger space. The main neurovascular constituents include the vertebral

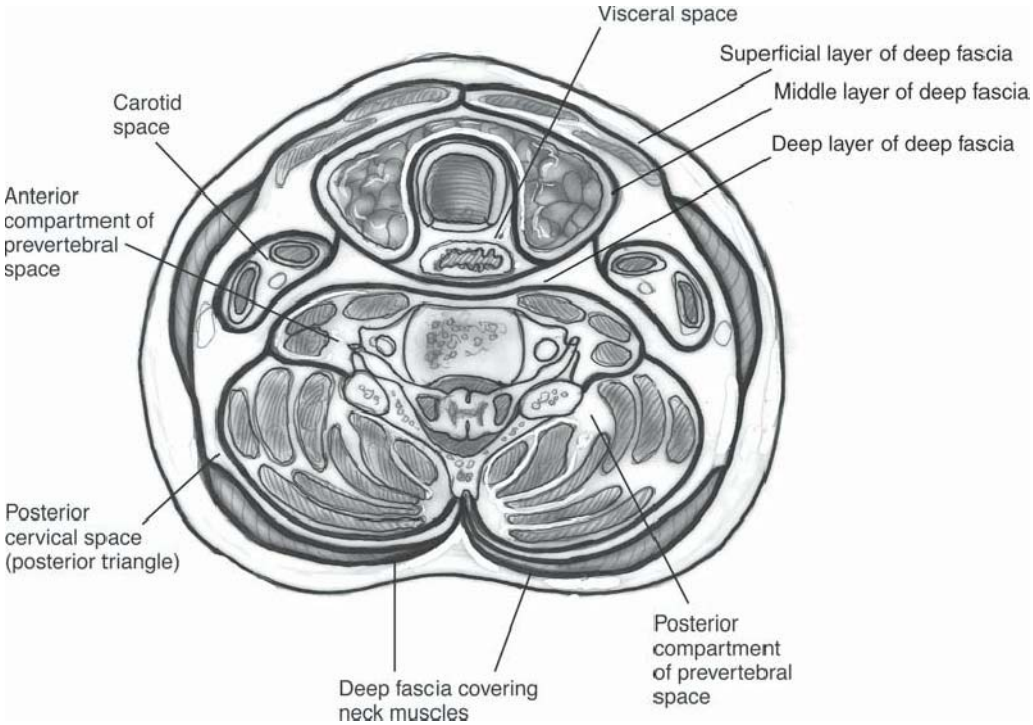

Figure 55.2 Cross section of the neck at the thyroid level.

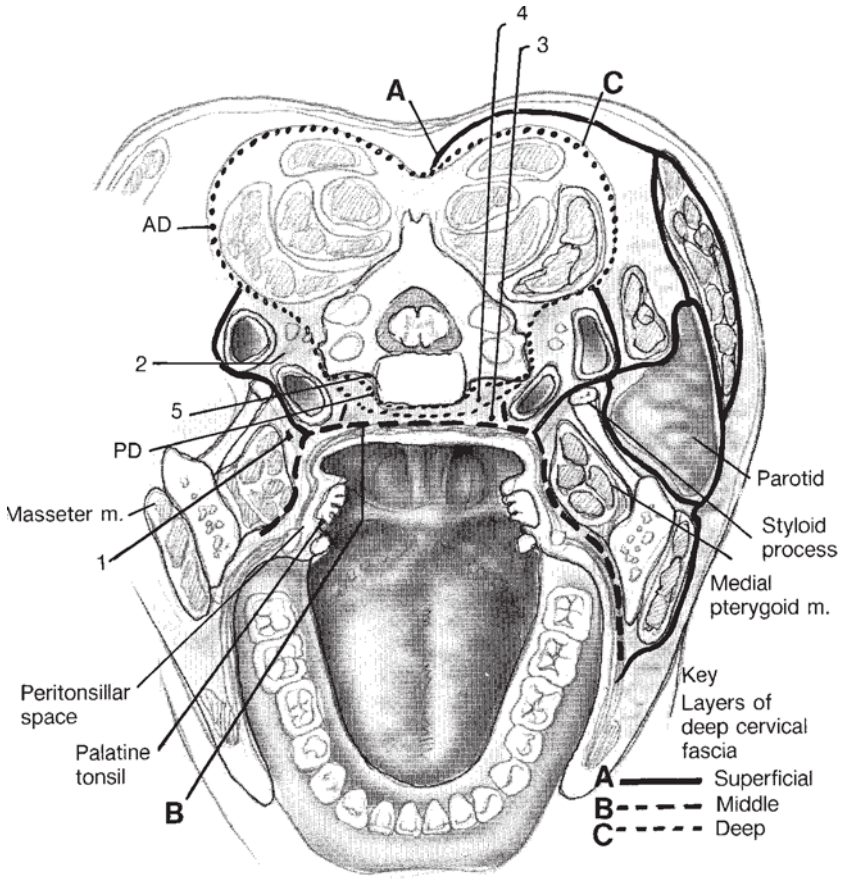

Figure 55.3 Cross section of the neck at the level of the oropharynx shows the anatomic relations of the deep neck spaces. *1*, parapharyngeal space; *2*, carotid space; *3*, retropharyngeal space; *4*, danger space; *5*, prevertebral space; AD, alar division of deep layer; PD, prevertebral division of deep layer.

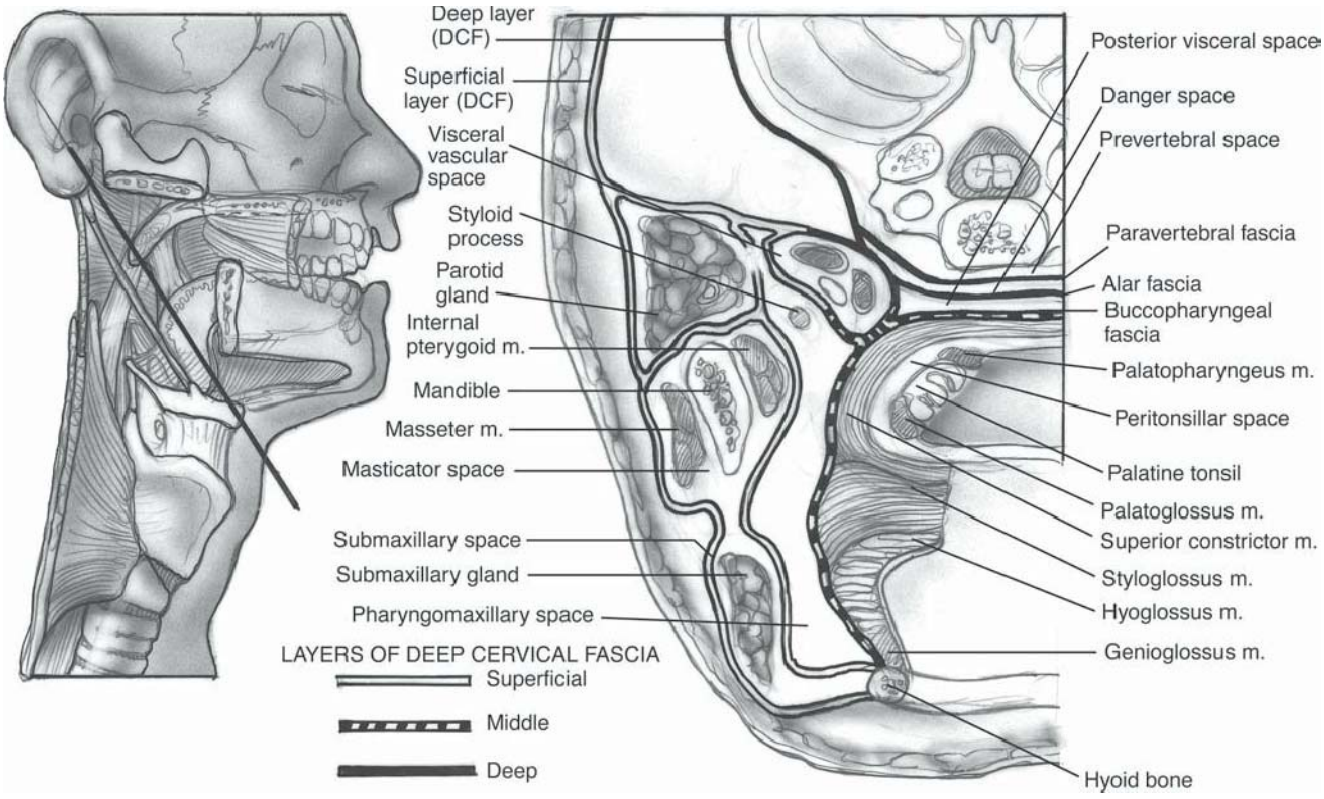

Figure 55.4 Oblique section through the neck shows the anatomic relations of the spaces limited to above the hyoid bone to the spaces that transverse the entire neck. The important relation between the parapharyngeal (pharyngomaxillary) space and the other spaces is evident.

vessels, phrenic nerve, and brachial plexus. The paraspinous, prevertebral, and scalene muscles are located within this space as well. Direct extensions of infection are from the vertebrae (e.g., Pott's abscess) or penetrating injuries (12).

Carotid Space

Also referred to as the visceral vascular space, this is a potential space enclosed by the carotid sheath extending from the skull base to the thorax (Fig. 55.4). Its contents include the carotid artery, IJV, vagus nerve (cranial nerve X), and sympathetic plexus. Spread is generally from the adjacent parapharyngeal space, penetrating trauma, or IVDA (12).

Spaces above the Hyoid Bone

Parapharyngeal Space

Also known as the lateral pharyngeal, peripharyngeal, or pharyngomaxillary space (Figs. 55.3–55.5). This has classically been described as an inverted pyramid with the base at the skull base superiorly, and the apex at the greater cornu of the hyoid bone inferiorly. The lateral borders are the lateral pterygoid muscle, mandible, and parotid gland. The medial boundaries include the superior constrictor and levator and tensor veli palatini muscles, all enveloped by the middle layer of the deep cervical fascia. It lies posterior to the medial pterygoid muscle (where involvement will result in trismus) and pterygomandibular raphe, and anterior to the prevertebral fascia. This space is further split into the prestyloid and poststyloid compartments by the styloid process, which are anterior and posterior to this landmark, respectively. The poststyloid compartment houses neurovascular structures including: cranial nerves IX, X, XI, XII, the sympathetic chain, the carotid artery, and the IJV. The prestyloid compartment contains fatty tissue, the styloglossus and stylopharyngeus muscles, the deep lobe of the parotid gland, and lymph nodes. Several notable neurovascular structures course through this compartment as well: the internal maxillary artery; and the auriculotemporal, lingual, and inferior alveolar nerves. The parapharyngeal space serves as a hub for infectious spread from several deep neck spaces. The carotid space travels through the parapharyngeal space en route to the mediastinum. Lateral spread of infection will communicate with the masticator space, inferior spread will reach the submandibular space, and posteromedial extension appears in the retropharyngeal space (12).

Submandibular and Sublingual Spaces

These two spaces communicate freely, and are hence presented together. It should be noted though that the terms submandibular or submaxillary space are commonly utilized in describing the combined submandibular and sublingual spaces. The superior border of these spaces is the mucosa of the floor of the mouth. They are limited by the hyoid bone posteroinferiorly, the mandible anteriorly and laterally, and the base of tongue posteriorly. The submandibular and sublingual spaces themselves are separated by the mylohyoid muscle, with the prior lying below and the latter lying above this landmark. Both spaces, however, communicate around the posterior edge of this muscle. It is for this reason that Ludwig's angina will result in a generalized swelling of the submandibular area along with elevation of the floor of the mouth. While underlying the mylohyoid, the submandibular space is further separated

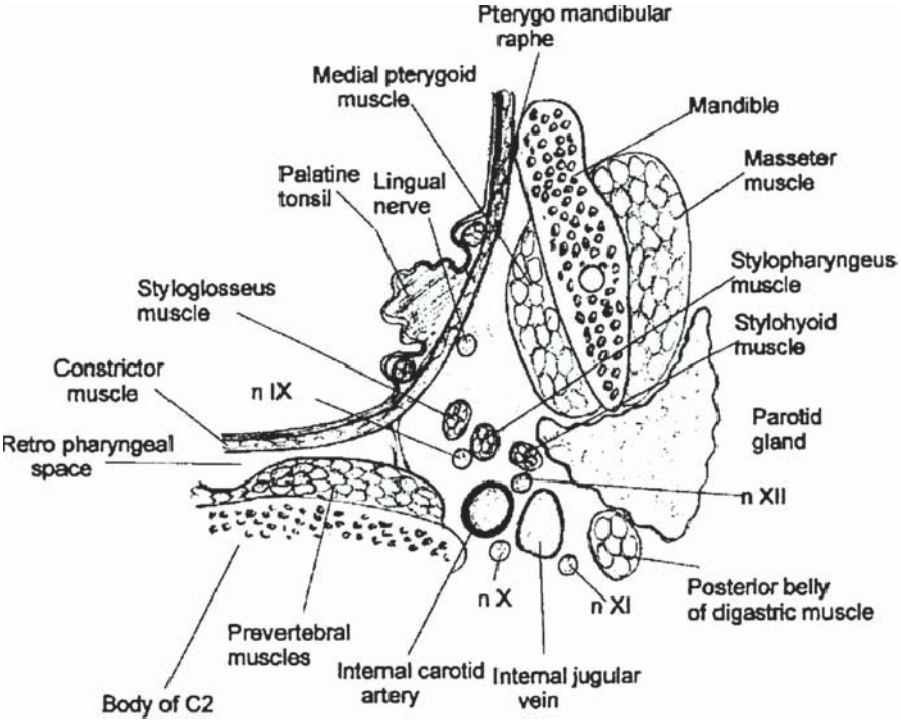

Figure 55.5 Schematic representation of the parapharyngeal space in an axial view at the C2 level.

from (but also freely communicates with) the submental space by the anterior belly of the digastric muscle. The sublingual space houses the hypoglossal nerve, the sublingual salivary gland, and Wharton duct. The submandibular gland sits in both the sublingual and submandibular spaces as it straddles the posterior edge of the mylohyoid muscle. The mylohyoid line is an oblique line along the mandible that aids in the evaluation of submandibular or sublingual space infections from odontogenic sources. The incisors to first molars lie above this line. Infections originating in the roots of these teeth generally present initially in the sublingual space. On the other hand, the second and third molars are situated below the mylohyoid line, with infectious processes of these tooth roots draining primarily to the submandibular or parapharyngeal space (12).

Parotid Space

This space, also known as the parotidomasseteric space, is created as the superficial layer of the deep cervical fascia envelopes the parotid gland, periparotid lymph nodes, facial nerve, posterior facial veins, and external carotid artery (Fig. 55.4). The fascia adheres tightly to the gland laterally. The resultant firm capsule deems differentiation of an abscess versus cellulitis within this space virtually impossible on physical examination, despite the relatively superficial location. In contrast, deficiency of the fascia along the medial border allows for communication of the gland with the prestyloid parapharyngeal space (12).

Masticator Space

This space is also formed by an investment of the superficial layer of the deep cervical fascia (Fig. 55.4). Its contents include the masseter, medial and lateral pterygoid muscles, body and ramus of the mandible, inferior alveolar vessels and nerves, buccal fat pad, and temporalis tendon. The masticator space may be divided into the masseteric space, between the mandibular ramus and masseter muscle; and the pterygoid space, between the mandibular ramus and pterygoid muscles. The masticator space is situated anterolateral to the parapharyngeal space and deep to the temporal space. Infections of this space are primarily from the third mandibular molar (12).

Peritonsillar Space

The peritonsillar space is sandwiched between the palatine tonsillar capsule medially, and the superior pharyngeal constrictor muscle laterally (Fig. 55.4). The anterior and posterior limits are formed by the palatoglossus and palatopharyngeus muscles or anterior and posterior pillars, respectively. The posterior third of the tongue serves as the inferior boundary. Delayed drainage of purulent collections from this space may result in parapharyngeal space extension (12).

Temporal Space

The temporal space is enclosed by the squamous temporal bone medially and the superficial temporalis fascia laterally. This space is further split into superficial and deep components by the temporalis muscle. Notable contents include the internal maxillary artery and the third division of the trigeminal nerve (V3) (12).

Spaces below the Hyoid Bone

Anterior Visceral Space

This space runs from the thyroid cartilage down to the level of the fourth thoracic vertebra (Fig. 55.2). The pharynx, esophagus, trachea, thyroid and parathyroid glands are the most notable components, all enclosed by the visceral division of the middle layer of the deep cervical fascia and nested behind the strap muscles. The most common portals of infection into this space include perforation of the anterior esophageal wall by trauma, foreign bodies, and endoscopic instrumentation (12).

Suprasternal Space

This is a potential space that sits just above the sternal notch, enveloped by the superficial layer of the deep cervical fascia. The suprasternal space of Burns features a small lymph node and bridging vessels between the anterior jugular veins (12).

BACTERIOLOGY

During the preantibiotic era, the organism most often isolated from deep neck space abscesses was *Staphylococcus aureus*. Since the introduction of antibiotics, aerobic Streptococcal species and non-Streptococcal anaerobes have become the chief offending agents in DNSIs. Most infections, however, are polymicrobial (13,14). These organisms generally represent members of oral flora, reflecting the most common site of origin: odontogenic infections. Practically speaking though, the organisms isolated will vary with the initial portal of entry. Notable aerobic species include *Streptococcus viridans, Streptococcus pyogenes, Staphylococcus epidermis*, and *S. aureus* (14,15). Two important relationships are that of *S. viridans, S. pyogenes*, and *S. aureus* with IVDA and *S. aureus* with infants. Methicillin-resistant *Staphylococcus aureus* (MRSA) has been increasingly associated with IVDA, infants, and immunocompromised patients as well (16–22). Currently, the most frequently isolated anaerobes include *Peptostreptococcus, Fusobacterium*, and *Bacteriodes* (6,14,19,23), though their overall prevalence is likely underestimated in most reports due to difficulty in culture growth. Production of beta-lactamase has led to the growing resistance of anaerobic agents to penicillin (23,24). *Eikenella corrodens* is increasingly found in head and neck infections, bringing with it a very clinically relevant resistance to clindamycin and metronidazole.

Gram-negative rods, such as *Haemophilus, Escherichia, Pseudomonas*, and *Neisseria*, are usually only seen in hospitalized, debilitated, or immunocompromised patients (3). *Klebsiella pneumoniae* is found to have a predilection for poorly controlled diabetics. Atypical and granulomatous

organisms, including *Actinomyces*, tuberculous and nontuberculous mycobacteria, cat scratch or *Bartonella henselae*, and tularemia (25,26), are seen far less frequently.

DIAGNOSIS

History, physical examination, laboratory tests, and diagnostic imaging yield vital information in diagnosing and managing patients with DNSIs. The first priority, however, is expedient and aggressive management of potential respiratory compromise. Upon confirmation or achievement of a secure airway, a comprehensive and careful evaluation is necessary in elucidating possible sources of infection in order to direct optimal therapeutic approaches. It is also important to note that many patients presenting to an otolaryngologist with a possible DNSI have already been placed on an outpatient antibiotic regimen, possibly altering the typical presenting symptoms and findings, underscoring the importance of a thorough evaluation (1,27).

History and Physical Examination

As with any disease process, a thorough history of the present illness must be solicited. This starts with a survey of symptom onset, intensity, duration, and any systemic inflammatory symptoms and signs such as pain, fever, swelling, malaise, fatigue, or redness. Localizing complaints of dyspnea, odynophagia, dysphagia, voice changes, drooling, trismus, and otalgia direct the clinician toward a possible site of infection (13,28–31). Potential instigating events including recent dental infection or procedures, sinusitis, pharyngitis, otitis, upper aerodigestive tract surgery, intubation, IVDA, blunt or penetrating trauma, or skin infection should be inquired about as well. Immunocompromised patients, most commonly those with diabetes, human immunodeficiency virus (HIV), acquired immunodeficiency syndrome, autoimmune diseases, malignancy, chemoradiotherapy treatment, or steroid use must be identified and attended to with a higher level of vigilance, as they tend to be susceptible to more virulent and atypical organisms in addition to a much more aggressive disease process (7,32,33).

The physical examination of any patient with a potentially life-threatening diagnosis must be accomplished in a systematic and complete manner. A general overview of the patient may reveal respiratory distress, labored breathing, anxiety, signs of dehydration, weakness, photophobia, limited neck motion, lethargy, altered voice, track marks from IVDA (6), or cognitive deficits. Deficiencies on cranial nerve examination can assist in localizing the source of the infectious process. The facial skin and scalp must be inspected for any signs of superficial infection, inflammation, or swelling. The presence of purulence, inflammation, or tenderness on otoscopic examination may direct the physician toward the presence of a Bezold's abscess (Fig. 55.6) or the rare occurrence of spread of a DNSI from an odontogenic source into the external auditory canal (34). While evaluation of the oral cavity will mainly focus on possible odontogenic sources of

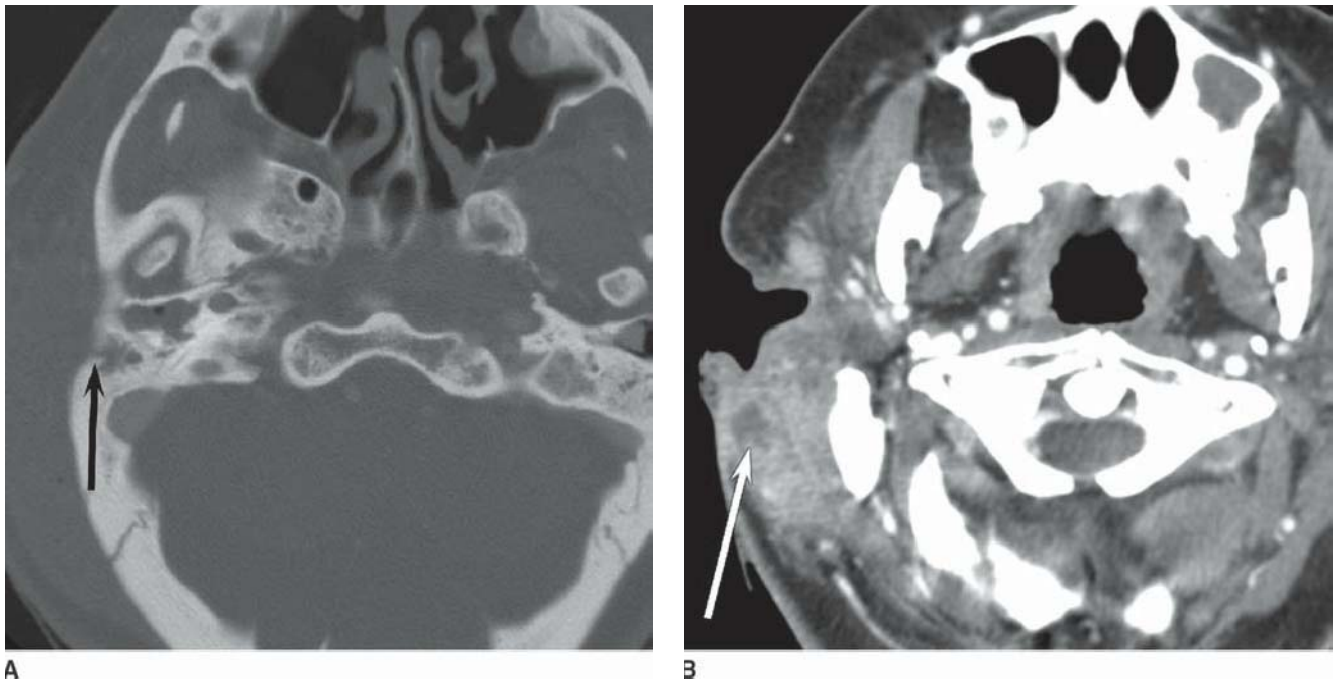

Figure 55.6 Coalescent mastoiditis with Bezold abscess. **A:** Axial contrast-enhanced CT on bone window shows complete opacification of underpneumatized right mastoid air cells with a lateral cortical breakthrough (*arrow*). The external auditory canal is also nearly completely opacified. **B:** More inferior image, on soft tissue windows, shows abscess (*arrow*) alongside the mastoid tip, involving the SCM (Bezold abscess).

infection, a survey for trismus, floor of mouth swelling, and salivary flow from Stensen's and Wharton's ducts is just as crucial. The oropharynx must be examined for signs of asymmetry, bulges, uvular deviation, inflammation, or swelling. The neck should be palpated for any crepitus, swelling, tenderness, or lymphadenopathy. The final component of the physical examination, awake fiberoptic laryngoscopy, is compulsory in any patient with signs of potential airway compromise such as dyspnea, dysphagia, stridor, odynophagia, hoarseness, and limited range of neck motion. The presence of deviation, swelling, or inflammation in the airway will obviously raise the level of urgency and shift the immediate priority from treatment of a potential DNSI to securing the airway. The most common symptoms and physical examination findings encountered in patients with specific DNSIs are elaborated on the following sections.

Laboratory Tests

Laboratory tests should be obtained concurrently with the history and physical examination. In anticipation of a possible trip to the operating room (OR), routine preoperative labs along with a complete blood count with differential, and complete metabolic panel must be drawn. When past or current medical history indicates, HIV screening, blood glucose levels, and tuberculin skin testing should be obtained. Additionally, blood cultures and available aspirate cultures are recommended. Cultures with positive gram stain but without growth raise the suspicion for an anaerobic organism (11). Given the relatively increased frequency of atypical and aggressive organisms associated with immunocompromised patients, it would be prudent to obtain acid-fast and fungal cultures in this population (35). While the majority of patients with a DNSI demonstrate an elevated white blood cell (WBC) count, patients with HIV and tuberculosis who had drainable abscesses often exhibit persistent leukopenia (WBC count < 8000 per milliliter) (6). It is also important to note the presence of leukocytosis in the background of steroid administration, potentially confounding the clinical picture when attempting to follow the response to medical or surgical therapy with serial WBC counts.

Imaging

Computed Tomography

The ability to identify the specific spaces involved, early or potential complications, and the nature of DNSIs has designated contrast-enhanced computed tomography (CECT) scanning as a critical component of the diagnostic work up (28). The scan itself is excellent for delineating both bony and soft tissue structures. The addition of intravenous contrast further assists in differentiating a well-formed abscess from a phlegmon or cellulitis and visualizing the great vessels. An abscess on CECT scan will demonstrate a central area of low attenuation or hypodensity with ring enhancement of its wall, surrounded by soft tissue edema. The presence of air on CECT scanning is also strongly predictive of an abscess (36). This modality does have certain noteworthy limitations however. Miller et al. (37) noted an improvement in accuracy from 77% to 89% when CECT scan was combined with a clinical examination, with similar findings in the pediatric population noted by Vural et al. (38). The quality of certain images can also be compromised by the presence of metal materials within the head and neck causing streak artifacts. Another drawback relates to the risk of radiation exposure, particularly in pediatric patients facing serial scans. Finally, intravenous contrast may be contraindicated in patients with allergies to these agents or with compromised renal function. Occasionally, with retropharyngeal abscesses, differentiation between a well-formed abscess and phlegmonous soft tissue edema may be difficult with CECT. In addition, although needle aspiration may be helpful with diagnosis in a questionable radiologic diagnosis, this procedure carries a false-positive rate of up to 25% (39).

Plain Film Radiography

While plain films have generally limited utility relative to other imaging modalities, they may be useful in the detection of certain types of DNSIs. Panorex jaw films may reveal an odontogenic source for certain DNSIs (11). Findings of tracheal deviation, subcutaneous emphysema, mediastinal widening, and pneumomediastinum on chest films are associated with possible thoracic collections or mediastinitis (29). In contrast, the usefulness of anteroposterior and lateral neck films in diagnosing retropharyngeal, prevertebral, and parapharyngeal abscesses has been questioned following the findings by Nagy and Backstrom (40) of a sensitivity of 83% for plain films versus 100% sensitivity with CECT scanning.

Magnetic Resonance Imaging

Relative to CECT scanning, magnetic resonance imaging (MRI) yields superior soft tissue differentiation, particularly in infections involving the prevertebral or parotid spaces, and intracranial cavity. Limitations of CECT scanning, including radiation exposure risk, streak artifacts, and intravenous dye allergies, are all circumvented with MRI (11). Additionally, magnetic resonance angiography is useful in the evaluation of potential vascular complications of DNSIs including thrombi, vessel narrowing, aneurysm, rupture, and pseudoaneurysm (41). While this modality may complement CECT scanning in select cases, the vast majority of patients do not undergo MRI due to the high cost, contraindication with metal or electrical implants, and lengthy time requirement posing considerable discomfort and risk in patients with dyspnea, dysphagia, and children who require sedation (39).

Ultrasonography

Frequently used in Europe for the evaluation of DNSIs, ultrasound is a less expensive and noninvasive alternative to CECT scanning that is gaining popularity in the United States.

Portability and the avoidance of radiation exposure in the pediatric population are additional advantages. Its major utility lies in guiding diagnostic or therapeutic needle aspirations in the setting of a stable airway (42,43). Due to the lack of anatomic detail needed for surgical planning, difficulty in interpretation and visualization of deeper lesions (39), the recommended role for ultrasound appears to be as an adjunct to CECT scanning or MRI (35).

MANAGEMENT

Successful management of DNSIs can be achieved by prompt and adequate treatment, emphasizing control of the airway, effective antibiotic therapy, and timely aspiration or surgical intervention when indicated. In addition, a thorough search for the initial infectious source must be carried out in order to prevent a recurrence.

Airway

Safe and secure airway maintenance is the most important initial therapeutic objective in the management of DNSIs (44). Hypoxia and asphyxia remain the most common causes of mortality rather than uncontrollable sepsis (45). Clear indications for watchful waiting versus intubation or tracheotomy do not always exist; therefore, each patient must be assessed individually. Keeping in mind the potential for rapid deterioration without warning, admission into a monitored unit with close and frequent observation by medical staff is critical. Signs of progressing stridor, dyspnea, or increased work of breathing are valuable clues of potential airway compromise. In the setting of clinical deterioration, early intubation or tracheotomy circumvents the performance of these procedures in more dire circumstances.

Options for managing the airway include conventional endotracheal intubation, awake fiberoptic intubation, and tracheotomy (46). Airway instrumentation during endotracheal intubation in an awake patient carries the risks of laryngospasm and possible abscess rupture with subsequent aspiration. Therefore, only an anesthesiologist or otolaryngologist with extensive experience should perform this procedure. The addition of nebulized epinephrine is helpful in reducing mucosal edema. Awake fiberoptic intubation, most commonly nasotracheal, has gained significant popularity as the availability of flexible fiberoptic scopes and subsequent experience level of operators have grown. The procedure requires the patient to sit in an upright position, preventing backward collapse of the tongue and pharyngeal walls. Inhaled nebulized lidocaine and nasopharyngeal "trumpets" coated with lidocaine jelly are generally effective in facilitating comfortable intubation in an awake patient. A tracheotomy set must be available should a surgical airway become necessary. It has been suggested that many retropharyngeal and true Ludwig's abscesses be managed surgically from the outset in the interest of avoiding emergent "slash" tracheotomies in suboptimal settings (6,14,47). In patients with significant airway edema, sepsis, or extensive collections where extubation within 48 to 72 hours is questionable or not expected, elective tracheotomy following successful intubation or tracheotomy under monitored anesthesia care and local anesthetics should be performed in favor of shorter hospital and intensive care unit (ICU) stays (47).

Medical Management

The species of pathogens that cause the overwhelming majority of DNSIs in immunologically sound or compromised individuals have been mentioned earlier in this chapter. This predictability in clinical circumstances allows for reasonable knowledge in administering appropriate empiric agents until cultures and sensitivities from aspirates or surgical drainage become available. Most cases involve mixed flora of gram-positive cocci and gram-negative rods along with beta-lactam–resistant anaerobes. Optimal coverage for these organisms is supplied by a penicillin in combination with a beta-lactamase–resistant antibiotic along with a drug effective against anaerobes (such as metronidazole or clindamycin). Patients susceptible to *Pseudomonas* should receive an anti-Pseudomonal penicillin (such as ticarcillin–clavulanate, piperacillin–tazobactam, or imipenem–cilastin), a quinolone (such as ciprofloxacin, or levofloxacin), or an aminoglycoside. Clindamycin or vancomycin should be administered to those at risk of a MRSA infection (7,23,48,49). Recent evidence (31,50) has shown that an uncomplicated abscess, particularly in a pediatric patient, contained within a lymph node (as seen on imaging) can be treated effectively with a 48- to 72-hour trial of antibiotics and close observation without surgical intervention. Concurrent treatment of predisposing comorbidities in adults and children will improve immune function as well. In cases where surgical drainage is required, parenteral antibiotics will be continued postoperatively until the patient is afebrile for 48 hours, and then switched to an oral agent for an additional 2 weeks. Supplemental intravenous hydration is also a vital component in supporting the host response to infection.

Surgical Drainage

The decision to institute surgical drainage is based on several factors. In questionable cases, a 48-hour period of careful observation and monitoring along with intravenous antibiotic therapy and hydration may be indicated prior to considering a trip to the operative suite. Progression of symptoms indicating surgical drainage can be manifest by persistent fevers, tenderness, swelling, and elevated WBC counts. This trial period must involve frequent examinations in order to accurately gauge the overall clinical status of the patient. Additional indications for drainage include potential airway compromise, critical condition from

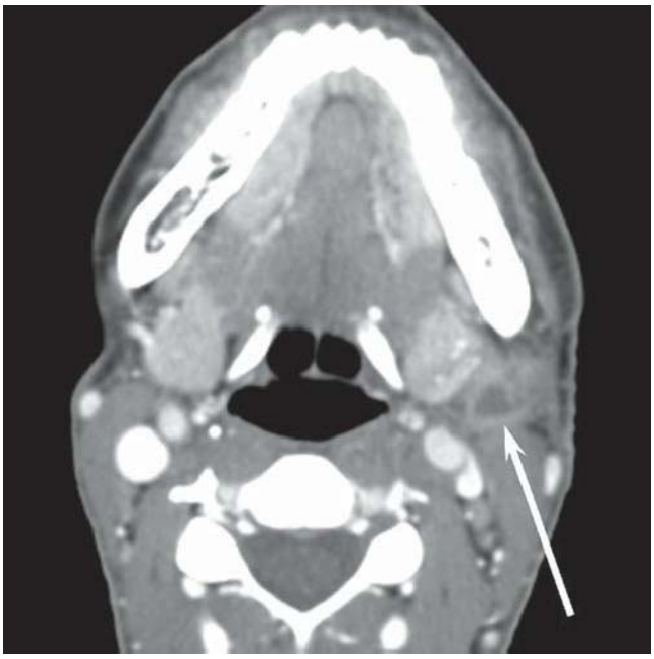

Figure 55.7 Tuberculous adenitis. Axial contrast-enhanced CT shows an abscessed lymph node (*arrow*) at the tail of the left parotid. TB-infected nodes may be of low density, or may become frankly abscessed.

complications or septicemia, and evidence of collections larger than 3 cm or involving multiple spaces (28,51). Surgical drainage can involve various approaches including transoral drainage, external cervical drainage, and less invasive methods such as needle aspiration or indwelling catheter placement (11). Upon accessing the cavity, a sample of purulent fluid or debrided tissue must be collected and submitted for culture and sensitivity. With regard to granulomatous diseases such as tuberculosis and atypical mycobacterial infections (Fig. 55.7), medical management, excisional biopsy, or needle aspiration is generally favored over incisional drainage in the interest of avoiding the potential for a persistently draining sinus tract.

Transoral and Intraoral Drainage

Peritonsillar space abscesses are approached transorally. Uncomplicated retropharyngeal abscesses are usually drained in this manner as well. Select parapharyngeal space infections lying immediately beneath the lateral pharyngeal wall may also be accessed transorally. Odontogenic collections limited to the alveolus can be addressed with simple tooth extraction and subsequent root drainage. Buccal space and shallow sublingual abscesses are entered through the intraoral mucosa. Finally, incision and dissection through the retromolar trigone and masseter muscle yields access to the masticator space (11). While spaces approached intraorally are amenable to drain placement, this practice is discouraged in more distal transoral routes (retropharyngeal, peritonsillar, or parapharyngeal) due to the risk of aspiration.

External Drainage

Collections within the anterior visceral, submandibular, parapharyngeal, prevertebral, and carotid spaces are generally drained with an external cervical approach. All involved spaces must be incised and drained with care taken to avoid injury to vital structures while utilizing the shortest route from the outside (35). Following access to the abscess cavity, loculations are broken and the space is thoroughly irrigated. Larger wounds undergoing considerable debridement will remain open and be packed with antimicrobial iodoform, eventually healing by secondary intention. Smaller cavities can be closed loosely with sutures and Penrose drain placement.

Needle Aspiration and Catheter Placement

Simple, unilocular collections in stable patients may be amendable to less invasive techniques. Palpable abscesses can be directly aspirated with a needle. Alternatively, introduction of an intravenous catheter permits irrigation within the cavity. Pigtail catheter placement with the Seldinger technique affords continued drainage and flushing (52). CECT or ultrasound guidance is usually necessary in localizing deeper collections (53,54). The main advantage of this modality is the avoidance of the potential morbidity associated with open surgical approaches including scarring, contamination with spread of infection, and neurovascular injury.

COMPLICATIONS

Despite expedient diagnosis, antibiotic administration, and surgical drainage, complications may occur. An important predisposing factor for a complicated DNSI is an immunocompromised host. Spread of infection to adjacent vital anatomic structures also occurs more commonly in the background of delayed presentation or diagnosis (30). Aggressive and vigilant management is vital in avoiding the potentially catastrophic outcomes associated with a complicated disease course.

Neurovascular Complications

Carotid artery pseudoaneurysm and rupture can occur with infectious spread to the carotid space. Patients most frequently present with a pulsatile neck mass (55). Additional findings include recurrent sentinel hemoptysis or bloody otorrhea, hematoma within the soft tissues of the neck, and hemodynamic collapse (11,56,57). Once recognized, the standard intervention is surgical ligation of the common carotid artery (56). If time permits, less invasive endovascular stenting or vessel occlusion in an interventional radiology suite may also be attempted (58,59).

Lemierre's syndrome, or IJV thrombophlebitis (Fig. 55.8), is a rare but serious complication of DNSIs (60,61). The anaerobe, *Fusobacterium necrophorum*, is the most common causative organism, with clinical manifestations of spiking fevers, neck stiffness, pulmonary and systemic

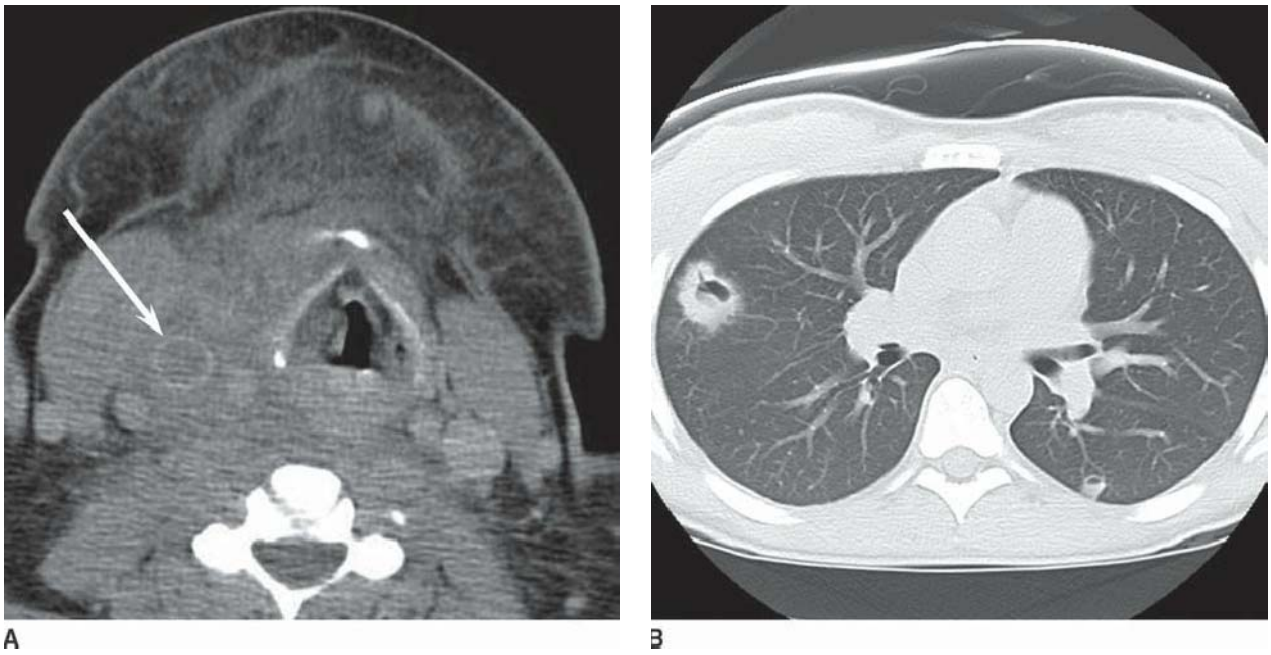

Figure 55.8 Internal jugular thrombophlebitis with Lemierre syndrome. **A:** Axial unenhanced CT shows hypodensity of the right IJV (*arrow*) with extensive surrounding fat infiltration. On contrast-enhanced CT, the vein would fail to enhance like the other vessels. Ultrasound may also be used to document disruption of venous flow. **B:** Axial CT on lung windows shows multiple cavitary lung masses with ill-defined borders, representing lung abscesses from infected emboli (Lemierre syndrome).

emboli, and tender swelling along the SCM and angle of the jaw (62). Diagnosis is confirmed with the finding of ring enhancement and a filling defect of the IJV due to a clot or purulence on CECT. Treatment involves beta-lactamase–resistant antibiotics with the addition of heparin anticoagulation in the presence of thrombus progression or septic emboli. Worsening symptoms or abscess formation in the setting of appropriate medical therapy is an indication for surgical ligation of the IJV (63). Retrograde spread of the thrombophlebitis may also result in a potentially fatal cavernous sinus thrombosis (64), which is managed with critical care support and intravenous antibiotics.

In addition to Lemierre syndrome, spread of infection to the upper carotid space and poststyloid parapharyngeal space may also lead to deficiencies in cranial nerves IX, X, XI, and XII (11). The classic triad of ptosis, anhydrosis, and miosis (Horner's syndrome) will be observed with involvement of the postganglionic sympathetic nerves. Central nervous system complications of DNSI spread include meningitis and intracranial abscess.

Additional Complications

Rupture of an abscess into the airway can result in serious outcomes including aspiration pneumonia, lung abscess, empyema, and even asphyxiation. Deeper spread of infection may cause osteomyelitis of the cervical vertebrae and mandible, which are generally addressed with long-term intravenous antibiotics (65). Systemic consequences of DNSIs include disseminated intravascular coagulation and sepsis, both of which carry high mortality rates despite intensive care management and resuscitative efforts (26,66).

SPECIAL CONSIDERATIONS

Mediastinitis

Extension of DNSIs from the head and neck into the mediastinum is a relatively rare but dreaded complication, carrying a mortality rate of approximately 40% (67,68). Infectious spread generally traverses the retropharyngeal, danger, prevertebral, or anterior visceral spaces with a mix of aerobic and anaerobic offending agents (69,70). Characteristic findings on physical examination include progressive chest pain and dyspnea, along with neck swelling. The classic finding on plain film or CECT scan of the chest is a widened mediastinum. Fluid collections, pneumomediastinum, and even pneumothorax may be present as well (71). Medical therapy requires broad spectrum antibiotics and ICU support. Superior mediastinal collections can generally be treated through a deep transcervical approach. Involvement of more inferior structures, however, necessitates thoracotomy with chest tube insertion (72).

Necrotizing Cervical Fasciitis

Necrotizing cervical fasciitis (NCF) is a rapid and diffuse spread of infection throughout multiple fascial planes associated with significant morbidity, and a mortality

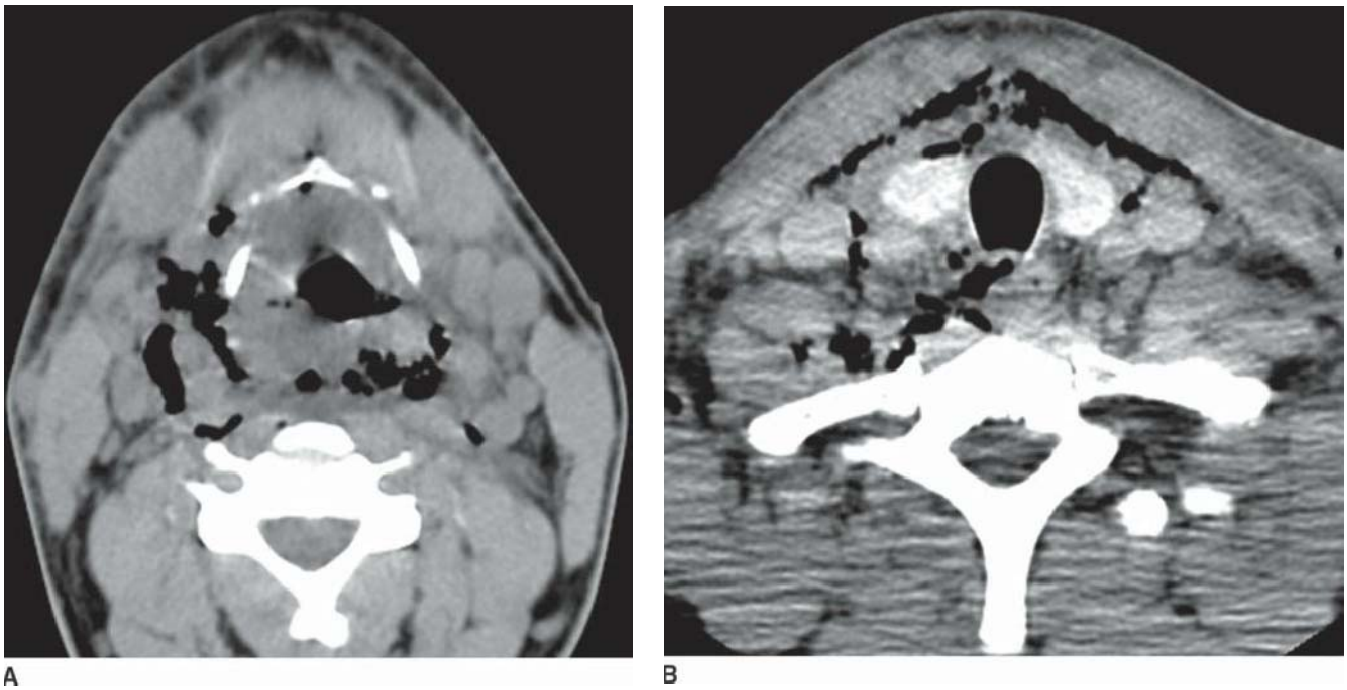

Figure 55.9 Necrotizing fasciitis. Axial unenhanced CT images at the level of the hyoid bone **(A)** and thyroid gland **(B)** show extensive gas formation throughout the deep fascial compartments of the neck. There is also extensive infiltration of the fat planes, which distinguishes this case of necrotizing fasciitis from perforation of the upper aerodigestive tract.

rate of approximately 30% (Fig. 55.9). Local extension with mediastinitis or systemic spread with sepsis is associated with an even poorer prognosis (73,74). As with most DNSIs, the predominant source is a polymicrobial odontogenic infection with a mixture of aerobes, anaerobes, *Clostridium*, and MRSA (74–76). Patients will have an extremely toxic appearance with spiking fevers. Striking ischemic discoloration of the skin, with erythema, crepitus, edema, and tenderness are observed on physical examination. Progression of the disease process may evolve into anesthetic and pale skin with blistering and sloughing (11). In addition to tissue gas, notable findings on CECT that distinguish this liquefaction necrosis from conventional cellulitis, abscess, or phlegmon include hypodense regions lacking loculations or peripheral enhancement (77). NCF is a potentially lethal entity that mandates intravenous broad-spectrum antibiotics within an ICU setting along with multiple trips to the OR for surgical debridement of nonviable tissue. Any correctible causes of immunocompromise leading to susceptibility of NCF must be addressed as well. Many patients with comorbidities including diabetes mellitus and cirrhosis succumbed to NCF, while those without these conditions usually recover (78). Adjuvant hyperbaric oxygen may be considered as an adjunctive treatment (79). Reconstruction with skin grafts or local and free tissue flaps can take place once the infectious process has resolved.

SPECIFIC DEEP NECK SPACE INFECTIONS

Retropharyngeal, Danger, and Prevertebral Spaces

The retropharyngeal space houses the nodes of Rouviere that lie just off the midline and receive drainage from the posterior two-thirds of the nose, paranasal sinuses, adenoids, pharynx, and eustachian tube. These lymphatics are rarely the cause of retropharyngeal space infections (RPSI) in children older than 5 years due to their involution by this age. Other causes, generally found in the older population, include penetrating or blunt trauma; instrumentation; intubation; placement of feeding tubes; and infection from neighboring spaces, most notably the parapharyngeal and prevertebral spaces (80).

Diagnosis of this entity may be challenging in its early stages, particularly in children. Sore throat may not be a typical complaint, but the child may refuse to eat due to discomfort. Trismus is not expected to be associated with RPSI, and its presence should raise the suspicion of parapharyngeal space extension. Swelling in the posterior nasopharynx may be confused with inflammation of the adenoids. Swelling below the nasopharynx will present along the posterior pharyngeal wall, usually seen off the midline. Additional findings include cervical adenopathy, slight elevation of temperature, and a muffled voice secondary to supraglottic swelling. Children may also feature irritability and nuchal

Figure 55.10 Retropharyngeal abscess. Axial contrast-enhanced CT shows a round abscess (*asterisk*) with an enhancing rim in the lateral retropharyngeal space. There is substantial surrounding edema. A lateral abscess such as this is likely the result of a suppurated node, whereas medial collections arise from direct inoculation.

rigidity. Mediastinal extension must be considered in the setting of respiratory distress. Lateral neck radiographs help confirm the diagnosis, with the classic measurement of the retropharyngeal space at level C-2 in adults or children of greater than 7 mm denoting an abnormality. At level C-6, retropharyngeal thickness greater than 22 mm in adults or 14 mm in children also denotes an abnormality. However, due to difficulty in positioning, interpretation of this area in infants is less reliable. CECT (Fig. 55.10), when possible, will help delineate the extent of the infection and possible spread to neighboring spaces (80,81). The workup will be augmented by aspiration of possible purulent fluid and culture specimens from the mass with an 18-gauge spinal needle.

Control of the airway prior to drainage of an RPSI can be accomplished with endotracheal intubation in uncomplicated cases. However, tracheostomy is recommended in the presence of an urgent need for airway control and large abscess due to the risk of rupture and subsequent purulent aspiration during intubation. With collections that are limited to the retropharyngeal space, above the hyoid bone, and easily visualized; a transoral approach to drainage can be undertaken (82,83). This procedure is performed with the patient in the Rose position in order to keep any drainage within the nasopharynx. RPSI that involve multiple spaces are located below the hyoid bone, and/or are difficult to visualize, are to be drained externally. A vertical incision can be made along the anterior border of the SCM muscle, or a horizontal curvilinear incision can be utilized. Dissection is carried down through the platysma muscle and superficial layer of the deep cervical fascia. The abscess cavity is then exposed following medialization of the trachea, and esophagus, and lateral retraction of the carotid sheath and SCM (83). Based on CECT findings, spread of infection below the clavicle into the mediastinum to the level of the fourth thoracic vertebra is an indication for a thoracic surgery consultation. Thoracic surgical intervention can range from superior mediastinotomy for upper mediastinal infections, to external lateral thoracotomy in the presence of significant extension into the chest cavity.

Prevertebral space infections may have a clinical course that differs from RPSI. Possible causes of prevertebral space and danger space infections include tuberculous Pott's abscesses, posterior extension of RPSI, trauma, previous spinal surgery, and extension of osteomyelitis. If located within the high-cervical area, an intraoral midline bulge may be seen. In contrast to RPSI, these infections usually demonstrate a more indolent course, with patients consequently having less striking complaints. Vague neck or shoulder pain, dysphagia, or respiratory distress is inconsistently reported. Typical CECT features of a danger space abscess are demonstrated in Figure 55.11. Management of these entities is generally similar to the approach to RPSI. In addition to the typical organisms previously described, infections caused by *Mycobacterium tuberculosis* or atypical mycobacterium should be considered in patients who fail to respond to the usual antimicrobial agents. While transoral drainage of high-cervical (C1–C3) collections is possible, it may be limited by the inability to adequately remove infected bone. Access to the prevertebral and danger spaces can be achieved through incisions made anterior or posterior to the SCM. Adequate tissue and fluid sampling from these collections is of particular importance given the relative frequency of atypical organisms (81,84).

Submandibular Space and Ludwig Angina

As elaborated on earlier in this chapter, the submandibular and sublingual spaces communicate freely behind the posterior edge of the mylohyoid muscle and are generally described together as the submandibular space. Infectious processes, however, can involve each subcompartment individually or together. Radiographically, spaces within the submandibular region can also be distinguished by their relationship to the anterior belly of the digastric muscle (Figs. 55.12 and 55.13). Although a number of infections are caused by sialadenitis or lymphadenitis (85), 70% of cases originate from dental or periodontal disease (67). As outlined earlier, and based on the mylohyoid line orientation, infections involving the incisors to first molars will present initially in the sublingual space, while the second and third molars will drain primarily to the submandibular space. The latter process is not common in children owing to delayed eruption of the third molar. The most severe manifestation of this entity, Ludwig's angina (Fig. 55.14), is defined as having: (a) all the tissues and

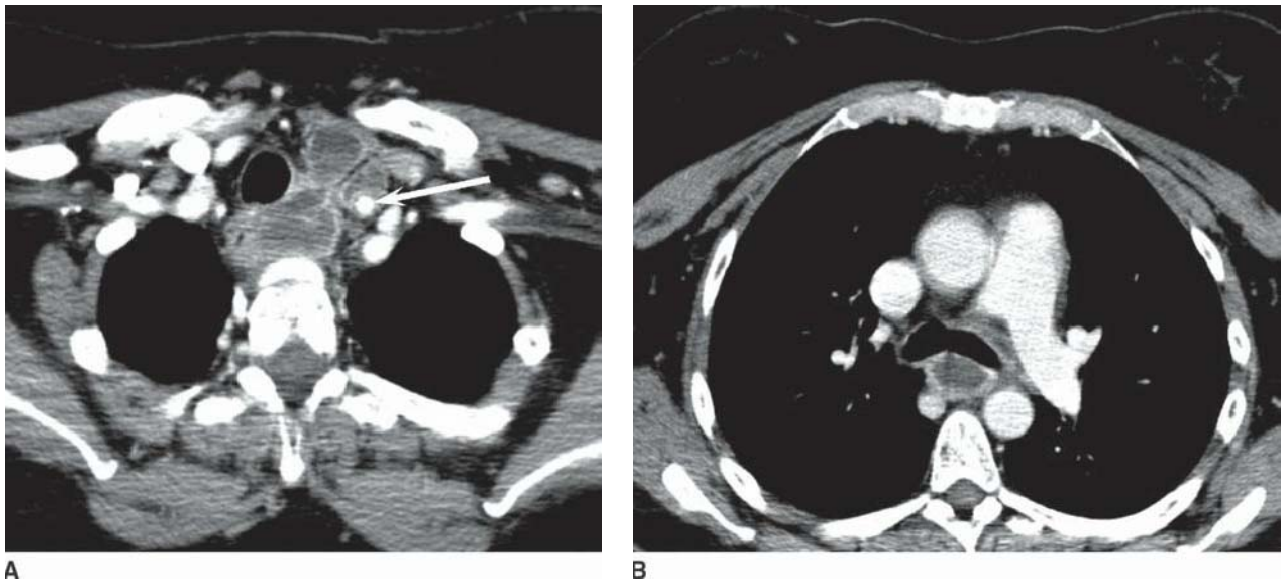

Figure 55.11 Danger space abscess. **A:** Axial contrast-enhanced CT shows a multilocular abscess of the lower neck involving the central compartment, the retropharyngeal space, and carotid sheath, with abscess surrounding the common carotid artery (*arrow*). **B:** More inferior image shows the retropharyngeal component of the abscess extending deep into the mediastinum, below the level of the T4 vertebra. Because the retropharyngeal space extends only to T2–T4, this infection must be located in the danger space, which extends to the diaphragm.

compartments of the floor of the mouth swollen and inflamed, (b) displacement of the tongue superoposteriorly toward the soft palate, (c) firm induration of the submandibular area and anterior neck, (d) trismus, and (e) voice changes and dyspnea (81).

Given that asphyxia is the most common cause of death in Ludwig's angina, airway protection is of paramount concern. Furthermore, with displacement of intraoral structures and rapid disease progression, tracheostomy is utilized much more frequently relative to other DNSIs (6,14).

Figure 55.12 Submandibular abscess. Axial contrast-enhanced CT shows an abscess within the submandibular triangle, displacing the submandibular gland (*asterisk*) posteriorly. The abscess wraps around the inferior mandible, so it likely arose from infection in a posterior molar tooth.

Figure 55.13 Submental abscess. Axial contrast-enhanced CT shows an ovoid abscess (*arrow*) medial to the anterior belly of the digastric muscle (*arrowheads*), with copious surrounding edema. Extensive fat infiltration and submandibular gland inflammation are restricted to the right side of the face and neck. Reactive edema is seen even into the right side of the larynx.

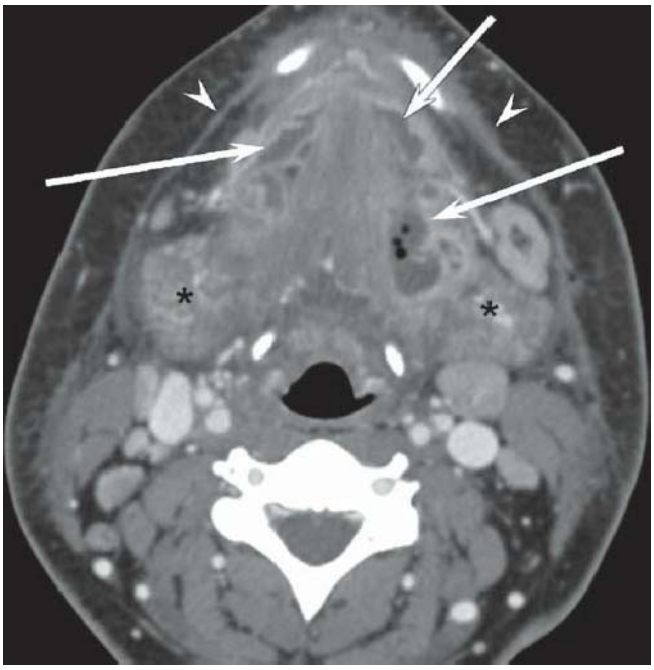

Figure 55.14 Ludwig angina. Axial contrast-enhanced CT shows diffuse infiltration of the fat planes in the submandibular, submental, and subcutaneous spaces. The platysma muscles (*arrowheads*) are thickened. The submandibular glands (*asterisks*) are inflamed. There is an extensive abscess (*arrows*) throughout the submandibular and submental spaces, with air locules indicating anaerobic infection.

Figure 55.15 Parapharyngeal abscess. Axial contrast-enhanced CT shows a large abscess involving both the peritonsillar space and the parapharyngeal space, with replacement of the parapharyngeal fat. The abscess extends laterally to the styloid process. The normal contralateral parapharyngeal fat is still visible (*arrows*).

A number of patients with confirmed Ludwig's abscess undergoing attempted fiberoptic intubation may require unplanned "slash" tracheostomies. Following control of the airway, surgical incision and drainage is indicated in the face of worsening symptoms despite the administration of appropriate antibiotics (86,87). Uncomplicated collections limited to the sublingual space can be approached intraorally. The surgical approach for Ludwig's angina, however, is accomplished with a horizontal submental incision 1 cm superior to the hyoid bone extending laterally in each direction to 3 cm below the angle of the mandible. Dissection is carried out from the hyoid bone to the mandibular symphysis through the platysma muscle and into the sublingual tissues. The cavity will generally contain a malodorous liquid material and/or frank pus. Since a true purulent collection is not always present, it is important to note that the need for surgical drainage and decompression should be dictated by physical examination findings rather than CECT scan (81).

Parapharyngeal Space

The relatively central location of the parapharyngeal space allows for the direct spread of infection from multiple neighboring deep neck spaces (Figs. 55.5 and 55.15). Common routes of extension include laterally from the peritonsillar space, posteriorly from the submandibular space, anteriorly from the retropharyngeal space, and medially from the parotid or masticator space. Consequently, a comprehensive evaluation must be carried out in order to exclude the involvement of any other spaces. The predominant organisms will also vary based on the portal of entry as discussed earlier in this chapter.

Infections of the prestyloid and poststyloid compartments will differ in presentation. The prestyloid compartment normally contains fat, connective tissue, lymph nodes, and muscle, while the poststyloid compartment houses the carotid sheath and cranial nerves IX to XII (11). Prestyloid infections typically present 7 to 10 days after an episode of tonsillitis or pharyngitis with the classic signs of trismus, swelling at the angle of the mandible, medial bulging of the pharyngeal wall, and systemic toxicity. Without involvement of the pterygoid musculature, trismus is generally absent in poststyloid infections. The medial bulge of the pharyngeal wall is not always seen in poststyloid infections, sometimes leading to a misdiagnosis such as fever of unknown origin. Potentially catastrophic neurovascular complications may be associated with poststyloid infections. Involvement of the carotid sheath can lead to IJV thrombosis, and carotid artery erosion or pseudoaneurysm. Ipsilateral Horner's syndrome or other cranial neuropathies are also possible (88).

Indications for incision and drainage of a parapharyngeal space infection include disease progression despite medical care, a demonstrable collection on imaging, or evidence of a neurologic and/or vascular complication (28,51,89). Despite the prominence of the lateral pharyngeal wall, a transoral incision is not advised due to the

risk of uncontrollable hemorrhage from the carotid sheath vessels. The functional status of all cranial nerves prior to surgical exploration should be documented to avoid attributing any preexisting deficits to the operation. The external approach is initiated with a horizontal incision two fingerbreadths inferior to the lower border of the mandible going from the lateral aspect of the hyoid tip to the anterior border of the SCM. The superficial layer of the deep cervical fascia is entered as the SCM is retracted posteriorly. The parapharyngeal space is then entered using blunt finger dissection up to the styloid process. Two additional landmarks must be noted. The tip of the greater cornu of the hyoid bone defines the inferior border of this space. Additionally, all the important neurovascular structures housed within the parapharyngeal space lie deep to the posterior belly of the digastric muscle (88).

Parotid Space

As described earlier, the parotid space is formed as the superficial layer of the deep cervical fascia envelopes the parotid gland. Diagnosis of an abscess may be difficult on physical examination alone due to the firm, adherent capsule lateral to the gland. However, medial extension of infection to the neighboring prestyloid parapharyngeal space can be observed intraorally. The infection is generally secondary to salivary stasis leading to parotitis in patients who are debilitated, postoperative, dehydrated, or have poor oral hygiene. The typical presentation is facial swelling overlying the parotid region without fluctuance or trismus. Purulent fluid may or may not be expressed from Stensen's duct (81). Parotitis is managed with rehydration and antimicrobials targeted against *S. aureus*. When a collection is evident on imaging, the abscess can be accessed through two different routes. An incision can be made through the skin over the prominence of the swelling parallel to the branches of the facial nerve. If the swelling is extensive, a Furstenberg incision can be made. This consists of a vertical preauricular incision extending from the zygoma and curving around the lobule onto the mastoid. The fascia overlying the gland is then widely exposed. Small stab incisions are then made through the fascia followed by bluntly spreading parallel to the facial nerve branches. Penrose drains can be placed for several days allowing the incision to close by secondary intention. Delayed scar revision can be done if desired (90,91).

Masticator Space

Masticator space infections generally involve the fascial sling containing the muscles of mastication: the temporalis, masseter, and pterygoids. Delay in diagnosis and treatment can lead to mandibular osteomyelitis. The most frequent infectious source is odontogenic, usually from the third molar teeth. Patients usually present with trismus and painful swelling over the angle and posterior mandible. Posterolateral swelling within the mouth may mimic a prestyloid parapharyngeal space infection (81). When imaging masticator space infections, MRI can be advantageous over CECT scan due to the lack of dental amalgam artifact (92). Management of the airway in these patients is a priority given the potential for obstruction. Severe trismus and swelling mandate awake fiberoptic intubation or tracheostomy prior to further management. Four approaches may be taken in draining masticator space collections: (a) Drainage can be performed externally. (b) An intraoral route through an incision into the alveolar–buccal groove below the third molar followed by subperiosteal dissection posteriorly deep to the masseter muscle. (c) Collections may also be drained through the offending dental socket following tooth extraction. (d) Select cases can be managed with needle aspiration and antibiotic coverage (90).

HIGHLIGHTS

- The majority of DNSIs in adults are of odontogenic origin, whereas acute pharyngitis and rhinosinusitis leading to retropharyngeal and parapharyngeal lymphadenitis is a common infectious source in children.
- Intravenous drug abuse, particularly in an inner-city environment, is a relatively common cause of DNSIs. However, it has been shown that abscesses caused by direct intravenous drug use seem to have a more favorable clinical course compared to those spreading from inflamed tissue.
- The majority of abscesses are polymicrobial. Due to differences in the portal of entry, offending microorganisms in adults and children will vary. Additionally, MRSA has been increasingly associated with intravenous drug abusers, infants, and immunocompromised patients.
- Inflammation of surrounding deep neck structures will manifest with associated signs and symptoms including pain, fever, swelling, dysphagia, odynophagia, trismus, respiratory difficulty, and toothache. The presence or absence of certain complaints will aid in identifying the specific site of infection.
- Ultrasonography is gaining popularity in the United States as an adjunct to CECT, especially in children undergoing serial image-guided therapeutic aspirations of infectious neck collections.
- Hypoxia and asphyxia remain the most common causes of mortality in DNSIs. When presented with signs of airway compromise, early intubation or tracheostomy circumvent the performance of these procedures under more dire circumstances. In situations where extubation within 48 to 72 hours is questionable or not expected, tracheotomy should be performed in favor of shorter hospital and ICU stays.
- Immunologically sound individuals should be

empirically administered a beta-lactamase–resistant penicillin combined with an agent effective against anaerobes. Antibiotics targeting specific organisms can be given once cultures and sensitivities are available.

- In most cases, immediate need for surgical drainage is obvious. In questionable cases, progression of symptoms such as fever, tenderness, swelling, and elevated leukocyte count despite 48 hours of medical management is an indication for surgical drainage or exploration. Additional indications include potential airway compromise, impending complications or septicemia, evidence of collections larger than 3 cm, or the involvement of multiple spaces.
- Complications are more common in immunocompromised hosts and in cases of a delayed presentation or diagnosis. Infections of certain spaces can lead to multiple neurovascular complications including carotid artery pseudoaneurysm or rupture, Lemierre's syndrome, or Horner's syndrome. Mediastinitis and NCF are potentially lethal entities that must be considered when managing any DNSI.
- Tracheostomy is the preferred approach to controlling the airway in Ludwig's angina and extensive masticator space infections due to the presence of obstructive tongue elevation and trismus, respectively. A surgical airway is also recommended in an urgent setting for patients with retropharyngeal collections due to the risk of abscess rupture and aspiration during intubation.

Upper Digestive Tract Anatomy and Physiology

56

Libby J. Smith *Roxann Diez Gross*

The upper aerodigestive tract is a single conduit that must integrate and separate two very different vital functional systems: breathing and swallowing. In the healthy state, the anatomic structures and their neural substrates exquisitely coordinate each function through sensory–motor integration. The ability to swallow safely is critical for nutrition, hydration, and quality of life; however, its significance is often taken for granted when the physiology and pathophysiology are not fully appreciated. Understanding the anatomy and physiology of deglutition is not only required to properly evaluate and treat patients with dysphagia but also necessary to maximize functional outcomes after surgical interventions for head and neck cancer.

Dysphagia is not a disease, but rather a symptom or a collection of symptoms that broadly describe difficulty swallowing. Under the umbrella term dysphagia, finer distinctions are made that refer to the phase of swallowing where impairments exist. For example, patients may have oral, pharyngeal, oropharyngeal, pharyngoesophageal, or esophageal dysphagia. Dysphagia can also vary in terms of severity from mild to severe. However, it is unknown how much aspiration in a particular patient will result in pneumonia. Some patients can only tolerate a minimal amount of aspiration, while others tolerate larger amounts. The end point of dysphagia is pneumonia or airway obstruction. Unfortunately, to date, there is no universally accepted, standardized system that can be used to objectively define severity levels. In addition, the evaluation and treatment of dysphagia are often complicated by the fact that some patients are acutely aware of difficulty swallowing, while others may not perceive its presence or recognize the symptoms.

The swallowing difficulty can develop gradually from neurologic or respiratory disease, or be acquired suddenly as a result of injury or surgery. The multitude of different etiologies for dysphagia can often be delineated with a thorough history and physical examination. Instrumental assessments of swallowing function provide additional information that will further characterize swallowing function so that treatment can be planned. Effective therapeutic interventions are based upon each patient's specific physiology. Swallowing exercises can increase muscle strength and range of motion of swallowing structures. Skill training can instruct patients to use swallowing maneuvers such as breath-holding before drinking. Compensatory strategies such as changing head position can also be used to alter swallowing biomechanics. Diet alterations can be instituted so that unsafe food consistencies are eliminated. Surgical interventions, such as vocal fold augmentation or esophageal dilatation, may be required as the primary treatment, or in addition to swallowing therapy.

The ability to eat and drink safely and efficiently is fundamental to our quality of life. The wide variety of food and liquid that we enjoy throughout each day requires precise management because of the shared function of the upper aerodigestive tract. Indeed, modern research has shown that the pharyngeal swallow is not a stereotypic reflex as it was first described; rather, it is a patterned motor response to sensory input. As such, pharyngeal muscle force and contraction duration must rapidly and consistently adjust depending upon what is to be swallowed (1,2). To accomplish this feat, separate and overlapping phases of swallowing use sensory–motor integration. Swallowing dysfunction can occur in each phase individually or collectively across them.

ANTICIPATORY PHASE

The anticipatory phase is often considered the first true step in swallowing because visual information, olfactory stimulation, and experience interact to form the initial motor plan (3). A common statement in the culinary profession is, "we eat with our eyes first." The adult has

a well-developed motor plan for swallowing different types of food and drink that is based upon appearance (visual processing), consistency (tactile processing), taste (chemical processing), and bolus size (proprioceptive processing). Most have experienced a sudden awareness that an item placed in the mouth did not match what was expected. This observation can be viewed as practical evidence that a *plan* had been violated. Another example that illustrates this concept can be seen when we perceive a liquid to be very hot or a food is suspected of being very spicy. When experience indicates these possibilities, a slower presentation to the mouth will follow and care will be taken to ensure a smaller bolus size because of the anticipated negative effects.

It is also at the anticipatory level where distinctions between food and nonfood items are made and where palatability is determined. Oral intake may be avoided as a result of the information perceived and processed during this phase. If an individual is forced to eat or drink an item that he or she has predetermined (anticipated) is unsafe or undesirable, then gagging, coughing, and dysphagic symptoms may be observed. It is important to note that these are not behaviors that can be controlled; rather, they are in response to sensory stimulation. The anticipatory phase provides the initial sensory input to cortical swallowing structures. In patients with dementia or other cognitive impairments, the sensory processing of visual, olfactory, and experiential information can be altered. As such, the motor plan implemented to swallow may not match that of the bolus itself, putting the patient at risk for dysphagia.

ORAL PREPARATORY PHASE

Once solid and semisolid food is placed in the mouth, it must first be prepared for the pharyngeal phase. The combination of mastication and saliva production is considered to be the first step in digestion. Saliva from the submental, sublingual, and parotid glands flows into the oral cavity to mix with the bolus and begin the chemical process of food breakdown. The mandible closes to crush solid food and the rotatory motion of mastication enables the molars to shear and shred the food. The muscles of mastication are the masseter, temporalis, medial pterygoid, and lateral pterygoid muscles (Table 56.1). The masseter, temporalis, and medial pterygoid muscles elevate the mandible,

TABLE 56.1 SUMMARY CHART OF PERIPHERAL SENSORY AND MOTOR COMPONENTS OF DEGLUTITION

Swallowing Phase	Action	Muscle	Nerve
Oral preparatory	Labial closure	Orbicularis oris	Facial nerve (CN VII)
	Mastication	Masseter	Mandibular nerve (CN V3)
		Temporalis	Mandibular nerve (CN V3)
		Medial pterygoid	Mandibular nerve (CN V3)
		Lateral pterygoid	Mandibular nerve (CN V3)
		Buccinator	Facial nerve (CN VII)
	Bolus formation	Genioglossus	Hypoglossal nerve (CN XII)
		Hypoglossus	Hypoglossal nerve (CN XII)
		Styloglossus	Hypoglossal nerve (CN XII)
		Palatoglossus	Pharyngeal branch (CN X)
	Tongue sensation	Anterior two-third	Lingual nerve (CN V3)
		Posterior one-third	Glossopharyngeal nerve (CN IX)
	Tongue taste	Anterior two-third	Chorda tympani nerve (CN VII)
		Posterior one-third	Glossopharyngeal nerve (CN IX)
Pharyngeal	Soft palate depression	Palatoglossus	Pharyngeal branch (CN X)
	Velopharyngeal closure	Levator veli palatini	Pharyngeal plexus (CN X)
		Tensor veli palatini	Trigeminal nerve (CN V3)
		Palatoglossus	Pharyngeal branch (CN X)
		Superior constrictors	Pharyngeal plexus (CN X)
	Vocal fold closure	Lateral cricoarytenoid	Recurrent laryngeal nerve (CN X)
		Interarytenoid	Recurrent laryngeal nerve (CN X)
		Thyroarytenoid	Recurrent laryngeal nerve (CN X)
	Laryngeal elevation	Mylohyoid	Trigeminal nerve (CN V3)
		Anterior belly, digastric	Trigeminal nerve (CN V3)
		Stylohyoid	Facial nerve (CN VII)
		Posterior belly, digastric	Facial nerve (CN VII)
		Geniohyoid	Cervical 1 (C1)
		Thyrohyoid	Cervical 1 (C1) via hypoglossal nerve (CNXII)
Esophageal	Upper esophageal segment *relaxation*	Cricopharyngeus	Pharyngeal plexus, recurrent laryngeal nerve (CN X)

while the lateral pterygoid depresses the mandible, thereby opening the mouth. Contraction of the masseter and medial pterygoid muscles also results in lateral mandible movements required for the rotary motions. Sensory and motor innervation to the muscles of mastication and salivary glands is provided by several branches of the trigeminal nerve. The cyclic motion of the mandible and motions of the tongue are mediated, in part, by a cortical central pattern generator (CPG). A CPG is essentially neural circuitry that generates rhythmic movement. It is important to remember that during this phase, the airway is open and active breathing continues. During mastication, respiratory rate becomes more rapid and irregular when compared to tidal breathing (4). If the bolus is not well controlled, solid food may fall into the open airway resulting in aspiration or asphyxiation. Also during mastication, the circular fibers of the orbicularis oris muscle work to actively close the lips and maintain the food or liquid within the oral cavity. An incompetent oral sphincter will result in drooling of saliva or loss of food and liquid out of the mouth. This circumstance is very embarrassing for patients and severely impacts the social aspects of meals. Neurologic diseases and surgical resections that prevent labial closure or impair sensation can cause anterior oral loss of food or liquid.

During mastication, the complex motions of the tongue move and guide prandial material by placing it between the molars, shifting food from side to side, and ultimately collecting it to form a single, cohesive, prepared bolus. Tongue motion is highly complex because it is composed of several intrinsic and extrinsic muscles that are oriented in multiple directions. The intrinsic lingual muscles are the superior and inferior longitudinal muscles, the transverse muscle (transverse lingualis), and the vertical muscle (vertical lingualis). Extrinsic lingual muscles are the genioglossus muscle that protrudes the tongue, the hypoglossus muscle to depress the tongue, and the styloglossus muscle that elevates and retracts the tongue. All of these muscles are innervated by the hypoglossal nerve (cranial nerve [CN] XII). The palatoglossus muscle is innervated by the pharyngeal branch of the vagus nerve (CN X) and elevates the back of the tongue to prevent premature spillage into the pharynx. In addition to muscle strength and coordination, adequate sensory input is necessary for safe swallowing.

Sensory processing by the tongue and oral cavity is required to adequately prepare the bolus and maintain its cohesion. Tactile sensation to the anterior two-thirds tongue is mediated by the lingual nerve (CN V3) and taste sensation is provided to this region by the chorda tympani nerve (CN VII). The glossopharyngeal nerve (CN IX) provides both sensory and taste to the posterior one-third of the tongue. Oral sensation is also basic to proprioception because the oral structures and changing bolus characteristics must continually interact until the bolus is perceived to be fully prepared to swallow.

Oral preparation through mastication essentially places everyone on a "pureed" diet, since humans do not swallow solid food whole. Difficulty swallowing pills can be attributed to both the anticipatory phase where fear and anxiety affect swallowing function in addition to volitional inhibition of mastication. Maintaining bolus cohesion and control is also needed for liquids and puree consistencies so that the next phase of swallowing can be accomplished.

ORAL TRANSFER PHASE

Once the bolus is prepared, it must be collected into a cohesive unit and moved to the posterior oral cavity. Oral transfer is accomplished by containing the bolus within the center of the tongue while the tongue tip contacts the alveolar ridge and pushes the bolus back across the hard palate using a wave-like propulsive force. During both the preparatory and transfer phases, sensory information is gathered in relation to bolus size and texture. Although it is not understood how humans have an intrinsic knowledge in relation to swallowing safety, the bolus will be subdivided if it is determined to be too large. Once the bolus reaches the posterior oral cavity, the lateral portions of the tongue press on the anterior facial pillars (innervated by CN IX) to terminate the oral phase and subsequently trigger the pharyngeal phase. Throughout the oral preparatory and transfer phases, the soft palate is pulled down and forward by the palatoglossus muscle (innervated by the pharyngeal branch, CN X) to maintain contact with the posterior tongue, thus sealing the oral cavity from the nasopharyngeal airway (Table 56.1). This mechanism allows maintenance of the bolus within the oral cavity while continuing to breathe through the nose (Fig. 56.1).

Oral dysphagia is present when the bolus is inadequately prepared or controlled. Poor dentition can lead to an inadequately prepared solid bolus that may have the potential to block the airway if aspirated. Failure to clear the oral cavity after a primary or secondary swallow can also result in aspiration after or between swallows. Reduced posterior oral control and/or weak velar depression may produce premature loss or "premature spillage" of a bolus into the pharynx or larynx before the pharyngeal phase of swallowing is "triggered." If the bolus cannot be controlled or transferred, gavage feedings may be necessary in order to bypass the oral cavity. A significant delay or failure to elicit the pharyngeal phase is classified as oral dysphagia, regardless of bolus location, since it is the oral tongue that must trigger the pharyngeal response. Impaired cognitive function or poor sensation can cause patients to "forget" to elicit the pharyngeal swallow. Significantly reduced lingual range of motion, as a result of surgery or neurologic disease, can impair tongue strength or prevent the posterior tongue from reaching the facial arches to trigger the swallow. Oral dysphagia can occur in isolation or concomitant with pharyngeal dysphagia. It is important to always keep in mind that the airway remains open during the oral preparatory and transfer phases because the patient is breathing; therefore, prandial aspiration can occur both before and after the swallow.

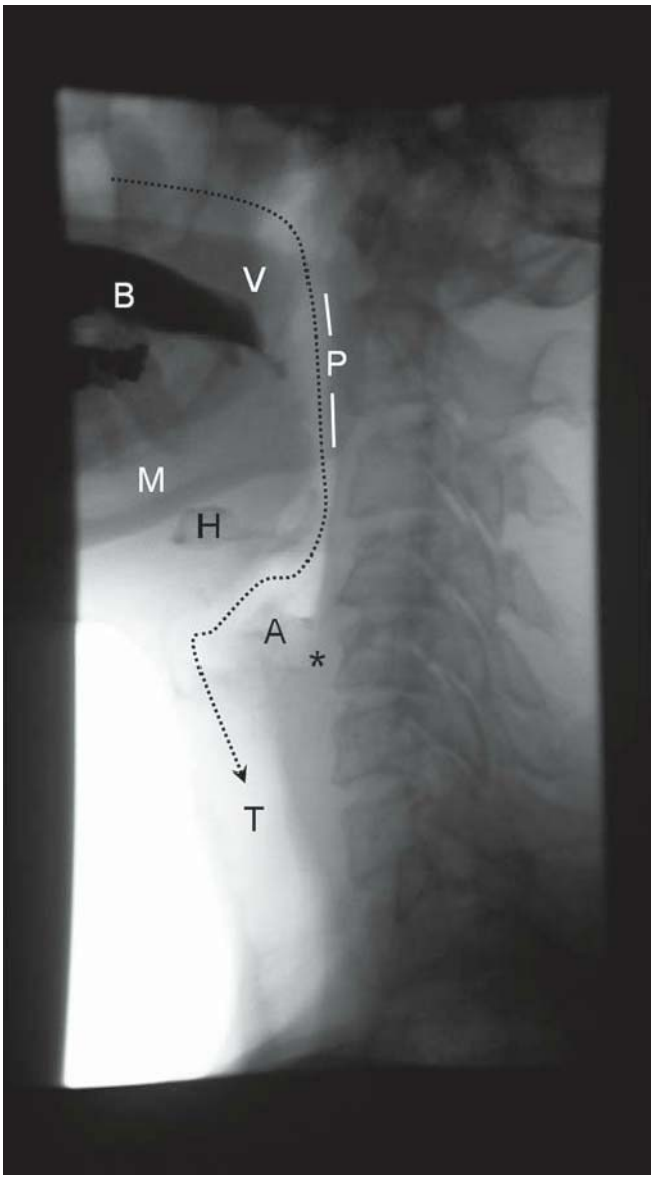

Figure 56.1 Posterior oral containment of the bolus. Note velar depression and airway continuity from the nasal passages to the trachea (*dotted line*). B, bolus; V, velum; M, mandible; H, hyoid; A, arytenoid; P, posterior pharyngeal wall, *, UES; T, trachea.

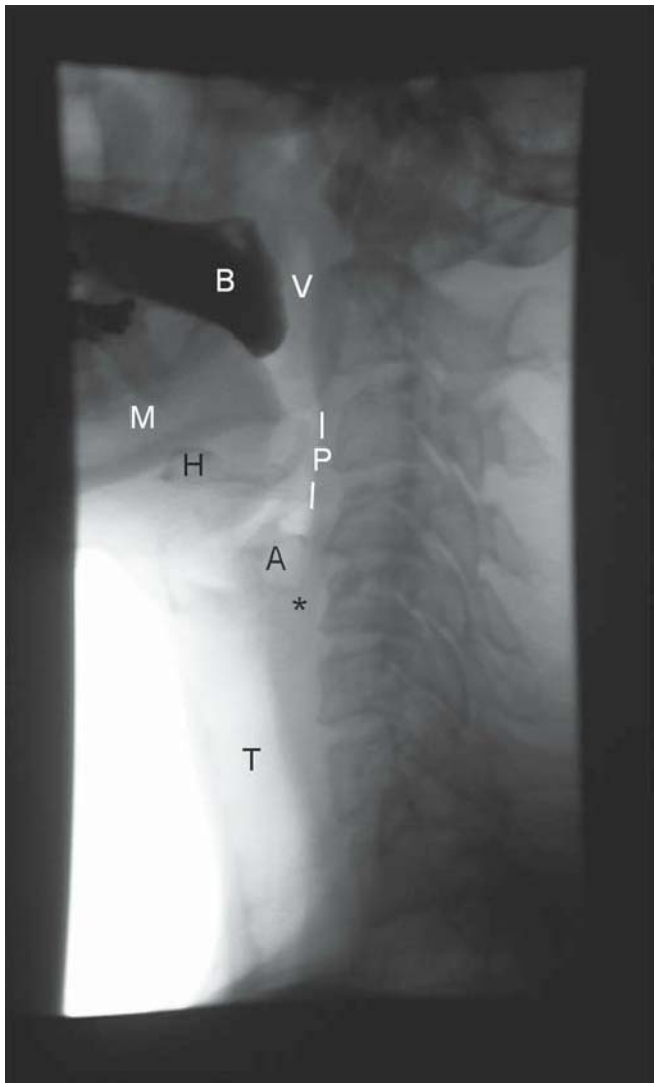

Figure 56.2 Elevation of the velum with subsequent closure of the nasopharynx. The hyoid and larynx are elevating. The arytenoids are about to approximate the petiole of the epiglottis to close the laryngeal aditus. B, bolus; V, velum; M, mandible; H, hyoid; A, arytenoid; P, posterior pharyngeal wall; *, UES; T, trachea.

PHARYNGEAL PHASE

The pharyngeal phase begins with elevation of the soft palate to seal the nasopharynx from the oropharynx (Table 56.1). Mediated by the sensory and motor fibers that are primarily contained in the pharyngeal plexus, velopharyngeal closure is the result of elevation and tensing of soft palate and contraction of the palatopharyngeal muscles, combined with anterior motion of the posterior pharyngeal wall (Passavant ridge, superior pharyngeal constrictor muscle). The adenoid pad and uvula may also aid in velopharyngeal closure. If the patient has velopharyngeal incompetence, they can experience nasal regurgitation during the swallow. Within milliseconds of velar elevation, the posterior tongue lowers to enable the bolus to enter the oropharynx (Fig. 56.2). The base of tongue retracts and exerts the primary propulsive force on the bolus. The upright epiglottis protects the airway by dividing the bolus and directing it into the lateral channels of the pharynx toward the hypopharynx. The larynx begins to elevate, moving in a superior and anterior trajectory. Activation of the thyrohyoid muscle (innervated by the first cervical nerve via the hypoglossus nerve) and the suprahyoid musculature (mylohyoid, anterior and posterior digastrics, stylohyoid, and geniohyoid muscles) results in the superior and anterior thrust of the hyoid bone to the mandible. During laryngeal elevation, the true and false vocal folds adduct (lateral cricoarytenoid, interarytenoid, and thyroarytenoid muscles, all innervated by the recurrent laryngeal nerve, CN X) as the arytenoid cartilages are drawn forward (5). Vocal

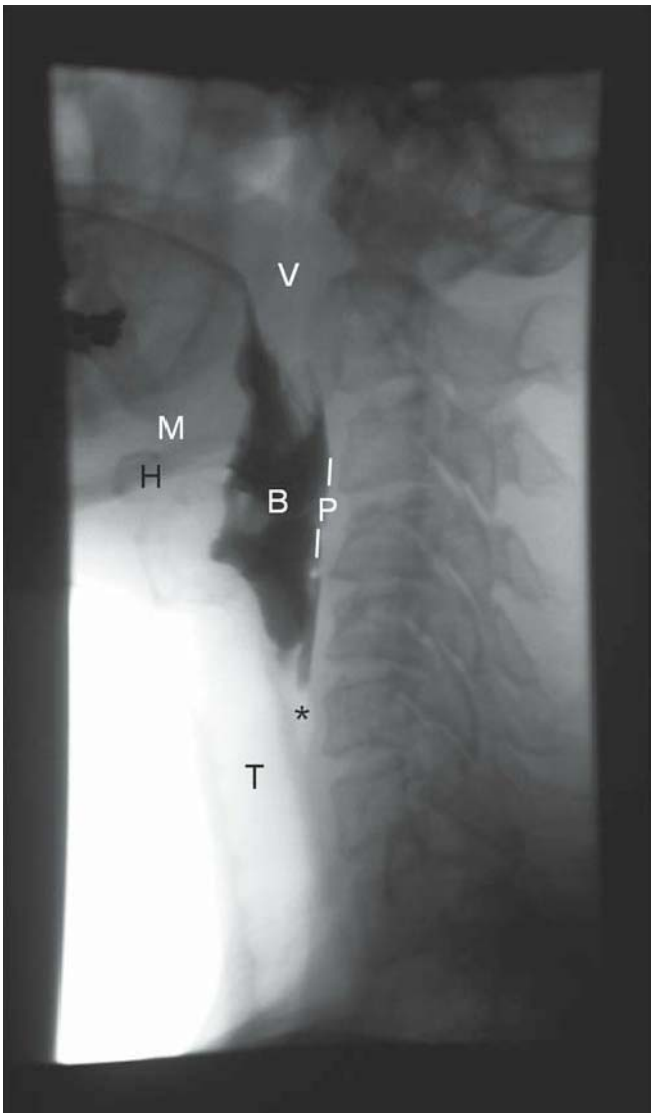

Figure 56.3 The hyolaryngeal complex elevated, with complete closure of the airway. The bolus is about to enter the UES. B, bolus; V, velum; M, mandible; H, hyoid; P, posterior pharyngeal wall; *, UES; T, trachea.

fold paralysis or severe vocal fold atrophy often results in glottic incompetence, which can result in aspiration during the swallow. The complex combination of base of tongue retraction, laryngeal elevation, and contraction of the ary-epiglottic muscles creates contact between the arytenoids and the epiglottic petiole (Fig. 56.3). This mechanism closes the laryngeal vestibule during pharyngeal bolus transit. Strong closure of the laryngeal entrance (aditus) can prevent aspiration and compensate for reduced glottal closure.

A common misconception is that the epiglottis inverts to protect the airway (6,7). In fact, the epiglottis has no motor innervation and cannot actively move. An upright epiglottis protects the airway by capturing and containing material within the valleculae. Epiglottic inversion is then biomechanically created by the combination of the tongue

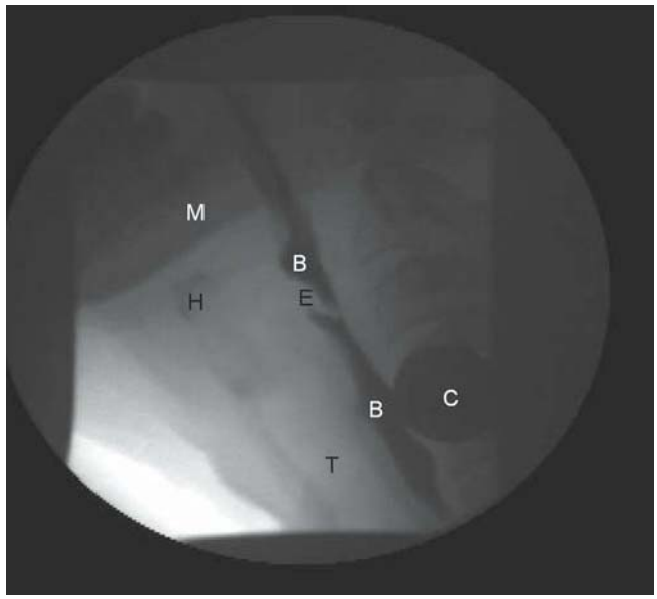

Figure 56.4 The inverted epiglottis within the bolus stream. The opaque circle is a coin, which is used to correct for magnification. B, bolus; M, mandible; H, hyoid; E, epiglottis; T, trachea; C, coin.

base retraction, hyolaryngeal elevation, and the weight of the bolus (Fig. 56.4). The inverted epiglottis can enter the upper esophageal sphincter (UES) and may help to direct the bolus into the esophagus. When epiglottic inversion does not occur, it suggests the presence of base of tongue weakness and/or is often associated with reduced hyolaryngeal elevation. Sometimes, all that is needed to promote epiglottic inversion is to increase bolus size or to alter the biomechanics by having the patient tuck the chin toward their chest during the swallow.

For the bolus to enter the esophagus, the tonic muscle fibers of the UES must relax to allow the bolus to enter the esophagus. The superior and anterior motion of the hyoid and larynx during the pharyngeal phase creates a traction force that opens the lumen. Hyolaryngeal elevation must be of sufficient height and duration to allow the entire bolus to pass through to the upper esophagus (Fig. 56.5). If the UES opening is limited in width and/or duration, truncation of the bolus and resultant residue in the post-cricoid region and/or pyriform sinuses (hypopharynx) can result. Aspiration of this residue can then occur after the swallow when the airway reopens for breathing.

Following the tail of the bolus by several milliseconds is a sequential contraction of the pharyngeal muscles starting with the superior constrictor, followed by the middle constrictor and then the inferior constrictor. The wavelike motion of the pharyngeal constrictors is often mistaken for peristalsis; however, peristalsis can only be present in a circumferential "tube." The function of the sequential motion of the pharyngeal constrictors is to maintain a closed system within the pharynx during bolus transit (by contacting the tongue base) and to provide a "clearing wave" to assure that the entire bolus leaves the pharynx in anticipation of

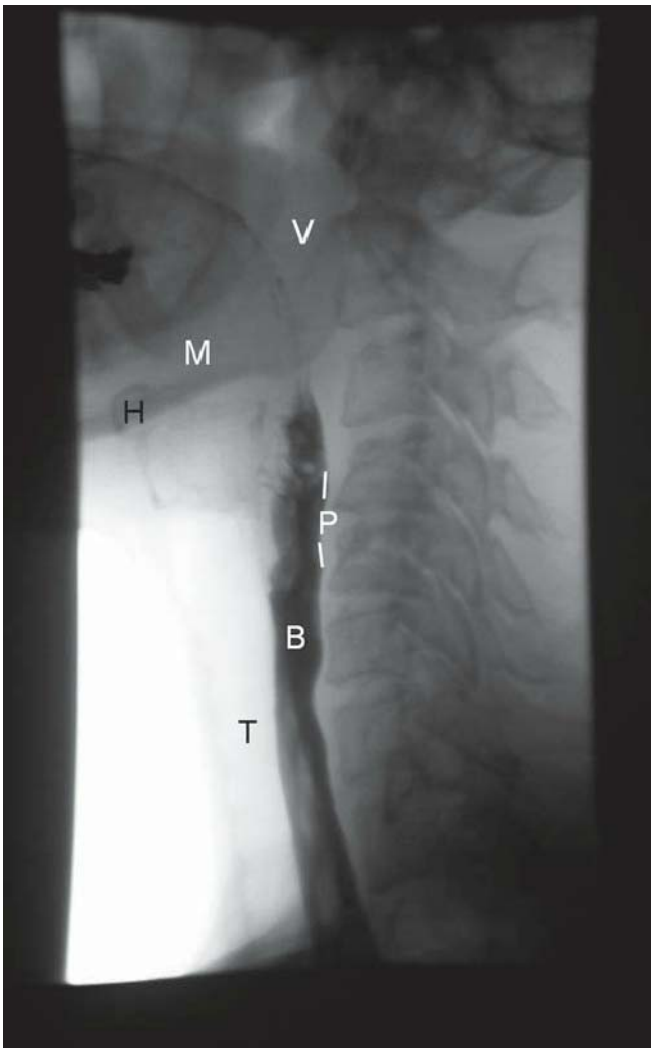

Figure 56.5 A relaxed UES, with the opening into the esophagus maintained by hyolaryngeal elevation. B, bolus; V, velum; M, mandible; H, hyoid; P, posterior pharyngeal wall; T, trachea.

airway opening. Patients who have had chemoradiation for the treatment of cancer in this region often have inadequate clearing of material due to weakness and reduced range of motion of these muscles, putting them at risk for dysphagia. The pharyngeal phase of swallowing transpires in approximately 1 second or less. This rapid sequence of events is controlled by bilateral CPGs located within the brainstem.

ESOPHAGEAL PHASE

Active closure of the UES prevents air from entering the esophagus during breathing and also protects the airway from invasion by refluxate from the esophagus and/or stomach. The primary muscle of the UES is the cricopharyngeal (CP) muscle within the inferior constrictor muscles, with dual innervations from the glossopharyngeal nerve (CN IX) via the pharyngeal plexus and the recurrent laryngeal nerve (CN X) (Table 56.1). Once the bolus enters the esophagus, the circular and longitudinal muscles enable peristalsis to transport the bolus until it reaches the lower esophageal sphincter (LES) at the distal esophagus. The LES is a single muscle that, like the UES, is tonic at rest. The LES relaxes with swallowing, enabling prandial material to enter the stomach. Esophageal dysphagia is present when either of the sphincter muscles (UES or LES) fails to open during deglutition (achalasia). Achalasia can be caused by a neurologic failure within the enteric nervous system scarring from radiation, or possibly repeated acid reflux.

A CP "bar" is a common finding on fluoroscopic swallowing studies but is not always a source of dysphagia unless it *impedes* bolus flow (Fig. 56.6). This finding can be due to hypertonicity and/or fibrosis of the muscle. This finding can also be the result of compensation to provide laryngeal protection in the face of esophageal dysmotility (esophageal–pharyngeal reflux). High-resolution esophageal manometry may be helpful in characterizing different types of esophageal dysphagia.

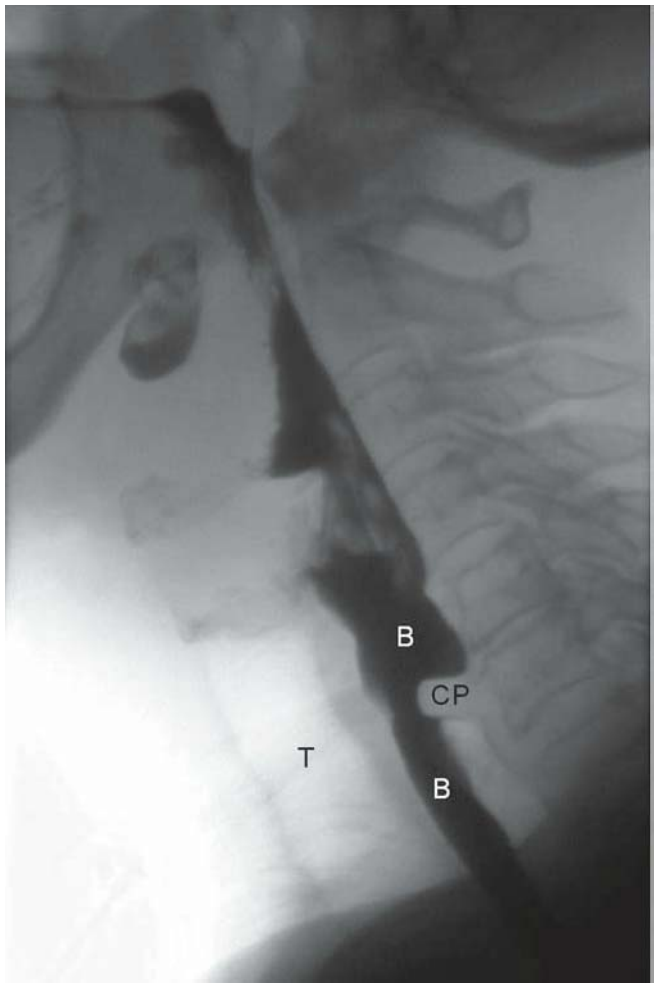

Figure 56.6 A CP bar. Although the fibers have not relaxed fully, the bar diverts but does not obstruct bolus flow. B, bolus; T, trachea; CP, cricopharyngeal muscle.

BREATHING AND SWALLOWING COORDINATION

The dual nature of the upper aerodigestive tract necessitates central inhibition of respiratory muscles during each swallow. Cessation of breathing, combined with airway closure is called deglutitive apnea. Another common misconception is that babies can simultaneously breathe and swallow; nonetheless, vocal fold adduction and deglutitive apnea are also present in infants (8,9).

Several investigators have identified a preferred coordination between breathing and swallowing, finding that most swallows are timed to occur during mid to early exhalation (10,11). Exhalation has been reported to occur almost exclusively following every swallow, even those that occur during the inhalation phase. A target lung volume was recorded in healthy subjects who were found to consistently swallow between 51% and 56% of their vital capacity, irrespective of respiratory pattern (12). Lung volumes above functional residual capacity are associated with positive subglottic air pressures that are generated during each swallow (13,14). Lung-thoracic unit recoil creates the positive pressure by compressing the closed respiratory system during deglutitive apnea. Spontaneous changes in pharyngeal swallowing function have been measured in healthy adults when swallows are timed to occur at extremes in lung volume. Changes in lung volume are associated with changes in the amount of subglottic pressure that is generated, indicating that respiratory signaling is also integrated into the sensory portion of each swallow. Emerging research points to the sensory receptors in the subglottis as the most likely structure that communicates the status of the respiratory system to the swallowing CPG (15–18). Due to the link between the respiratory system and swallowing, pulmonary disease such as chronic obstructive pulmonary disease is considered to be a primary risk factor for dysphagia because of the additional demands that deglutition places on the respiratory system (16,17)

HIGHLIGHTS

- Swallowing is not a stereotypic reflex, but rather a patterned motor response based upon the type of liquid or food to be swallowed.
- Diseases and treatments of the head and neck, such as cancer, can alter the ability to swallow, and therefore a high index of suspicion is necessary for these patients.
- Termination of the oral phase and triggering of the pharyngeal phase is created by the tongue contacting the facial pillars. Therefore, reduced tongue motion/strength could impair this transition to the next swallowing phase.
- The epiglottis does not move independently but rather is moved by other structures. An upright epiglottis splits the bolus around the larynx into the pyriform sinuses. With base of tongue motion, hyolaryngeal elevation, and the weight of the bolus, the epiglottis inverts. The lack of epiglottic inversion points to a deficiency in one or more of the factors that lead to its movement.
- Glottal incompetence can result in aspiration during the swallow. Strong closure of the laryngeal aditus superior to the level of the true vocal folds provides a layer of airway protection in this case.
- The superior-anterior motion of the larynx creates opening of the UES. Deficiencies in this movement due to surgery (such as suprahyoid release), scarring (such as chemoradiation), or neurologic deficiencies, will result in a shorting opening phase of the UES, despite normal relaxation of the cricopharyngeus muscle itself. This increases the possibility of postcricoid residue, which may be at risk of aspiration after the swallow is completed.
- Proper coordination of breathing and swallowing can improve the strength, and therefore efficiency, of the swallow.

SUMMARY

Oropharyngeal swallowing is a multifactorial process that requires precise coordination of multiple muscles and nerves. The wide variety of consistencies that are consumed necessitates a high degree of sensory input to assure that the motor output will provide the safest and most efficient swallow. Sensory processing begins before food is placed in the mouth and continues in the oral and pharyngeal cavity. A portion of sensory input is also received from the respiratory system. Dysphagia can develop when there is a disruption at any level of sensory-motor integration. Therefore, knowledge of the anatomy and physiology of the upper aerodigestive tract in relation to swallowing is critical for the optimal care of patients.

Functional Assessment of Swallowing

57

Maggie A. Kuhn *Peter C. Belafsky*

Dysphagia is common and costly. The prevalence of swallowing disorders in adults over 50 ranges from 7% to 22% (1,2), with estimations as high as 50% in high-risk individuals (3). Dysphagia affects 30% of patients in hospitals and as many as 75% of individuals in nursing homes. Risk factors for dysphagia are numerous and include advancing age, acid reflux, stroke, head and neck cancer, head injury, amyotrophic lateral sclerosis, pseudobulbar palsy, Alzheimer disease, Parkinson disease, multiple sclerosis, muscular dystrophy, and myasthenia gravis. Dysphagia is a leading cause of death in most of these disorders (4,5). The incidence of dysphagia after stroke has been reported to be as high as 81% (3,6). Concurrent chemoradiation for head and neck cancer is associated with a 45% incidence of prolonged feeding tube-dependent dysphagia and an incidence rate for aspiration of 59% (7,8). Complications of dysphagia include malnutrition, dehydration, aspiration pneumonia, pulmonary abscess, and death. In 2001, the yearly expenditure for an individual dependent on tube feeding was $30,000 and Medicare spent 6% of its annual durable medical equipment budget ($670 million) on enteral feeding supplies alone. The cost of treating community-acquired pneumonia in the United States is $4.4 billion annually. The otolaryngologist is frequently the first specialist consulted to evaluate individuals with dysphagia. The purpose of this chapter is to review the indications and techniques for the functional assessment of swallowing.

DYSPHAGIA SYMPTOM INDICES

Dysphagia is a symptom not a disease. The symptoms of dysphagia can range from the isolated sensation of a lump in the throat to profound swallowing dysfunction and complete dependence on nonoral tube feedings. A significant percentage of patients reporting dysphagia will have no objective evidence of swallowing dysfunction. In addition, some patients with profound swallowing dysfunction will report only mild symptoms. Because dysphagia is frequently a symptom-driven disease, it is important to be able to accurately quantify the severity of the patient's complaints. The 10-item Eating Assessment Tool (EAT-10) is a validated self-administered disease-specific symptom inventory for dysphagia (Table 57.1) (9). It has proven useful in assessing initial symptom severity and in monitoring treatment efficacy. It has recently been translated into Spanish, Chinese, Japanese, and Portuguese. Dysphonia and reflux often accompany the symptom of dysphagia, and all patients presenting to our center also receive the 10-item Voice Handicap Index and the 9-item Reflux Symptom Index (Tables 57.2 and 57.3) (10,11).

CLINICAL SWALLOW EVALUATION

The clinical swallow evaluation (CSE) is used for the initial assessment of patients with dysphagia. Simply stated, the CSE consists of a comprehensive deglutition-focused history and physical as well as observing patients as they consume food or liquid. The study is usually performed before proceeding with a diagnostic instrumental swallowing examination as it helps assess and direct the need for further instrumental assessment. The CSE is indicated in patients reporting dysphagia or in individuals with suspected swallowing dysfunction suggested by weight loss, vocal fold immobility, malnutrition, history of prolonged intubation, dementia, head injury, head and neck cancer, recent cardiothoracic or head and neck surgery, stroke, or progressive neurologic disease.

The CSE begins with a comprehensive medical and feeding history from the patient, family member, or collateral source if the patient is incapable of communicating. The history begins with details of the patient's complaint or indication for the referral. It is important to review the

primary medical diagnosis, past medical and surgical history, comorbid conditions, and medications. A directed review of systems should focus on the presence of any tubes as well as the patient's airway, pulmonary, gastrointestinal, and neurologic status. History of prior speech or swallow dysfunction and any therapy or medical treatment received is elicited. Attention should also be paid to the individual's psychiatric and cognitive status, memory, and social history.

The feeding history helps the clinician establish a differential diagnosis and identify the site of suspected swallowing dysfunction. It begins with a thorough description of the patient's current feeding practices, specifically the type and amount of substances consumed, methods of feeding (straw, cup, utensils) and timing (duration and frequency) of feeding. Details regarding the onset and severity of the swallowing problem are elicited. When and where the problem occurs, localization of the problem, presence of coughing, choking, pain (odynophagia) or sticking, associated weight loss as well as the impact on the individual's quality of life are assessed. A patient's report of "cervical" dysphagia is unreliable, however, as 30% of individuals localizing the swallowing dysfunction to the neck will have a primary esophageal etiology

for their symptom. Alternatively, an individual localizing the dysphagia to the chest will almost always have an esophageal phase swallowing disorder. The effect of diet modification such as food consistency, lubrication, temperature, timing, and postures should also be noted. In general, solid food dysphagia suggests an obstructive problem whereas liquid dysphagia suggests a neurologic disorder.

The clinician then performs the examination and observation portion of the CSE. Minimal equipment is required and includes a tongue blade, light source, food, and liquid as well as feeding devices such as a spoon, syringe, or straw. It is useful to have suction available during the observed swallow.

General characteristics of the patient are assessed including level of alertness, ability to participate in the examination as well as overall posture and tone. Careful attention should be paid to the patent's articulation, resonance, voice quality, and pitch. A wet vocal quality suggests laryngeal penetration and difficulty managing saliva. The presence of dysarthria or hypernasality is an ominous sign and frequently indicates a progressive neurologic disorder. The rate and quality of breathing as well as the presence of a tracheotomy are noted.

Evaluation of the oral cavity and oropharynx includes inspection of the lips, tongue, jaw, teeth, and palate for general structure, quality, symmetry, and sensation. Voluntary movement of the jaw, tongue, lips, and velum is assessed with particular attention to strength, symmetry, accuracy, and range of motion. A tongue blade is used to elicit a gag reflex by touching the tonsillar pillar or tongue base. A normal response involves tongue protrusion, pharyngeal contraction, and jaw extension. The relationship between an intact gag reflex and safe swallowing function, however, has been brought into question (12). Other involuntary movements such as the transverse tongue reflex (lateral tongue motion in response to tactile stimulus on the lateral tongue border) may be assessed. The abnormal presence of primitive reflexes (biting, routing) should be noted. The oral cavity is inspected for the presence, quality, and quantity of secretions.

The remaining structures of the pharynx and larynx are hidden from direct examination during the CSE. The clinician may assess the suppleness of the neck musculature and the movement of the larynx during a dry swallow. If the larynx does not palpably elevate with swallowing, the patient will have a diminished ability to open the upper esophageal sphincter (UES) and deglutition may be affected. The patient is asked to cough and throat clear to confirm the presence of these protective mechanisms. Though the subjective evaluation of cough strength and quality have not been shown to accurately predict swallowing dysfunction (13), objective aerodynamic measures, particularly expiratory phase peak flow during voluntary cough, are associated with penetration and aspiration among those with neurologic disorders (14,15).

For observed swallowing trials, ice chips, water, or food is selected by the clinician based on the suspicion for aspiration given the patient's history and physical examination. Use of straws, utensils, and syringes may be used by the patient or examiner to facilitate entry into the mouth. The patient's ability to hold the bolus in the oral cavity is assessed and is best accomplished with pureed and solid foods. During and immediately following the swallow, the examiner monitors for cough, repeated swallows, wet vocal quality, and voice changes. The effort required for swallow as well as a rough timing of the swallow can be assessed. Only one swallow should be required to pass an administered bolus. The presence of a second or third swallow for a single bolus suggests disordered swallowing.

The clinical swallow evaluation serves a variety of purposes. Most critically, it attempts to identify those at risk for aspirating oral intake. Its accuracy for this task is disputed and continues to be studied. The CSE has been criticized for its inability to detect pharyngeal phase swallowing dysfunction and for its poor sensitivity in predicting aspiration (16). Silent aspiration, by definition, is identified only by direct observation of the pharyngeal

phase of swallowing and is reported in up to 59% of dysphagic patients (17). The consequences of missed aspiration on CSE may be significant (18). Videofluoroscopic swallow studies (VFSS) and flexible endoscopic evaluation of swallowing (FEES) may detect silent aspiration in one-quarter to one-third of individuals missed by CSE (19–21). When compared with FEES to evaluate dysphagic patients following acute stroke, the presence of two or more positive findings on CSE has revealed a sensitivity for aspiration of 86% and a specificity of only 30% (22). Adding pulse oximetry to a water swallow may improve the sensitivity for aspiration in acute stroke patients (23). Daniels et al. (24) retrospectively reviewed acute stroke patients with fewer than two positive findings on CSE and found that they had no increased risk of poor outcome, namely aspiration pneumonia, than their counterparts who underwent VFSS. However, given the morbidity associated with aspiration, the CSE yields unacceptably high false negative and positive rates to be an effective unimodality screening exam or reliable diagnostic tool for swallowing dysfunction. Dysphagic patients with an abnormal CSE or those with a normal CSE who are at a high risk of aspiration will require further evaluation with an instrumental assessment of swallowing function.

FLEXIBLE ENDOSCOPIC EXAMINATION OF SWALLOWING/FLEXIBLE ENDOSCOPIC EVALUATION OF SWALLOWING WITH SENSORY TESTING

FEES was first described by Susan Langmore et al. (25) in 1988. The study provides direct visualization of the pharynx and larynx immediately before and after a swallow. The equipment required to perform FEES includes a flexible endoscope, viewing monitor, recording equipment, and commercially available food testing materials. Although the examination requires an endoscope and recorder, technologic advances and equipment miniaturization allow the study to be performed in the clinic or at the bedside in a hospital or nursing home setting. The examination can be performed by a solo practitioner but it is easier to have an assistant available to help feed the patient.

The patient is seated upright in a position appropriate for eating. Topical nasal anesthesia is commonly avoided although standardized doses of atomized saline, oxymetazoline, and cocaine have not been shown to have an effect on laryngopharyngeal (LP) sensory thresholds (26). The endoscope is passed through the more patent nasal cavity. The velum and ability of the palate to close against the posterior nasopharyngeal wall is evaluated. The velopalatal port should close completely and can be assessed with a swallow, hum, or nasal phoneme. After assessing the palate, the symmetry of the pharynx at rest and the quantity of pooled secretions in the pyriform sinuses and endolarynx is assessed. Pooled saliva in the pyriforms suggests profound swallowing dysfunction and is predictive of the presence of aspiration (27). The larynx is inspected for lesions, inflammation, and vocal fold mobility. Vocal fold movement is assessed with the patient performing the "/eee/-sniff" maneuver. Vocal fold immobility is highly predictive of aspiration and nearly 25% of individuals with unilateral immobility will aspirate thin liquids (28). The endoscope is positioned in the "home" position in the pharynx just above the tip of the epiglottis (Fig. 57.1). The patient's ability to close the supraglottis and protect the airway is assessed with the breath hold maneuver. The degree of pharyngeal muscular contraction is evaluated by having the patient perform the pharyngeal squeeze maneuver (PSM) (29). The patient is instructed to deliver a voluntary, forceful, high-pitched "/eee/," and pharyngeal muscular contraction is evaluated by assessing the motion of the lateral hypopharyngeal walls and corresponding narrowing of the pyriform sinuses (Fig. 57.2). The PSM is classified as normal or abnormal only. Attempts at quantifying the degree or laterality of pharyngeal weakness with the PSM have lacked reproducibility (30). The PSM has been validated with objective assessments of pharyngeal strength on fluoroscopy (31). Patients with an absent PSM are significantly more likely to aspirate. After the assessment of pharyngeal strength, LP sensory testing is performed.

The addition of sensory testing to the FEES procedure is termed flexible endoscopic evaluation of swallowing with sensory testing (FEESST). FEESST directly evaluates LP sensation by assessing the ability of a tactile stimulus to elicit the laryngeal adductor reflex (LAR) (32–34). Sensory

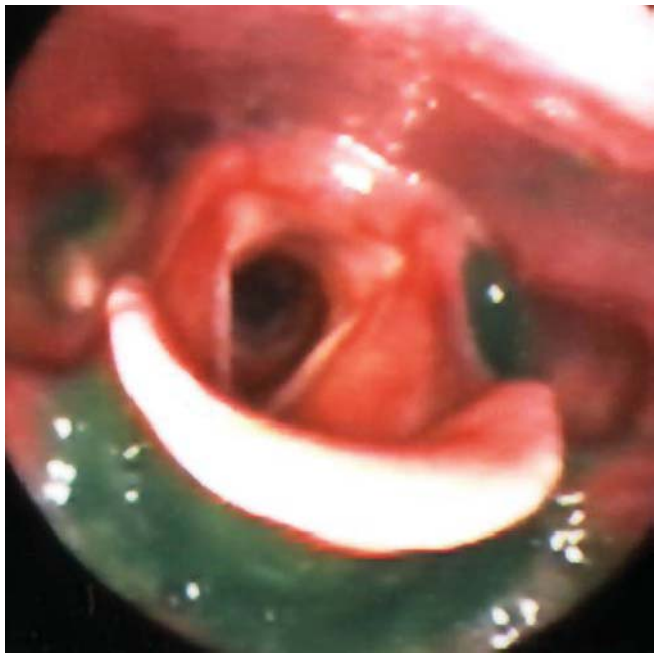

Figure 57.1 FEES with the tip of the endoscope in the home position just above the tip of the epiglottis. Note the premature spillage of green liquid into the vallecula and down the hypopharyngeal gutters into the pyriform sinuses.

testing may be grossly performed with the tip of the flexible endoscope or formally quantified with a LP air-pulse stimulator. A pulse of air is delivered to the mucosa over the aryepiglottic fold through a side-channel on the flexible endoscope. The pressure of the air-pulse delivered through the endoscope (mm Hg) may be varied to quantify the amount of stimulus required to elicit the LAR.

The LAR is a brainstem-mediated, involuntary reflex arc providing airway protection from ingested material (35). The LP mucosa receives innervation from the internal branch of the superior laryngeal nerve and is the afferent component of the LAR. The recurrent laryngeal nerve is the efferent component, and in response to a unilateral stimulus, produces brief and rapid bilateral contraction of the thyroarytenoid muscles. Aviv et al. (36) described normative sensory thresholds to calibrated pulses of air. An individual with normal LP sensation demonstrates LAR at a pulse pressure of less than 4 mm Hg. Those requiring greater pressure are identified as having moderate (4 to 6 mm Hg) or severe sensory impairment (greater than 6 mm Hg). These thresholds correlate with psychophysical testing, or patient-reported sensation of delivered air pulses (33). Aviv et al. (37) reported a strong association between pharyngeal motor dysfunction on the PSM and decreased LP sensation. They demonstrated that isolated pharyngeal motor dysfunction with intact LP sensation is predictive of penetration and aspiration with pureed consistencies, and an isolated LP sensory deficit with an intact PSM is predictive of penetration and aspiration with thin liquids. Nearly all patients with an absent LAR and absent PSM aspirate both thin liquids and puree (38,39). After the assessment of LP sensation, the patient is administered food and beverage.

Before the patient is fed, s/he is asked to take a "dry" swallow. During the swallow, eversion of the epiglottis that occurs as a consequence of laryngeal elevation and lingual retraction causes a *whiteout* on the video monitor. Assessments of swallowing function must be made before and after the whiteout occurs. The inability to achieve whiteout on a dry swallow suggests profound swallowing dysfunction. All food and beverage is impregnated with green food coloring (McCormick & Co, Inc., Sparks, MD). The decision to begin the examination with food, liquid, or ice chips is determined by the information garnered from the initial examination. If the patient has an intact LAR but absent PSM, the patient is first administered water. The water is fed by teaspoon if limited bolus sizes are desired. If larger bolus sizes are administered, the patient is asked to sip from a straw. A cup sip is difficult to perform with a flexible endoscope in the nose, and a flexible straw that articulates to 90 degrees is an important piece of equipment to have available during the examination. If the patient has an absent LAR but an intact PSM, the patient is first administered puree. We utilize applesauce as our standard puree substance (Mott's Inc., Rye Brook, NY). The applesauce has a long shelf life, does not require refrigeration, and can be kept in the examination room. If the patient has an absent LAR and absent PSM, the patient is first administered a small ice chip. Ice chips are preferred in this situation for several reasons. The cold from the ice provides additional sensory information to the patient that may assist with deglutition. Furthermore, ice is easier to control in the oral cavity than thin liquid and, if aspirated, will readily melt and poses little harm to the patient. Suspected aspiration of a given bolus requires repetition of the same volume and viscosity to confirm aspiration. Determining that a particular consistency is safe occurs only after repeated successful trial as dysfunction is often uncovered after fatiguing the swallowing apparatus or triggering an irregular breathing pattern. If the patient passes the water and puree consistencies, more challenging solids or pills may be administered.

The food is placed in the oral cavity and the patient is instructed not to swallow until instructed. Loss of the bolus into the pharynx before the initiation of swallow is called premature spillage. Following the swallow, the endoscope is advanced from the home position into the laryngeal vestibule and the passage of material into the laryngeal inlet (penetration) or passage of material below the vocal folds (aspiration) is evaluated. The ability for slow motion video playback is essential to evaluate the presence of aspiration during the swallow. Penetration and aspiration may occur before, during, or after the swallow. In general, aspiration before the swallow occurs in 25% of cases of aspiration and indicates oral and pharyngeal dysfunction, aspiration during the swallow occurs in 10% of cases of aspiration and indicates a neurologic disorder with a sensory deficit, and aspiration after the swallow occurs in 65% of cases of aspiration and indicates lingual or pharyngeal weakness or outlet obstruction through the UES. The presence of penetration and aspiration can be quantified with the penetration aspiration scale (PAS) (40) (Table 57.4). Also noted are pharyngeal residue, coughing, throat clearing, or a secondary reswallow. Postswallow regurgitation out of the esophagus into the pharynx (esophagopharyngeal reflux) is called "the rising tide sign" and may indicate the presence of a Zenker diverticulum or profound esophageal dysmotility. In the presence of intact pharyngeal strength and diminished or absent LP sensation, it may be difficult to determine if aspiration occurred during the whiteout phase of the examination. In this case, a brief tracheoscopy may be performed at the end of the FEES to identify silent aspiration.

TABLE 57.4 PENETRATION ASPIRATION SCALE

Score	Description
1	Food/beverage does not enter the airway
2	Food/beverage enters the airway, remains above the vocal folds with no visible residue present after the swallow
3	Food/beverage enters the airway, remains above the vocal folds with visible residue present after the swallow
4	Food/beverage penetrates to the level of vocal folds with no visible residue present after the swallow
5	Food/beverage penetrates to the level of vocal folds with visible residue present after the swallow
6	Food/beverage penetrates below the level of vocal folds with no visible residue present in the subglottis after the swallow
7	Food/beverage penetrates below the level of vocal folds with visible residue present in the subglottis despite a patient's response to clear
8	Food/beverage penetrates below the level of vocal folds with visible residue present in the subglottis and an absent patient response to clear

For individuals who demonstrate abnormal swallowing, modified consistencies and therapeutic maneuvers may be performed at the end of the examination. The chin tuck may help eliminate vallecular residuals. The supraglottic swallow and food thickeners may address premature spillage and aspiration occurring before and during the swallow. An ipsilateral head turn to the side of vocal fold immobility or pharyngeal weakness will divert the bolus away from the affected location and may improve swallowing safety. A monitor positioned across from the patient will allow the clinician to perform FEES biofeedback or "bioFEESback." This can assist with teaching airway protection and with communicating the effectiveness of various swallowing maneuvers.

Various clinicians have attempted to compare the utility of FEES with VFSS. A number of studies have confirmed that FEES provides information about swallow initiation, penetration, aspiration, and presence of pharyngeal residue that is at least as reliable as that obtained from VFSS (20,41–44). FEES may be a more sensitive indicator of penetration and aspiration than VFSS (45,48). Investigation suggests that both studies have good inter-rater reliability when the standardized PAS is used (42,45). Advantages of FEES include its portability, relatively low cost, lack of radiation exposure in addition to the ability to evaluate various food substances and assess for pooling of saliva, laryngeal inflammation, neoplasm, and vocal fold function. The primary benefits of VFSS include the ability to evaluate bolus movement through the pharyngoesophageal segment (PES), the ability to screen the esophagus, and the ability to precisely quantify objective swallowing parameters such as PES opening, laryngohyoid displacement, and pharyngeal timing measures. Table 57.5 compares the relative advantages of FEES and VFSS.

VIDEOFLUOROSCOPIC SWALLOW STUDY

Radiographic assessment of swallowing function evaluates the laryngopharynx, esophagus, or both. The VFSS traditionally refers to the radiographic swallow evaluation of the oral cavity and pharynx and represents the gold-standard modality to evaluate the UES. Alternatively, radiographic visualization of the esophagus is termed an esophagram or barium swallow (46).

Because patients are exposed to radiation during VFSS, appropriate indications should be identified before a patient undergoes the evaluation. Indications include dysphagia, odynophagia, aspiration, chronic cough, and postoperative evaluation. The purpose of VFSS is to identify behaviors and abnormalities that result in risks to a patient's nutritional status or the respiratory system during feeding. Given that the evaluation itself may expose the dysphagic examinee to risk of aspiration, the examiner must choose following each swallow exercise whether or not to continue. As such, the evaluation may be truncated for safety at the expense of gathering information.

Unlike FEES and CSE, VFSS allows for thorough evaluation of the oral phase of swallowing. Bolus formation, effective tongue motion, and swallow initiation are uniquely and readily characterized during VFSS (47). Additionally, the function of the linguapalatal valve, which alternately contains the bolus within the oral cavity and releases it into the pharynx, is only adequately assessed on lateral projections during VFSS. When compared to FEES, VFSS offers the additional advantages of velopharyngeal valve assessment, evaluation of UES opening, real-time recording of transitions between phases of swallowing and esophageal screening, which can be readily performed as an adjunctive evaluation in the same setting as VFSS.

VFSS is performed with a patient seated in a fluoroscopic radiography suite with equipment capable of rapid sequence image capture. During the examination, swallows of different quantities and consistencies of barium are captured in both lateral and frontal projections. The frontal view allows for superior visualization of the vallecula and piriform sinuses as well as certain abnormalities such as Zenker diverticulum. Owing to the propensity of esophageal abnormalities to result in dysphagia, a screen of the esophagus is also performed.

A standardized protocol of bolus consistencies and volumes should be followed for all examinations to allow for comparisons between sequential exams, different patients, and normative data. Complaint-specific tasks, such as pill swallows, should also be included if possible and safe. Following the standardized protocol, abnormalities may be targeted by specific compensatory maneuvers. The efficacy of compensatory strategies can be evaluated fluoroscopically.

Reporting objective measures when evaluating VFSS has been advocated to aid in standardizing the description of swallowing dysfunction and predicting success of intervention (48). Objective data gathered from fluoroscopic exams allow for comparisons to normative values, serial examinations, and other individuals. Included in these objective data are measures of timing and displacement. Timing measures reflect both bolus transit and timing of swallowing gestures, including hyoid displacement and PES opening. Calculation of bolus transit and gesture timing as well as their resultant coordination allows for characterization of "delayed" and "prolonged" swallowing abnormalities. Both result in increased risk of aspiration to the examinee.

With proper patient positioning and calibration, spatial measurements can be made on digitized images collected during VFSS. Commonly measured are maximum hyoid displacement, pharyngeal constriction ratio (PCR), maximum PES opening, and maximum approximation of the larynx and hyoid. The PCR is a surrogate measure of pharyngeal clearance pressure (49), traditionally measured by pharyngeal manometry. It is calculated by dividing the lateral pharyngeal area during maximal contraction by the area while a 1cc bolus is held in the oral cavity. Normative data for the PCR have been described (50). A normal PCR (within two standard deviations for an age-matched control) predicts a satisfactory result following an intervention to increase UES size, such as cricopharyngeal myotomy. The increased availability of VFSS compared to pharyngeal manometry yields this measurement especially valuable.

TRANSNASAL ESOPHAGOSCOPY

Advances in flexible endoscopic technology have led to the evolution of ultrathin endoscopes that are easily and safely passed transnasally for evaluation of the upper aerodigestive tract in the unsedated patient (51). Since 2000, transnasal esophagoscopy (TNE) has been popularized by otolaryngologists, and its applications continue to expand (52–54). Though initially thought to be inferior to conventional peroral esophagoscopy in image quality and diagnostic ability (55,56), TNE using the ultrathin distal chip videoendoscope has been shown to offer equivalent image quality and diagnostic accuracy as standard methods of sedated, peroral esophagoscopy (57–59). Furthermore, TNE affords both direct and indirect cost savings, improved safety profile, and better patient tolerance when compared to conventional esophagogastroduodenoscopy (EGD) (60,61). Comparison studies have found patient tolerance of unsedated TNE to be equivalent or superior to sedated EGD (62,63). Over 70% of patients prefer to have unsedated TNE (64).

Indications for TNE may be esophageal, extraesophageal, and interventional (65). The most common indication for TNE is a screening evaluation for patients with reflux, dysphagia, and globus, accounting for 80% of examinations (66). Although the need to screen the esophagus in patients with symptoms of LP reflux is uncertain, there is evidence that extraesophageal reflux symptoms,

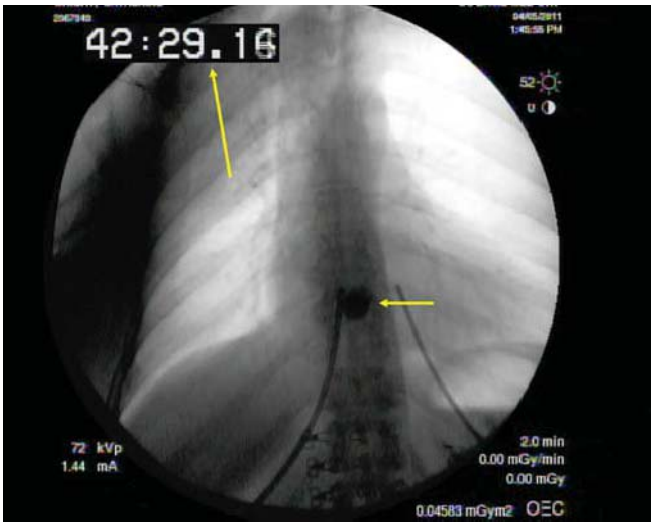

Figure 57.3 Fluoroscopic video-esophagram displaying a 13 mm barium tablet stuck in the midportion of the esophagus (*short arrow*). The patient is localizing the location of dysphagia to the cervical region with her right hand (*long arrow*).

especially chronic cough, better predict the presence of esophageal adenocarcinoma than the typical reflux symptoms of heartburn and regurgitation (67). Other less common indications for TNE include unexplained weight loss, hemoptysis, chest pain, odynophagia, and evaluation of suspected esophageal foreign body. Esophageal pathology is extremely common in patients after definitive treatment for head and neck cancer. Among head and neck cancer patients evaluated with TNE greater than 3 months after treatment, 63% had esophagitis, 23% had esophageal stricture, 9% had candidiasis, 8% had Barrett metaplasia, and 4% had a second primary malignancy (68). Thus, we routinely perform esophagoscopy in all individuals 3 months after definitive treatment for head and neck cancer.

Patients do not accurately identify the source of their dysphagia. Approximately one-third of patients who localize their swallowing dysfunction to the cervical region will have an esophageal etiology for their symptom (Fig. 57.3). Thus, in the absence of an identifiable oropharyngeal cause of the symptom of dysphagia, patients with solid food dysphagia should have their esophagus screened regardless of where they localize the symptom. TNE has enabled the otolaryngologist to perform a variety of office-based interventions. The expanding list of unsedated office procedures performed via TNE includes biopsy, stricture and web dilation, botulinum toxin injection, foreign body retrieval, tracheoesophageal puncture, and feeding tube insertion (69,70).

To perform TNE, an unsedated patient is seated upright in a standard ENT examination chair (Fig. 57.4). Cardiac monitoring is not necessary and ideally the patient is kept nil per OS for 3 hours prior to the procedure. Although a full stomach may enhance nausea, it is not a contraindication to the procedure. The patient's nasal cavity is sprayed with 1:1 oxymetazoline 0.05% and lidocaine 4%. If the patient has a hypersensitive gag reflex, the patient may

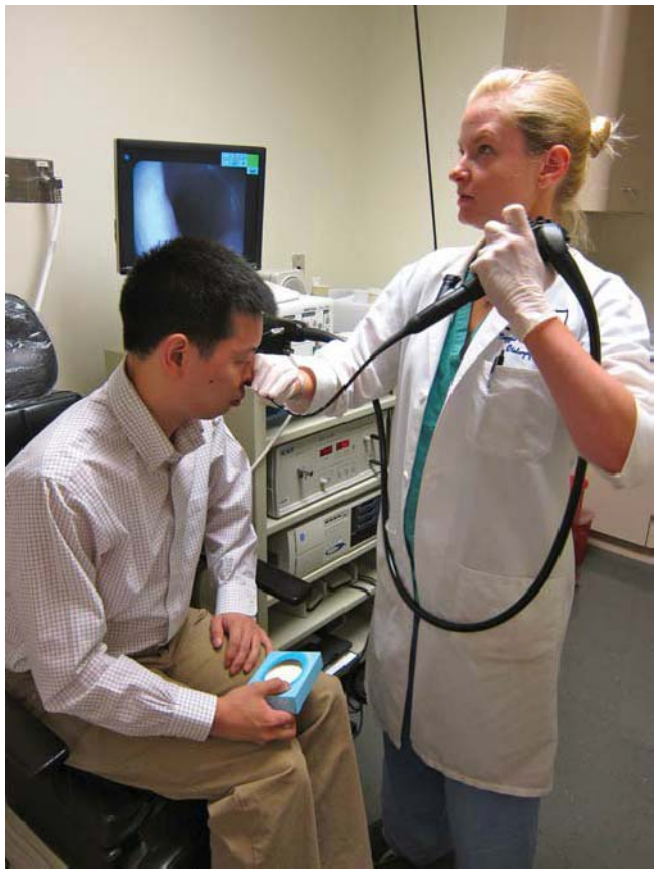

Figure 57.4 Positioning for office-based unsedated TNE.

be given two teaspoons of 2% viscous lidocaine to gargle and swallow. Distal chip esophagoscopes are capable of air insufflation, water instillation, and suction and have a working port allowing for biopsy, injection needle, laser fiber, and guide wire placement.

The endoscope is lubricated with 2% viscous lidocaine and passed through the more patent nasal cavity. Supraesophageal structures including the nasopharynx, velum, oropharynx, larynx, and hypopharynx are first examined. After the laryngeal examination, the endoscope is placed just above the tip of the epiglottis in the home position. A hand is placed on the patient's shoulder and the patient is asked if s/he is comfortable enough to continue. Eye contact is made with the patient and s/he is then instructed that s/he will be asked to swallow the endoscope. The eye contact and human touch are essential to keep the patient at ease and reduce anxiety. The esophagus is entered by placing the tip of the endoscope into the pyriform sinus and asking the patient to lean forward, flex the chin toward the neck, and swallow. Instructing the patient to "close your lips and pretend you are swallowing a big piece of spaghetti," often provides reassurance as to the benign nature of the procedure. While the patient swallows, the scope is advanced through the UES into the cervical esophagus (71). If there is difficulty passing the scope into the esophagus, a teaspoon of 2% viscous lidocaine may be placed into the

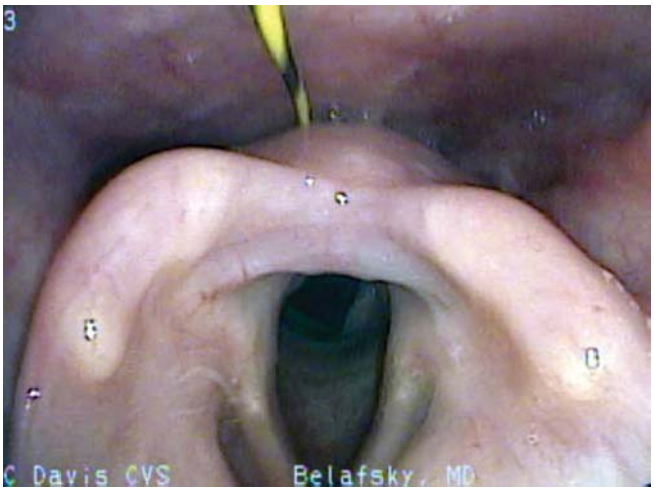

Figure 57.5 Placement of a guide wire through the transnasal endoscope and into the esophagus in a patient with a Zenker diverticulum. The endoscope can be advanced over the guide wire once it has been safely passed 30 to 40 cm into the esophagus.

patient's oral cavity. The patient is instructed to hold the lidocaine in the mouth and, as the endoscope is positioned in the pyriform sinus near the esophageal inlet, the patient is asked to flex their chin toward the chest and swallow. The lidocaine bolus will open the UES during deglutition and will lubricate the endoscope as it passes into the esophagus. If this is not successful in allowing entrance into the esophagus, the examination should be terminated and a fluoroscopic swallow study obtained to rule out the presence of cricopharyngeal dysfunction or a Zenker diverticulum. If known cricopharyngeal dysfunction or Zenker diverticulum exists, intubating the esophagus can be performed with the assistance of a guide wire (Hydra Jagwire Guidewire, Boston Scientific, Natick, MA). The guide wire is placed through the esophagoscope and advanced under direct vision into the esophagus as the patient is instructed to swallow (Fig. 57.5). If the guide wire enters a diverticulum or cannot traverse an obstructing cricopharyngeus or cervical stenosis, it will curl and be seen reentering the pharynx. If the guide wire can be passed 30 to 40 cm without curling back into the pharynx, the clinician can be assured that it has safely traversed the diverticulum and UES. The esophagoscope can then be passed safely over the guide wire into the esophagus without the risk of perforation. Once the endoscope is safely in the midesophagus, the wire can be removed.

Once the esophagus is entered, the endoscope is immediately advanced to the midportion of the esophagus. Keeping the tip of the endoscope in the region of the UES is uncomfortable and will promote gagging. This region will be thoroughly examined at the end of the procedure as the endoscope is withdrawn. The esophagus is immediately suctioned of air and fluid and the examiner's free hand is again placed on the patients shoulder and eye contact is made. The patient is reassured that "this is as bad as the procedure is going to get" and asked "are you comfortable enough to proceed with the examination?" If there is noticeable discomfort or gagging, the procedure is terminated and an examination under intravenous sedation is scheduled. The midportion of the esophagus is then insufflated with air and the esophagoscope is advanced to the gastroesophageal (GE) junction. The presence of diverticula, abnormal dilation, foreign body, motility abnormality, esophagitis, web, ring, stricture, or neoplasm is noted. Figure 57.6 displays the most common findings identified

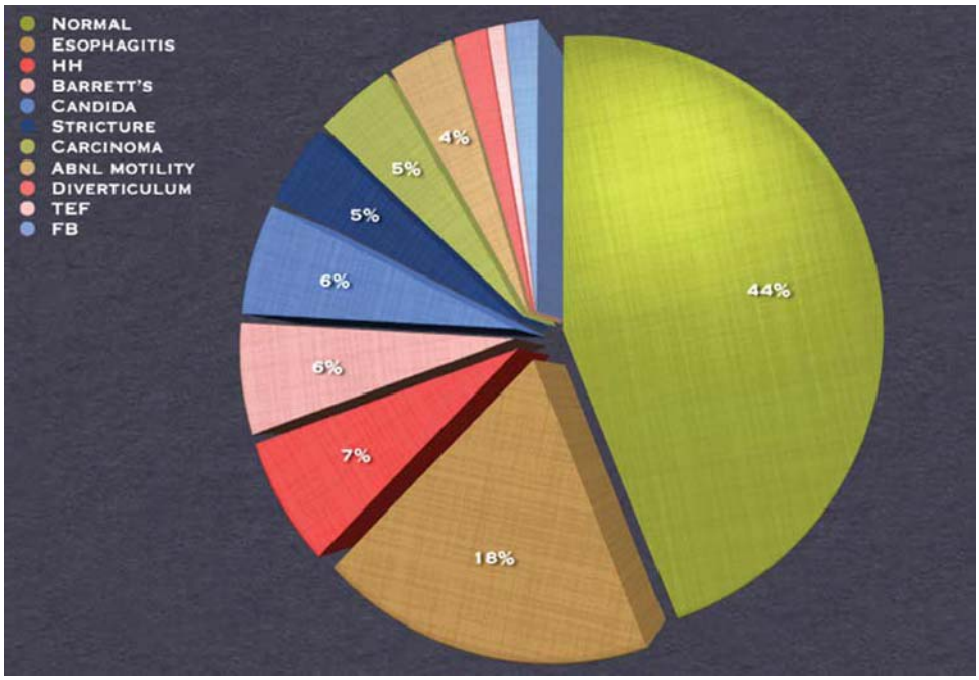

Figure 57.6 Most common findings reported on unsedated TNE. (HH, hiatal hernia; TEF, tracheoesophageal fistula; FB, foreign body).

on TNE. Lastly, the position of the squamocolumnar junction (Z-line), normally situated at the GE junction, is noted from above the lower esophageal sphincter (LES) and from below the LES during a retroflexed view from within the stomach. The stomach is suctioned free of air at the end of the procedure and the esophagoscope is carefully withdrawn. Withdrawing the endoscope will center the tip and provide an optimal view during removal.

Complications from TNE are rare. In 3% of patients, the 5.1 mm endoscope cannot be passed through a tight nasal vault (53). Epistaxis and vasovagal reaction, the most commonly reported complications, occur in fewer than 3% of patients (72). Because TNE is performed on unsedated patients, cardiopulmonary complications associated with traditional peroral esophagoscopy under sedation are reduced (73).

A functional esophagoscopy, or a *FEES of the esophagus* may be performed in patients with suspected esophageal phase dysphagia. The examination was initially described by Belafsky and Rees (74) in 2009 and is entitled **G**uided **O**bservation **O**f **S**wallowing in the **E**sophagus (GOOSE). A FEES is initially performed with the transnasal esophagoscope per the description earlier in the chapter. At the end of the FEES, the endoscope is passed through the UES into the cervical esophagus. Normal esophageal emptying time is approximately 13 seconds. Any residue present in the esophagus after this time suggests an esophageal abnormality (74). The GOOSE may be performed by offering the patient boluses of puree, liquid, cracker, and pills with the scope held in a series of three positions: above the aortic compression, above the LES, and retroflexed within the stomach (Fig. 57.7) (74). During this procedure, organic esophageal pathology, abnormal esophageal motility, and bolus transit time may be evaluated. In a study comparing the utility of GOOSE to fluoroscopy and manometry, GOOSE had a 71% concordance with fluoroscopy and an 83% concordance with manometry (74). GOOSE identified pathology not recognized on fluoroscopy and manometry in 62% of patients.

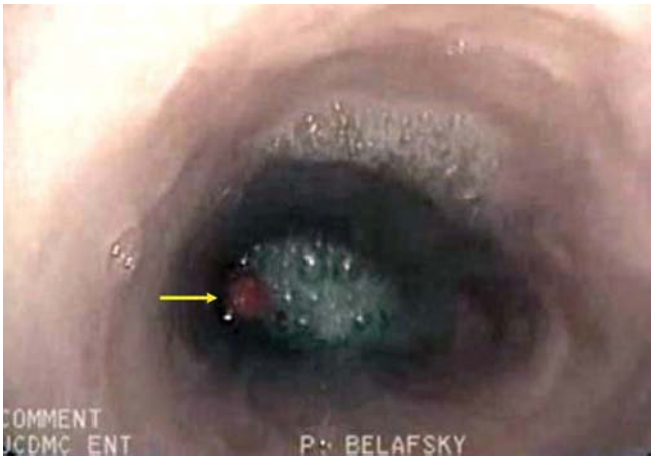

Figure 57.7 GOOSE in a patient with the complaint of pills getting stuck in the cervical region displays a pill (*arrow*) and liquid esophageal stasis above a distal esophageal peptic stricture. The stricture is not visualized on the image distal to the stasis.

HIGH-RESOLUTION MANOMETRY

Although endoscopy provides a direct view of the aerodigestive tract from the nasal vestibule to gastric body, it is limited in its ability to objectively quantify pharyngeal and esophageal motility and upper and LES function. The introduction of high-resolution manometry (HRM) into the functional assessment of swallowing significantly increases the clinician's ability to diagnose and classify disordered deglutition. Solid-state HRM typically has 36 circumferential sensors spaced 1 cm apart. Pharyngeal and esophageal motility are characterized by using pressure topography plots (Fig. 57.8). HRM has proven beneficial in distinguishing between pharyngeal weakness, poor pharyngeal and UES relaxation, incomplete upper esophageal relaxation, esophageal body motility, and LES function. Our HRM protocol involves a 5-minute assessment of UES and LES baseline function followed by the evaluation of twelve 5-mL water swallows. Pharyngeal peak pressures are evaluated from the soft palate to the UES. Then UES baseline, UES relaxation, and pharyngeal-UES coordination are evaluated. These pressure relationships are essential in evaluating a patient for surgery on the UES. The best candidates for cricopharyngeus muscle myotomy have elevated UES residual pressure, elevated hypopharyngeal intrabolus pressure, and normal pharyngeal and hypopharyngeal peak pressures. Individuals with absent hypopharyngeal pressure are unlikely to get benefit from myotomy (Fig. 57.9). A comprehensive discussion regarding the classification of esophageal motility disorders on HRM is beyond the scope of this chapter. Table 57.6, however, depicts the Chicago Classification of esophageal motility disorders on HRM (75).

TABLE 57.6 THE CHICAGO CLASSIFICATION OF ESOPHAGEAL MOTILITY DISORDERS ON HRM

Classification	Description
Esophageal aperistalsis without impaired LES relaxation	Failed peristalsis in all tests swallows with or without a hypotensive LES. If associated with a hypotensive LES is considered consistent with scleroderma
Achalasia	Esophageal aperistalsis with impaired LES relaxation
Hypertensive esophageal peristalsis	Further classified as distal esophageal spasm, compartmentalized esophageal pressurization, and nutcracker esophagus
Functional esophageal obstruction	Incomplete deglutitive LES relaxation in the setting of preserved esophageal peristalsis

Absent pharyngeal contraction (*black arrow*).

HIGHLIGHTS

- The EAT-10 is useful for evaluating dysphagia symptom severity and monitoring response to therapy.
- The CSE is indicated for initial assessment of swallowing complaints. Cough, wet vocal quality, and repeat swallows are indicative of swallowing dysfunction.
- CSE fails to identify silent aspiration that would otherwise be detected by VFSS or FEES.
- VFSS affords evaluation of oral, pharyngeal, and esophageal phases of swallowing.
- Objective measures of timing and displacement obtained during VFSS allow for comparisons among serial examinations, populations of individuals, and normative data.
- During FEES, swallow trigger delay, presence of residue, vocal fold mobility, and pharyngeal strength can be assessed.
- LP sensation is evaluated by eliciting the LAR during FEESST.
- TNE can be performed safely and comfortably in the office with only topical anesthesia, obviating the need for sedation and cardiac monitoring.
- TNE detects a variety of esophageal abnormalities including motility disorder, stricture or ring, foreign body, diverticulum, Z-line irregularity, esophagitis, and hiatal hernia.
- HRM is a useful adjunctive instrument for assessing pharyngeal and esophageal motility, sphincter pressure, and coordination.

58 Nonsurgical Management of Swallowing Disorders

Shaum S. Sridharan *Cathy L. Lazarus* *Milan R. Amin*

Swallowing disorders refer to any dysfunction in the complex cascade of normal deglutition. It is the task of the clinician to not only investigate the site of dysfunction, but also to try to help rebalance the system to prevent symptoms of dysphagia and aspiration pneumonia. This chapter provides a comprehensive overview of medical and rehabilitative modalities in the management of swallowing disorders. With the proper identification of the underlying reason(s) for dysphagia, appropriate therapy can be initiated by physicians and speech and language pathologists.

Treatment for oropharyngeal dysphagia should be based on a thorough instrumental assessment of oropharyngeal swallowing, including the modified barium swallow (MBS) procedure (1–4). This radiographic procedure, also known as a Videofluoroscopic Swallow Study (VFSS), involves giving a patient specific bolus types of various volumes and consistencies (calibrated bolus volumes of liquids, cup sips, pudding, and masticated consistencies, as appropriate) and examining their effects on the swallow. The radiographic examination provides a view of the oropharyngeal anatomy and allows the clinician to identify any abnormalities of the oropharyngeal swallow. The radiographic study should identify the patient's physiologic swallow disorders, rather than merely symptoms of the disorders, such as penetration (material in the airway entrance), aspiration (material below the vocal folds), and residue (food remaining in the oral cavity, valleculae, pharyngeal wall, pyriform sinuses). Appropriate treatment strategies cannot be determined until the physiologic swallow abnormalities (such as reduction in tongue base posterior motion, reduction in laryngeal elevation, and anterior motion) have been identified.

Once the anatomic and/or physiologic swallow disorders have been defined on fluoroscopy, the clinician determines the effects of rehabilitative strategies on the patient's swallow. The goal of the rehabilitative strategies is to improve swallow safety (i.e., elimination of aspiration) and efficiency (i.e., improving the speed of the swallow and reducing the amount of residue within the oral cavity and pharynx). These strategies can be compensatory in nature, including postures and sensory augmentation, or can be direct treatment techniques designed to alter swallow physiology, including swallow maneuvers. Some patients are able to begin or resume some type of oral diet using the postures that demonstrated success on fluoroscopy. Others may require use of swallow maneuvers during meals. Some patients, however, exhibit swallow function that is so impaired as to preclude an oral diet. The treatment strategies will be based on the patient's oropharyngeal anatomy and abnormal swallow physiology. In addition, the strategies employed will be determined by the patient's medical diagnosis, including the patient's overall medical condition, mental status, cognitive ability, motivation level, and speech/language ability. Thus, treatment planning begins at the time of the diagnostic procedure. The report of the VFSS should identify the symptoms of the swallow disorders, the physiologic swallow disorder, the rehabilitative strategies tried on fluoroscopy and their effects, and the specific treatment plan.

COMPENSATORY TREATMENT PROCEDURES

Compensatory treatment techniques are designed to redirect the bolus flow through the oral cavity and pharynx. They are techniques that are designed to eliminate aspiration, one of the symptoms of dysphagia, but are not designed to alter the swallow physiology. These techniques can be implemented by caregivers, and, therefore, are useful for patients of all ages and cognitive levels. Compensatory treatments include: (a) postures; (b) heightening sensory input; (c) modifying bolus volume and speed of feeding; (d) modifying food viscosity/texture, and (e) intraoral prosthetics.

Postures

Postures alter the flow of the bolus through the oral cavity and pharynx (Table 58.1). *Chin tuck posture* is used when the pharyngeal swallow (i.e., pharyngeal motor response) is delayed and aspiration occurs before the swallow triggers (1). This posture widens the vallecular space, creating a space for liquids and food to catch in the valleculae during the delay. Chin tuck posture also narrows the airway entrance, with closer approximation of the arytenoids to the epiglottic base and is useful for patients who demonstrate reduced airway closure (5). The tongue base is situated closer to the posterior pharyngeal wall (PPW) during chin tuck posture, providing additional airway protection by deflecting the bolus more posteriorly during the swallow (1,6,7). In addition, for those patients with reduced tongue base posterior motion, resulting in poor bolus clearance past the tongue base and residue on the tongue base, valleculae, and pharyngeal wall, chin tuck posture improves bolus clearance within this region, resulting in reduced upper pharyngeal residue (7). This technique has been found useful in eliminating aspiration in neurologically impaired and in surgically treated head and neck cancer patients (8–10).

The *head back posture* is useful for those patients who demonstrate difficulty propelling the bolus out of the oral cavity into the pharynx, as frequently observed in oral cancer patients and dysarthric patients with impaired tongue mobility (1). This posture allows gravity to propel the bolus into the pharynx. This posture, however, should be used with caution, since patients may aspirate more easily, particularly on thin liquids. Voluntary airway closure techniques, described below, are useful in protecting the airway during use of this posture. Patients with fairly severe pharyngeal phase swallow disorders should not use this posture.

The *head rotation posture* is useful for those individuals who demonstrate unilateral muscular disorders. For example, patients with unilateral pharyngeal weakness typically demonstrate residue on the weak side of the pharynx. Patients will benefit from head rotation to the weaker side, since this posture effectively closes off the weaker side and allows the bolus to clear through the pharynx and pyriform sinus region on the undamaged side (1). This posture is also useful for those patients with reduced cricopharyngeal opening, which can result in pyriform sinus residue that can enter the airway after the swallow (11,12). Head

TABLE 58.1 RATIONALE FOR USE OF COMPENSATORY POSTURES TO IMPROVE SWALLOW FUNCTION

Disorder Seen on MBS	Posture Utilized	Rationale
Impaired oral tongue function (reduced manipulation/propulsion of the bolus) resulting in prolonged oral transit times and oral residue	Head back	Utilizes gravity to propel material into the pharynx
Delayed triggering of the pharyngeal motor response (aspiration before the swallow)	Chin tuck	(a) Narrows the airway entrance (i.e., arytenoids are situated closer to epiglottic base); (b) situates the tongue base closer to the PPW, providing extra airway protection; and (c) widens the vallecular space, allowing the bolus to sit in this space rather than enter the airway before the swallow triggers
Reduced tongue base posterior motion (resulting in oropharynx residue and potential aspiration after the swallow)	Chin tuck	Situates the tongue base more posteriorly and closer to the PPW, improving bolus clearance past this region
Unilateral laryngeal dysfunction (aspiration during the swallow)	Head rotation to the impaired side of the larynx	Improves glottic closure, as extrinsic pressure is applied to the thyroid cartilage
Reduced laryngeal closure (aspiration during the swallow)	Head rotation to the damaged side combined with chin tuck	Places epiglottis in more protective position, narrows airway entrance and improves glottic closure
Reduced pharyngeal contraction—bilateral (resulting in residue and aspiration after the swallow)	Side-lying posture	Allows pharyngeal residue to collect on the lateral pharyngeal wall rather than near the glottis, so it reduces risk of subsequent aspiration
Unilateral pharyngeal paresis/paralysis (resulting in aspiration after the swallow)	Head rotation to the damaged side	Closes damaged side of pharynx and channels bolus through undamaged side, as well as improves pressure generation on bolus
Unilateral oral weakness (impaired bolus control, manipulation and propulsion through oral cavity resulting in oral residue)	Head tilt to stronger side	Improves bolus control and facilitates improved oral transit of bolus into pharynx by channeling bolus through stronger side of oral cavity
Cricopharyngeal dysfunction	Head rotation	Pulls cricoid cartilage away from PPW, improving opening and reducing intralumen UES pressure

rotation is also useful for those patients who are aspirating during the swallow due to vocal cord paralysis or following hemilaryngectomy. The patient rotates the head toward the paretic/surgical side, improving glottic closure (1,9). Combinations of postures are frequently used, particularly head rotation and chin tuck. These are particularly effective for those individuals who demonstrate a unilateral pharyngeal weakness as well as reduced airway closure (1,9).

Side-lying posture is used when pharyngeal clearance is reduced, resulting in residue that enters the airway after the swallow (1,2). In this posture, the patient is lying down on his side with his head propped up slightly. Residue will still be present after the swallow when using this maneuver, but the residue will remain on the lateral pharyngeal wall and will be cleared on subsequent dry swallows.

Head tilt posture is useful when a patient exhibits a unilateral oral and/or pharyngeal weakness (1,2). The head is tilted toward the unimpaired or stronger side, to allow the bolus to clear the oral cavity and pharynx on the stronger side. This posture is useful after hemiglossectomy and also for patients who are dysarthric with hemiparesis of the tongue, as this posture allows for improved oral control and propulsion of the bolus into the pharynx, resulting in improved oral phase swallow functioning. Head tilt is also useful to improve clearance of the bolus through the pharynx for those patients with unilateral pharyngeal paresis or paralysis (Table 58.1).

Sensory Enhancement Techniques

Therapy techniques that utilize sensory enhancement are helpful for those patients who have reduced sensory awareness, delayed initiation of lingual activity (often seen in patients with oral apraxia), and delayed triggering of the pharyngeal swallow. These techniques involve providing a preswallow sensory stimulus to improve initiation of lingual activity and/or triggering of the pharyngeal swallow. These techniques can include downward pressure on the tongue with a spoon, introducing boluses with other tastes, such as sour, or changing temperature and texture of the bolus (1,2,13,14). Carbonated boluses have been found to improve the oropharyngeal swallow, specifically, reducing pharyngeal transit time, percent pharyngeal residue, and aspiration (15). Another technique includes the use of thermal/tactile stimulation to improve triggering of the pharyngeal swallow (16,17). Slightly larger bolus volumes may provide increased sensory input and may result in improved oral initiation, as can boluses that require chewing. A slightly firmer bolus (i.e., pastes vs. liquids) can have the same effect.

Modifying Bolus Volume and Speed of Feeding

The ideal volume of food or liquid that will initiate triggering of the pharyngeal swallow will vary among patients. In addition, for those patients who demonstrate pharyngeal phase motility disorders resulting in pharyngeal residue, two to three repeat dry swallows are often needed to clear the pharynx. Thus, often taking smaller bolus volumes and eating at a slower pace, allowing time to reswallow to clear residue will reduce the risk of aspiration in these patients.

Bolus Consistency (Diet) Changes

Eliminating specific food consistencies is the last resort in compensatory diet modification. It is often unpleasant for the patient to be told that thin liquids must be eliminated from the diet. However, if other compensatory or direct therapy strategies do not eliminate aspiration or improve swallow efficiency, certain consistencies must be eliminated from the diet. In general, if a patient demonstrates reduced oral tongue control, delayed triggering of the pharyngeal swallow, or reduced airway closure, thin liquids might need to be eliminated, whereas slightly thicker consistencies would be indicated. For those patients who demonstrate reduced lingual strength or reduced bolus clearance through the pharynx, the latter impairment due to reduced tongue base posterior movement, reduced pharyngeal wall contraction, reduced hyo-laryngeal elevation and anterior motion, and cricopharyngeal dysfunction, thinner bolus consistencies are indicated, such as thin and thick liquids.

Intraoral Prosthetics

Intraoral prosthetics can help compensate for anatomic deficits, such as resection of a portion of the tongue, resection of part or all of the soft palate, neurologic damage that results in reduced lingual range of motion, or neurologic damage that results in palatal paresis. A *palatal lift* aids in velopharyngeal closure by lifting the paralyzed soft palate. A *palatal obdurator* seals off the velopharyngeal port for those patients who undergo soft palate resection, preventing material from entering the nasopharynx and improving intraoral pressure (18,19). A *palatal augmentation* prosthesis lowers the palatal vault for those patients who have undergone oral cancer resection. This prosthesis allows the remaining lingual tissue to contact the augmentation so that the tongue can control, seal, and propel a bolus of food through the oral cavity. A palatal augmentation prosthesis can benefit patients who have had a significant portion of the oral tongue resected, resulting in improved transport of the bolus through the oral cavity and reduced oral residue (19,20). The speech-pathologist works collaboratively with the maxillofacial prosthodontist to construct the prosthesis. For patients undergoing oral cancer surgery, construction of the prosthesis should begin 4 to 6 weeks postoperative. For those patients undergoing radiotherapy, construction typically begins at least 6 to 8 weeks after completion of treatment. In those patients with total glossectomy, the palatal augmentation prosthesis is typically fairly large because the augmentation portion needs to be

near the remaining muscles comprising the floor of mouth in order to assist with bolus control and clearance through the oral cavity. Additional swallow exercises are provided and should be practiced with the prosthesis in place to maximize its use for swallowing and speech.

THERAPY PROCEDURES

Direct therapy procedures are designed to change the swallow physiology by altering specific components of the oral and/or pharyngeal phases of swallowing. These can include exercises to improve or increase muscle strength, range of motion, and control. They can also improve the sensory-motor integration of the swallow or alter the timing and coordination of various aspects of the swallow (1,21,22).

RANGE OF MOTION, RESISTANCE, AND CONTROL EXERCISES

Exercise programs are designed to improve function of the target muscle or muscle groups to improve swallow physiology. Range of motion exercises are designed to increase range of the target muscle (23,24) and can include the jaw, lips, oral tongue, tongue base, pharyngeal constrictors, larynx, and hyoid-related musculature. They are often prescribed for head and neck cancer patients and stroke patients with dysarthria and dysphagia. They are also prescribed for those patients with dysphagia due to generalized weakness and deconditioning, particularly older patients who have been hospitalized for prolonged periods. Changes in the timing, coordination, and degree of muscle activity for swallowing occur with normal aging and with bolus volume and viscosity (5,13,25–34) and can place older, medically debilitated patients at risk for developing swallowing problems. Tongue range of motion exercises have been found to improve swallow function, specifically, oropharyngeal swallow efficiency in surgically treated oral cancer patients (23). Lingual range of motion exercises have also been prescribed for patients with progressive neurologic impairment, such as Parkinson disease (PD), multiple sclerosis (MS), and amyotrophic lateral sclerosis (ALS). However, it is commonly believed that tongue range of motion and strengthening exercises are not indicated for these patients, as active lingual exercise programs are thought to fatigue the muscles, resulting in poorer function for speech and swallowing. There are little data, however, to refute or support this theory.

Strengthening exercises involve active resistance to increase muscle strength and often target the tongue, lips, jaw, and suprahyoid muscles. Tongue strength has been found to be reduced in the elderly healthy population (35–37) and in patients with stroke, traumatic brain injury, ALS, PD, and oral cancer treated with radiotherapy (35,38–42). Lingual strengthening/resistance exercises have been found to increase tongue strength in young and elderly healthy individuals (43,44) and have been found to improve tongue strength and swallowing function in the stroke population (45).

The *pharyngeal squeeze maneuver* is also designed to improve pharyngeal contraction for swallowing (46) In this maneuver, the patient says a forceful "eee" in order to effect increased pharyngeal muscle contraction. Change/improvement in pharyngeal constrictor motion when using this maneuver can be easily visualized with fiberoptic laryngoscopic examination

Lingual control exercises can improve bolus control for chewing (1,3). These exercises involve manipulation of material such as a piece of licorice within the oral cavity to work on bolus seal, lateral trafficking of the bolus, bolus retrieval from the teeth, and sealing and propelling the bolus posteriorly through the oral cavity.

The Shaker exercise is a strengthening exercise program to improve upper esophageal sphincter (UES) opening for swallowing (47,48). This rehabilitation exercise involves a program of head-raising to strengthen the suprahyoid muscles involved in UES opening. In healthy asymptomatic elderly individuals, the Shaker exercise program resulted in increased UES opening diameter and a decrease in hypopharyngeal intrabolus pressure (47). In dysphagic patients with reduced UES opening, the Shaker exercise program resulted in significantly increased UES opening, increased anterior laryngeal excursion, reduction of pharyngeal residue, and elimination of postdeglutitive aspiration (48). There is evidence that respiratory strength training can have a positive impact on swallowing by training expiratory, suprahyoid, and velar muscles. Sapienza (49) reported that respiratory strength training improved swallowing in dysphagic Parkinson patients, with a reduction in pharyngeal delay time, improvement in speed and extent of hyolaryngeal motion during the swallow. In addition, subsequent studies have shown improved respiratory driving pressure in PD and MS patients employing respiratory strength training (50). This could lead to improved vocalization and decreased rates of aspiration in neurologically impaired patients (51,52). There is also evidence that the Lee Silverman Voice Training (LSVT), a voice exercise program designed to improve voice and speech in the Parkinson patient, can improve swallowing, specifically, by improving oral transit times, triggering of the pharyngeal swallow, and reducing percentage oral residue (53). In addition, the LSVT program has been found to improve tongue strength and quality of life (54), as measured by the SWAL-QOL, a swallowing quality of life measure (55).

SENSORY-MOTOR INTEGRATION PROCEDURES

Thermal-tactile stimulation has been used as a preswallow alerting mechanism for the central nervous system. This technique involves rubbing the anterior faucial arches with a size 00 cold laryngeal mirror and instructing the patient to swallow (1). It has been found to improve triggering of

the pharyngeal motor response in patients with delayed triggering of the pharyngeal swallow (16,17). Thermal/tactile stimulation combined with a sour stimulus has been found to result in a similar reduction in swallow latency (56). This technique can be performed in isolation (i.e., dry swallows or.5mL amounts of water for those patients who are nonoral) or intermittently during meals, as appropriate.

MANEUVERS

Maneuvers are designed to alter the physiology of the swallow, specifically, the pharyngeal phase, placing specific aspects of the pharyngeal swallow under voluntary control (Table 58.2). The *supraglottic swallow* is designed to improve airway closure before and during the swallow at the level of the glottis (2,57). Patients are instructed to hold their breath, swallow, and cough. The super supraglottic swallow is designed to improve airway closure before and during the swallow at the level of the airway entrance (i.e., laryngeal vestibule) and glottis (2,57,58). The *super supraglottic swallow* involves a tighter breath hold than that used with the supraglottic swallow and is designed to achieve arytenoid to epiglottic base contact for closure of the laryngeal vestibule (57,58). In patients having undergone supraglottic laryngectomy, the super supraglottic swallow is designed to achieve arytenoid to tongue base contact for vestibular closure. The patient is instructed to: (a) hold your breath very tightly while bearing down with the abdominal muscles, (b) swallow, and (c) cough. This maneuver has also been found to increase extent of laryngeal elevation during the swallow (22). Patients are often taught to exhale slightly before holding their breath tightly, as most individuals swallow during an exhalation, which may increase subglottic pressure during the swallow and reduce the risk of aspiration (59,60). The super supraglottic swallow maneuver requires a fair degree of cognitive functioning, attention, sequencing, and memory.

The *effortful swallow* is designed to improve tongue base posterior motion during the swallow and improve pressures to clear the bolus past the tongue base (1,3,24,61–63). This maneuver is helpful for those patients who demonstrate reduced tongue base posterior motion, a disorder that can result in residue on the tongue base, valleculae, and upper pharyngeal wall. The patient is instructed to squeeze hard with the tongue and throat muscles during the swallow. This maneuver can result in improved bolus clearance past the tongue base and through the upper pharynx. This maneuver is often combined with chin tuck posture, the latter places the tongue closer to the pharyngeal wall to maximize bolus clearance past the tongue base.

The *Mendelsohn maneuver* is designed to increase the extent and duration of laryngeal elevation and anterior motion during the swallow, thereby increasing the width and duration of cricopharyngeal opening during the swallow (22,64) (Fig. 58.1). This maneuver can also improve the coordination of the pharyngeal events occurring during the pharyngeal swallow (22). The patient is instructed to swallow normally, and in the middle of the swallow, when the larynx is felt to elevate, the patient is instructed to keep his larynx elevated for 2 seconds, then relax (Fig. 58.1).

The *tongue-hold maneuver* (also called the Masako maneuver) is designed to increase the extent of anterior motion of the PPW (65) (Fig. 58.2). This maneuver involves anchoring of the tongue tip between the teeth (or gums in edentulous patients), which places the tongue base in a more anterior position. This results in greater

TABLE 58.2 RATIONALE FOR USE OF SWALLOW MANEUVERS TO ALTER SWALLOW PHYSIOLOGY AND IMPROVE SWALLOW FUNCTION

Disorder Seen on MBS	Swallow Maneuver	Rationale
Impaired or delayed glottic closure; delayed triggering of the pharyngeal motor response	Supraglottic swallow	Breath hold improves glottic closure before and during the swallow
Impaired airway entrance closure	Super supraglottic swallow	Effortful breath hold facilitates arytenoid anterior motion to epiglottic petiole and maintains early airway entrance closure
Reduced tongue base posterior motion	Effortful swallow	Effort increases tongue base posterior motion
Reduced motion of the pharyngeal constrictors	Masako (tongue-hold) maneuver	Slightly anterior position of tongue base results in compensatory increase in anterior motion of pharyngeal constrictors
Reduced laryngeal motion and reduced cricopharyngeal opening	Mendelsohn maneuver	Increases extent and duration of laryngeal elevation, resulting in increased width and duration of UES opening
Discoordinated swallow	Mendelsohn maneuver	Effort improves timing and coordination of muscular events during pharyngeal swallow

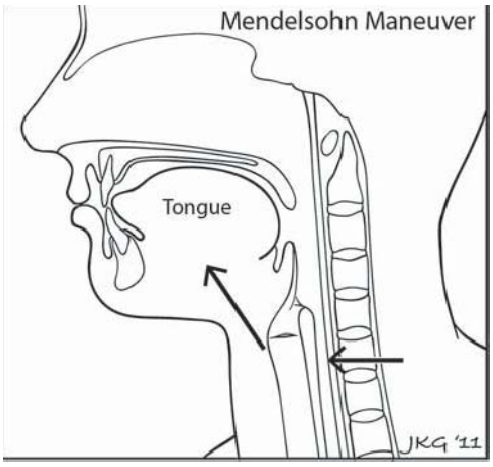

Figure 58.1 The Mendelsohn maneuver.

anterior motion of the PPW in order to make contact with the tongue base during the swallow (65). This technique is useful for those patients with reduced tongue base to pharyngeal wall contact and resultant reduction in bolus clearance past the tongue base. This exercise is designed to be a range of motion exercise for the pharyngeal constrictors and should be practiced with saliva or very small (1/2 mL) amounts of water. This exercise should not be practiced with food or liquid boluses, since anchoring of the tongue tip might result in reduced bolus control and aspiration.)

Surface electrode electromyography and electroglottography have been used as biofeedback tools when teaching swallow maneuvers, providing visual feedback of muscle activity during maneuver attempts. These maneuvers include the effortful swallow and the Mendelsohn swallow maneuvers, designed to improve tongue base posterior motion, laryngeal elevation, and UES opening for swallowing. These biofeedback techniques have resulted in improved swallow functioning, with increased muscle activity, improved temporal coordination of the swallow, and resumption of oral intake in stroke patients with chronic dysphagia and patients with MS (66–68). Nasendoscopy can provide biofeedback for patients when learning airway protection maneuvers, such as the supraglottic and super supraglottic swallow, as vocal fold motion and arytenoid to epiglottic base contact can be easily visualized with this technique (57).

Some patients must always use swallow maneuvers and postures during meals and, therefore, observation of fatigue when using maneuvers should be noted on fluoroscopy and during the course of therapy. Swallow functioning should be reevaluated with instrumental assessment, including VFSS or fiberoptic endoscopic examination of swallowing after a course of swallow therapy, to determine whether function has improved such that some type of oral diet can be implemented, a diet upgrade can be implemented, or to determine the need for continued use of postures and/or maneuvers during meals (2,69).

Neuromuscular electrical stimulation (NMES) is a technique that has traditionally been used for the limbs, but has only recently been introduced to improve swallowing. This technique involves the delivery of therapeutic electrical stimulation to facilitate muscle contraction through surface electrode placement in the region of the submental or thyrohyoid muscles (70,71). Stimulation of either region is believed to contribute to hyolaryngeal elevation for swallowing. Few studies examining the effects of NMES on swallowing, however, have been conducted in a systematic, quantitative, and methodologically replicable fashion. Burnett et al. (72) systematically examined differential stimulation of muscles to augment laryngeal elevation at rest and found that combined stimulation of the mylohyoid and thyrohyoid muscles resulted in greater degree of laryngeal elevation than single muscle stimulation. Power et al. (73) found that electrical stimulation can have a negative effect on swallowing, with lengthened swallow response time following stimulation at certain stimulation frequencies. Transcutaneous delivery of electrical stimulation, in recent studies, has not been shown to consistently target the submental or strap muscles responsible for anterosuperior movement of the larynx during swallowing (74). When muscles other than the mylohyoid or thyrohyoid are innervated, the larynx will actually be depressed which, in theory, could increase the likelihood of aspiration. Authors attempting to observe physiologic changes in

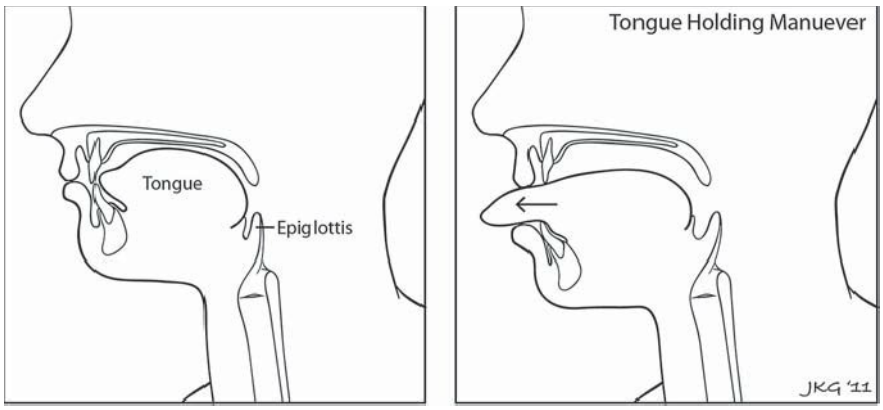

Figure 58.2 The tongue-hold maneuver.

swallow in normal patients receiving NMES have shown a propensity for patients to experience hyo-laryngeal depression and incomplete false vocal fold closure (75–77). NMES for swallowing remains a controversial treatment technique that requires additional research to examine the physiologic basis for and use in swallowing treatment.

Not all patients are candidates for direct swallow treatment, such as those with severe cognitive impairment. However, management decisions should be made based on the results of the instrumental evaluation, including compensatory strategies to be used during meals, for those patients taking some type of an oral diet. Compensatory strategies are also typically prescribed for patients with progressive neurologic disease, such as ALS, and can include modifying posture, diet type, bolus volume, and adding sensory enhancements, such as carbonation (78) (Table 58.2).
